Tips in use per part	12	12
Tool life (parts per tool)	200	4700
Cost per tip	$1.25	$28.50

   a. Which tool material would you recommend?
   b. On what basis?

7. A 2-in.-diameter bar of steel was turned at 284 rpm, and tool failure occurred in 10 min. The speed was changed to 132 rpm, and the tool failed in 30 min of cutting. Assume that a straight-line relationship exists. What cutting speed should be used to obtain a 60-min tool life of V_{60}?
8. Table 21-6 shows a cost comparison for four tool materials. Show how the data in this table were generated.
9. Refer to Problem 1. Show the relationship between cutting speed and tool temperature. What does this mean with regard to tool failure?
10. The outside diameter of a roll for a steel (AISI 1015) rolling mill is to be turned. In the final pass, the starting diameter = 26.25 in. and the length = 48.0 in. The cutting conditions will be feed = 0.0100 in./rev and depth of cut = 0.125 in. A cemented carbide cutting tool is to be used, and the parameters of the Taylor tool life equation for this setup are $n = 0.25$ and $C = 1300$. It is desirable to operate at a cutting speed such that

the tool will not need to be changed during the cut. Determine the cutting speed that will make the tool life equal to the time required to complete this turning operation. (Problem suggested by Groover, *Fundamentals of Modern Manufacturing: Materials, Processes, and Systems*, 2nd ed., John Wiley & Sons, 2002.)

11. Using data from Problems 8 and 10, determine the necessary horsepower for the machine tool to make this cut.
12. Figure 21-E shows a sketch of a single-point tool and its associated tool signature. Put the signature from the tool in Figure 21-C in the same order as shown in Figure 21-E. Which tool would produce the larger F_c given that both are cutting at the same V, f_r, and DOC in the same material?

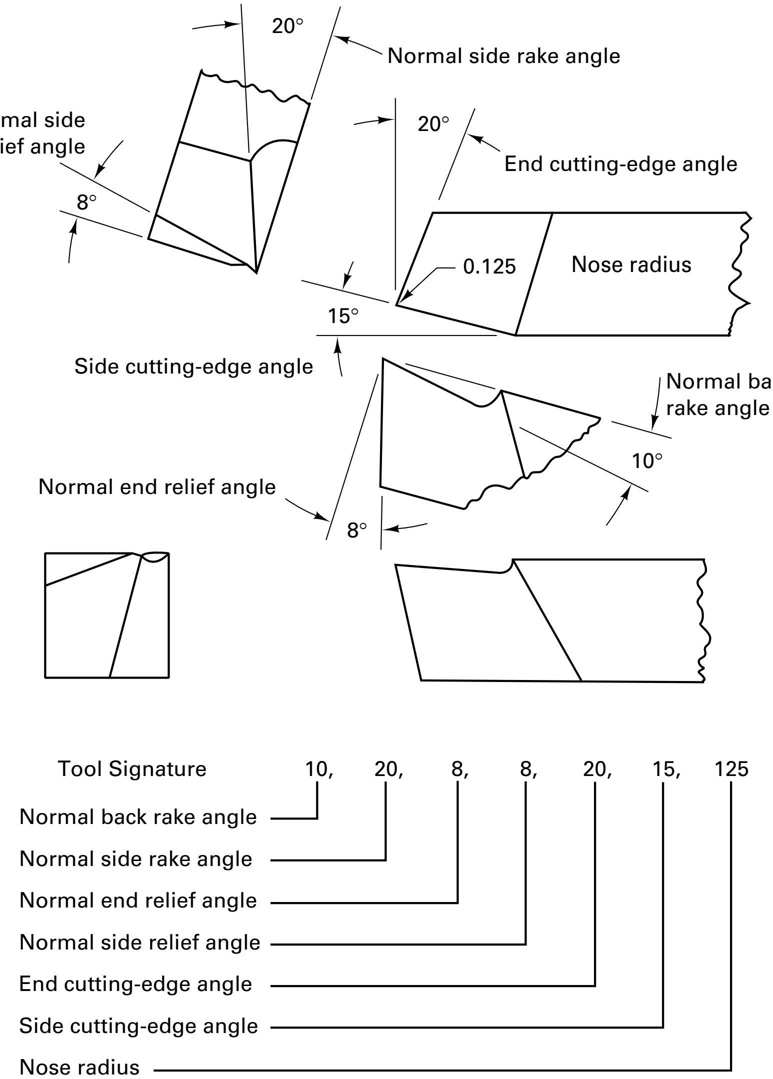

FIGURE 21-E

Chapter 21 CASE STUDY

Comparing Tool Materials Based on Tool Life

The Linus Drilling Company is trying to decide on what kind of inserts to use in their indexable insert drills. These drills do not cut at dead center but rather form a thin center slug that is pushed out of the way by the drill body. These indexable drills often provide a marked productivity improvement compared to conventional HDD drills, particularly when they are combined with coated insert tools. The company is trying to determine which type of insert to use in the drill for machining some hot rolled 8620 steel shafts using triangular inserts. The operating cost of the machine tool is $60.00 per hour. It takes about three minutes to change the inserts and about 30 seconds to unload a finished part and load a new part in the machine. The company is currently using uncoated inserts at the following operating conditions—400 sfpm and 0.020 ipr. These speeds and feeds resulted in each cutting edge producing about 40 pieces before the tool's cutting edge became dull. The tool was then indexed. Since it was a triangular tool, each tool had 6 cutting edges available before it had to be replaced. At these speeds and feeds, the drilling time was 4.8 minutes and the production rate was 11 parts per hour, while the machining cost per piece was $4.80 ($1.00/min × 4.8 min/pc.). The manufacturing engineer on the job, Brian Paul, has found three new tool materials being used in triangular insert tools. They are listed in Table CS-21 along with the data for the uncoated tool. The new materials are TiC-coated carbide, Al_20_3-coated carbide and a ceramic-coated insert with a single side, low force groove geometry. The expected cutting conditions, speeds and feeds, are given in the table along with Brian's estimates of the production rates in pieces per hour for each of these new tool materials. The low force groove geometry tools can only be used three times—they cannot be flipped over—so only three cutting edges are available per insert before it has to be replaced. Brian has argued that even though the ceramic-coated inserts cost more, they result in a lower cost per piece, considering all the costs. Determine the machining cost per piece, the tool changing cost per piece, and the tool cost per piece which make up the total cost per piece, and verify Brian's belief that these coated tools will provide some cost savings.

TABLE CS.21 Cost Comparison of Four Tool Materials, Based on Equal Tool Life

	Uncoated	TiC-Coated	Al_2O_3-coated	Al_2O_3 LFG
Cutting speed (surface ft/min)	400	640	1100	1320
Feed (in/rev)	0.020	0.022	0.024	0.028
Cutting edges available per insert	6	6	6	3
Cost of an insert ($/insert)	4.80	5.52	6.72	6.72
Tool life (pieces/cutting edge)	192	108	60	40
Tool change time per piece (min)	0.075	0.075	0.075	0.075
Nonproductive cost per piece ($/pc)	0.50	0.50	0.50	0.50
Machining time per piece (min/pc)	4.8	2.7	1.50	1.00
Machining cost per piece ($/pc)	4.80			
Tool change cost per piece ($/pc)	0.08			
Cutting tool cost per piece ($/pc)	0.02			
Total cost per piece ($)	5.40			
Production rate (pieces/hr)	11	18	29	38
Improvement in productivity based on pieces/hr (%)	0	64	164	245

CHAPTER 22

TURNING AND BORING PROCESSES

22.1 INTRODUCTION

Turning is the process of machining external cylindrical and conical surfaces. It is usually performed on a machine tool called a lathe, as shown in Figure 22-1, using a cutting tool. The workpiece is held in a workholder. More details on lathes are shown later in this chapter. As indicated in Figure 22-2, relatively simple work and tool movements are involved in turning a cylindrical surface. The workpiece is rotated and the single-point cutting tool is fed longitudinally into the workpiece. If the tool is fed at an angle to the axis of rotation, an external conical surface results. This is called *taper turning*. If the tool is fed to the axis of rotation, using a tool that is wider than the depth of the cut, the operation is called *facing*, and a flat surface is produced on the end of the cylinder.

By using a tool having a specific form or shape and feeding it radially or inward against the work, external cylindrical, conical, and irregular surfaces of limited length can also be turned. The shape of the resulting surface is determined by the shape and size

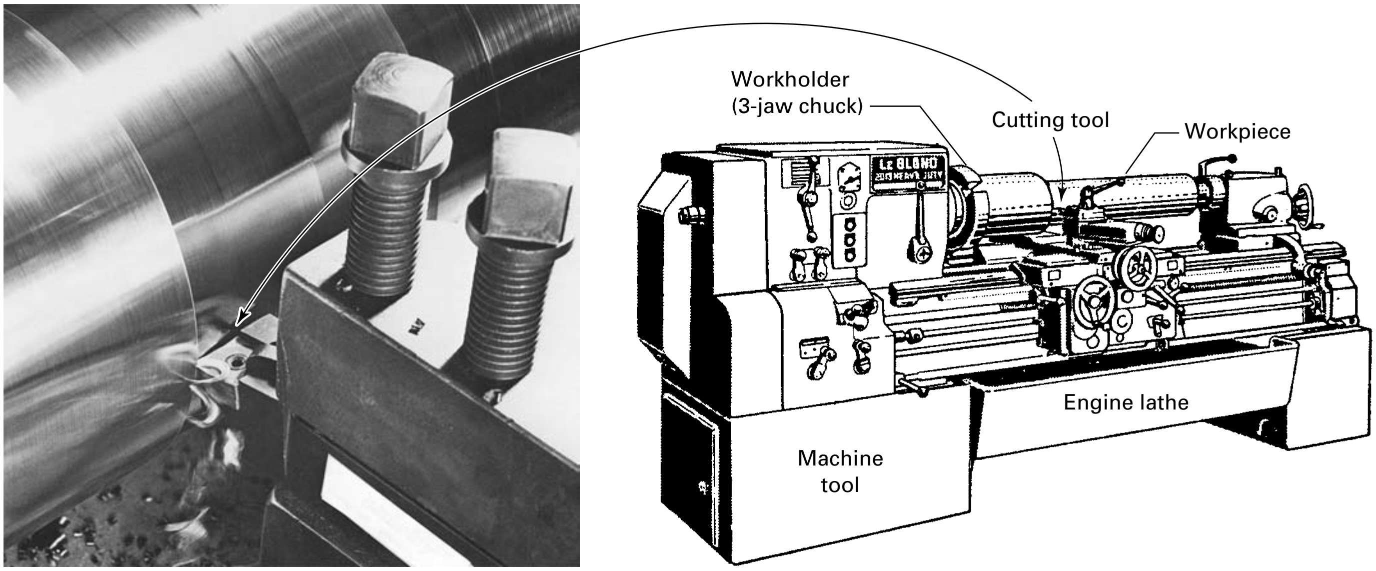

FIGURE 22-1 Schematic of a standard engine lathe performing a turning operation, with the cutting tool shown in inset.

FIGURE 22-2 Basic turning machines can rotate the work and feed the tool longitudinally for turning and can perform other operations by feeding transversely. Depending on what direction the tool is fed and on what portion of the rotating workpiece is being machined, the operations have different names. The dashed arrows indicate the tool feed motion relative to the workpiece.

of the cutting tool. Such machining is called *form turning*. If the tool is fed all the way to the axis of the workpiece, it will be cut in two. This is called *parting* or *cutoff*, and a simple, thin tool is used. A similar tool is used for *necking* or *partial cutoff*.

Boring is a variation of turning. Essentially, boring is internal turning. Boring can use single-point cutting tools to produce internal cylindrical or conical surfaces. It does not create the hole but, rather, machines or opens the hole up to a specific size. Boring can be done on most machine tools that can do turning. However, boring also can be done using a rotating tool with the workpiece remaining stationary. Also, specialized machine tools have been developed that will do boring, drilling, and reaming but will not do turning. Other operations, like *threading* and *knurling*, can be done on machines used for turning. In addition, drilling, reaming, and tapping can be done on the rotation axis of the work.

In recent years, turning centers have been developed that use turrets to hold multiple-edge rotary tools in powered heads. Some new machine tools feature two opposing spindles with automatic transfer from one to the other and two turrets of tools.

22.2 FUNDAMENTALS OF TURNING, BORING, AND FACING TURNING

Turning constitutes the majority of lathe work. The cutting forces, resulting from feeding the tool from right to left, should be directed toward the headstock to force the workpiece against the workholder and thus provide better work support.

If good finish and accurate size are desired, one or more roughing cuts are usually followed by one or more finishing cuts. Roughing cuts may be as heavy as proper chip thickness, cutting dynamics, tool life, lathe horsepower, and the workpiece permit. Large *depths of cut* and smaller feeds are preferred to the reverse procedure, because fewer cuts are required and less time is lost in reversing the carriage and resetting the tool for the following cut.

On workpieces that have a hard surface, such as castings or hot-rolled materials containing mill scale, the initial roughing cut should be deep enough to penetrate the hard materials. Otherwise, the entire cutting edge operates in hard, abrasive material throughout the cut, and the tool will dull rapidly. If the surface is unusually hard, the cutting speed on the first roughing cut should be reduced accordingly.

Finishing cuts are light, usually being less than 0.015 in. in depth, with the feed as fine as necessary to give the desired finish. Sometimes a special finishing tool is used, but often the same tool is used for both roughing and finishing cuts. In most cases, one finishing cut is all that is required. However, where exceptional accuracy is required, two finishing cuts may be made. If the diameter is controlled manually, a short finishing cut ($^1/_4$ in. long) is made and the diameter checked before the cut is completed. Because the previous micrometer measurements were made on a rougher surface, it may be necessary to reset the tool in order to have the final measurement, made on a smoother surface, check exactly.

In turning, the primary cutting motion is rotational, with the tool feeding parallel to the axis of rotation (Figure 22-3). The desired cutting speed established the necessary rpm (N_s) of the rotating workpiece. The feed f_r is given in inches per revolution (ipr).

The depth of cut is d, where

$$d = \text{DOC} = \frac{D_1 - D_2}{2} \text{ inches} \tag{22-1}$$

The length of cut is the distance traveled parallel to the axis L plus some allowance or overrun A to allow the tool to enter and/or exit the cut.

Here is how the inputs to the turning process are determined. First it is necessary that the engineer select the cutting speed, V, in feet per minute, the feed (f_r), and the depth of cut, based on what material is being machined, what tool material is being used,

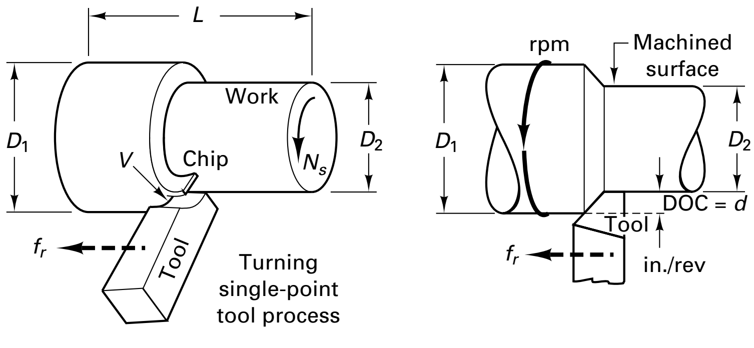

FIGURE 22-3 Basics of the turning process normally done on a lathe. The dashed arrows indicate the feed motion of the tool relative to the work.

and other factors like what process is being performed. The rpm value for the machine tool can be determined by

$$N_s = \frac{12V}{\pi D_1} \tag{22-2}$$

(using the larger diameter), where the factor of 12 is used to convert feet to inches. The cutting time is

$$T_m = \frac{L + A}{f_r N_s} \tag{22-3}$$

where A is overrun allowance, and f_r is the selected feed in inches per revolution.

Example of Turning

The 1.78-inch diameter steel bar shown in Figure 1-10 is to be turned down to a 1.10-inch diameter on a standard engine lathe. The overall length of the bar is 18.750 inches, and the region to be turned is 16.50 inches. After turning, the bar looks like stage 2. The part is made from cold-drawn free-machining steel (this means the chips breakup nicely) with a Bhn of 250. Since you want to take the bar from 1.78 to 1.10, you have a total depth of cut, d, of 0.34 inch (0.68/2). You decide you want to make two cuts, a roughing pass and a finishing pass. Rough at $d = 0.300$ and finish with $d = 0.04$ inches. Looking at the table for selecting speed and feed (Figure 20-4), you select $V = 100$ fpm and feed $= 0.020$ ipr because you have selected high-speed steel cutting tools.

The bar is held in a chuck with a feed through the hole in the spindle and is supported on the right end with a live center. The ends of the bar have been center drilled. Allowance should be 0.50 inches for approach (no overtravel). Allow 1.0 minutes to reset the tool after the first cut. To determine the inputs to the lathe, we calculate the spindle rpm:

$$N_s = 12V/\pi D_1 = 12 \times 100/3.14 \times 1.78 = 214$$

But your lathe does not have this particular rpm, so you select the closest rpm, which is 200. You don't need any further calculations for lathe inputs as you input the feed in ipr directly.

The time to make the cut is

$$T_m = \frac{L + ALL}{f_r \times N_s} = \frac{16.50 + 0.50}{0.020 \times 200} = 4.25 \text{ min}$$

You could reduce this time by changing to a coated carbide tool that would allow you to increase the cutting speed to 925 sfpm. (See table). The time for the second cut will be different if you change the feed and/or the speed to improve the surface finish. Again from the table in Figure 21-4, speed = 925, feed = 0.007, so

$$N_s = 12 \times 925/3.14 \times 1.10 = 3213 \text{ with 3200 rpm the closest value:}$$

$$T_m = \frac{L + ALL}{0.007 \times 3200} = 0.75 \text{ min}$$

The metal removal rate is

$$\text{MRR} = \frac{\text{volume removed}}{\text{time}} = \frac{(\pi D_1^2 - \pi D_2^2)L}{4L/f_r N}$$

(omitting the allowance term). By rearranging and substituting N_s, an exact expression for MRR is obtained:

$$\text{MRR} = 12 V f_r \frac{(D_1^2 - D_2^2)}{4D_1} \tag{22-4}$$

Rewriting the last term

$$\frac{D_1^2 - D_2^2}{4D_1} = \frac{D_1 - D_2}{2} \times \frac{D_1 - D_2}{2D_1}$$

Therefore, since

$$d = \frac{D_1 - D_2}{2} \text{ and } \frac{D_1 - D_2}{2D_1} \cong 1 \quad \text{for small } d$$

then,

$$\text{MRR} \cong 12\, V f_r d \text{ in.}^3/\text{min} \tag{22-5}$$

Note that Equation (22-5) is an approximate equation that assumes that the depth of cut d is small compared to the uncut diameter D_1.

BORING

Boring always involves the enlarging of an existing hole, which may have been made by a drill or may be the result of a core in a casting. An equally important and concurrent purpose of boring may be to make the hole concentric with the axis of rotation of the workpiece and thus correct any eccentricity that may have resulted from the drill starting or drifting off the center line. Concentricity is an important attribute of bored holes.

When boring is done in a lathe, the work usually is held in a chuck or on a faceplate. Holes may be bored straight, tapered, with threads, or to irregular contours. Figure 22-4 shows the relationship of the tool and the workpiece for boring. Think of boring as internal turning while feeding the tool parallel to the rotation axis of the workpiece, with two important differences.

First, the relief and clearance angles on the tool should be larger and the tool overhand (length to diameter) must be considered with regard to stability and deflection problems.

Given V and f_r for a cut of length L, the cutting time is

$$T_m = \frac{L + A}{f_r N_s} \tag{22-6}$$

where $N_s = 12V/\pi D_1$ for D_1,the diameter of bore, and A, the overrun allowance. The metal removal rate is

$$\text{MRR} = \frac{L(\pi D_1^2 - \pi D_2^2)/4}{L/f_r N}$$

where D_2 is the original hole diameter.

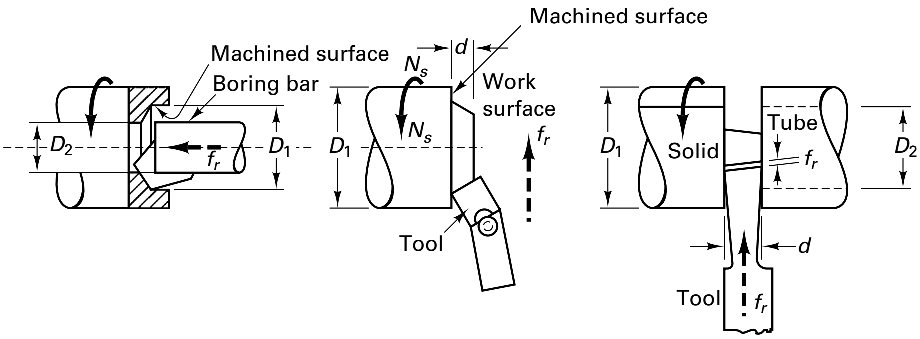
$$\text{MRR} \cong 12\, V f_r d \tag{22-7}$$

(omitting allowance term), where d is the depth of cut.

In most respects, the same principles are used for boring as for turning. Again, the tool should be set exactly at the same height as the axis of rotation. Larger end clearance angles help to prevent the heel of the tool from rubbing on the inner surface of the hole. Because the tool overhang will be greater, feeds and depths of cut may be reduced to reduce forces that cause tool vibration and chatter. In some cases, the boring bar may be made of tungsten carbide because of this material's greater stiffness.

FACING

Facing is the producing of a flat surface as the result of the tool being fed across the end of the rotating workpiece, as shown in Figure 22-4b. Unless the work is held on a mandrel, if both ends of the work are to be faced, it must be turned end for end after the first end is completed and the facing operation repeated.



(a) Boring a drilled hole (b) Facing from the cross side (c) Cutoff or parting

FIGURE 22-4 Basic movement of boring, facing, and cutoff (or parting) process.

The cutting speed should be determined from the largest diameter of the surface to be faced. Facing may be done either from the outside inward or from the center outward. In either case, the point of the tool must be set exactly at the height of the center of rotation. Because the cutting force tends to push the tool away from the work, it is usually desirable to clamp the carriage to the lathe bed during each facing cut to prevent it from moving slightly and thus producing a surface that is not flat.

In the facing of castings or other materials that have a hard surface, the depth of the first cut should be sufficient to penetrate the hard material to avoid excessive tool wear.

In facing, the tool feeds perpendicular to the axis of the rotating workpiece. Because the rpm is constant, the cutting speed is continually decreasing as the axis is approached. The length of cut L is $D_1/2$ or $(D_1 - D_2)/2$ for a tube.

$$T_m = \text{cutting time} = \frac{L + A}{f_r N} \text{ minutes}$$

$$= \frac{\frac{D_1}{2} + A}{f_r N}$$

$$\text{MRR} = \frac{\text{VOL}}{T_m} = \frac{\pi D_1^2 d f_r N}{4L} = 6V f_r d \quad \text{in.}^3/\text{min} \tag{22-8}$$

where d is the depth of cut and $L = D_1/2$ is the length of cut.

PARTING

Parting is the operation by which one section of a workpiece is severed from the remainder by means of a cutoff tool, as shown in Figure 22-4c. Because parting tools are quite thin and must have considerable overhand, this process is more difficult to perform accurately. The tool should be set exactly at the height of the axis of rotation, be kept sharp, have proper clearance angles, and be fed into the workpiece at a proper and uniform feed rate.

In parting or cutoff work, the tool is fed (plunged) perpendicular to the rotational axis, as it was in facing. The length of cut for solid bars is $D_1/2$. For tubes,

$$L = \frac{D_1 - D_2}{2}$$

In cutoff operations, the width of the tool is d in inches, the width of the cutoff operation. The equations for T_m and MRR are then basically the same as for facing.

DEFLECTION

In boring, facing, and cutoff operations, the speeds, feeds, and depth of cut selected are generally less than those recommended for straight turning because of the large overhang of the tool often needed to complete the cuts. Recall the basic equation for deflection of a cantilever beam, modifying for machining,

$$\delta = \frac{Pl^3}{3EI} = \frac{F_c l^3}{3EI} \tag{22-9}$$

In equation 22-9, l represents the overhang of the tool, which greatly affects the deflection, so it should be minimized whenever possible. In equation 22-9,

E = modulus of elasticity

I = moment of inertia of cross section of tool

$P = F_c$ = applied load or cutting force

where $I = \pi D_1^2/64$ solid round bar

$I = \pi(D_1^4 - (D_2^4))/64$ bar with hole

D_1 = diameter of tube or bar

D_2 = inside diameter of the tube

Deflection is proportional to the fourth power of the boring bar diameter and the third power of the bar overhand. Select the largest-diameter bar diameter and minimize the overhand. Use carbide shank boring bars ($E \cong 80{,}000{,}000$ psi), and select tool geometries that direct cutting forces into the feed direction to minimize chatter. The reduction of the feed or depth of cut reduces the forces operating on the tools. The cutting speed usually controls the occurrence of chatter and vibration. See the dynamics of machining discussion in Chapter 20.

Any imbalance in the cutting forces will deflect the tool to the side, resulting in loss of accuracy in cutoff lengths. At the outset, the forces will be balanced if there is no side rake on the tool. As the cutoff tool reaches the axis of the rotating part, the tool will be deflected away from the spindle, resulting in a change in the length of the part.

PRECISION BORING

Sometimes bored holes are slightly bell mouthed because the tool deflects out of the work as it progresses into the hole. This often occurs in castings and forgings where the holes have draft angles so that the depth of cut increases as the tool progresses down the bore. This problem can usually be corrected by repeating the cut with the same tool setting; however, the total cutting time for the part is increased. Alternately, a more robust setup can be used. Large holes may be precision bored using the setup shown in Figure 22-5, where a pilot bushing is placed in the spindle to mate with the hardened ground pilot of the boring bar. This setup eliminates the cantilever problems common to boring.

Because the rotational relationship between the work and the tool is a simple one and is employed on several types of machine tools, such as lathes, drilling machines, and milling machines, boring is very frequently done on such machines. However, several machine tools have been developed primarily for boring, especially in cases involving large workpieces or for large-volume boring of smaller parts. Such machines as these are also capable of performing other operations, such as milling and turning. Because boring frequently follows drilling, many boring machines also can do drilling, permitting both operations to be done with a single setup of the work.

DRILLING

Drilling, discussed in detail in Chapter 23, can be done on lathes with the drill mounted in the tailstock quill of engine lathes or the turret on turret lathes and fed against a

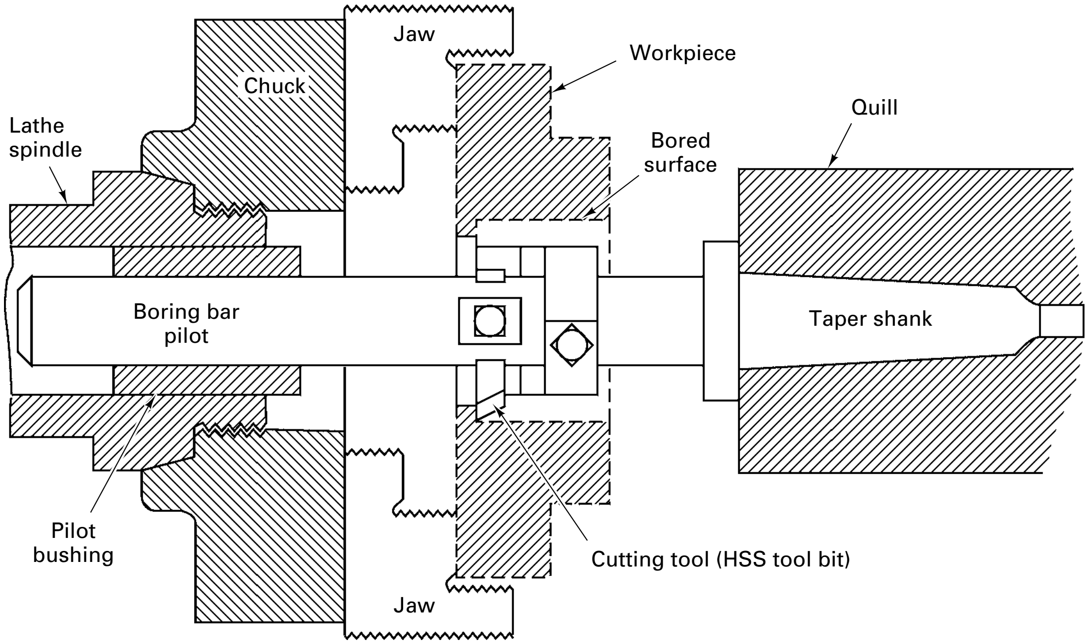


FIGURE 22-5 Pilot boring bar mounted in tailstock of lathe for precision boring large hole in casting. The size of the hole is controlled by the rotation diameter of the cutting tool.

rotating workpiece. Straight-shank drills can be held in Jacobs chucks, or drills with taper shanks mounted directly in the quill hole can drill holes online (center of rotation). Drills can also be mounted in the turrets of modern turret centers and fed automatically on the rotational axis of the workpiece or off axis with power heads. It also is possible to drill on a lathe with the drill bit mounted and rotated in the spindle while the work remains stationary, supported on the tailstock or the carriage of the lathe.

The usual speeds used for drilling should be selected for lathe work. Because the feed may be manually controlled, care must be exercised, particularly in drilling small holes. Coolants should be used where required. In drilling deep holes, the drill should be withdrawn occasionally to clear chips from the hole and to aid in getting coolant to the cutting edges. This is called peck drilling. See Chapter 23 for further discussion on drilling.

REAMING

Reaming on a lathe involves no special precautions. Reamers are held in the tailstock quill, taper-shank types being mounted directly and straight-shank types by means of a drill chuck. Rose-chucking reamers are usually used (see Chapter 23). Fluted-chucking reamers may also be used, but these should be held in some type of holder that will permit the reamer to float (i.e., have some compliance) in the hole and conform to the geometry created by the boring process.

KNURLING

Knurling produces a regularly shaped, roughened surface on a workpiece. Although knurling also can be done on other machine tools, even on flat surfaces, in most cases it is done on external cylindrical surfaces using lathes. Knurling is a chipless, cold-forming process. See Figures 22-6 and 22-18 for examples. The two hardened rolls are pressed against the rotating workpiece with sufficient force to cause a slight outward and lateral displacement of the metal to form the knurl in a raised, diamond pattern. Another type of knurling tool produces the knurled pattern by cutting chips. Because it involves less pressure and thus does not tend to bend the workpiece, this method is often preferred for workpieces of small diameter and for use on automatic or semiautomatic machines.

SPECIAL ATTACHMENTS

For engine lathes, taper turning and milling can be done on a lathe but require special attachments. The *milling attachment* is a special vise that attaches to the cross slide to hold work. The milling cutter is mounted and rotated by the spindle. The work is fed by means of the cross-slide screw. *Tool-post grinders* are often used to permit grinding to be done on a lathe. Taper turning will be discussed later. *Duplicating attachments* are available that, guided by a template, will automatically control the tool movements for turning irregularly shaped parts. In some cases, the first piece, produced in the normal manner, may serve as the template for duplicate parts. To a large extent, duplicating lathes using templates have been replaced by numerically controlled lathes and milling is done with power tools in NC turret lathes.

FIGURE 22-6 (a) Knurling in a lathe, using a forming-type tool, and showing the resulting pattern on the workpiece; (b) knurling tool with forming rolls. *(Courtesy of Armstrong Brothers Tool Company.)*

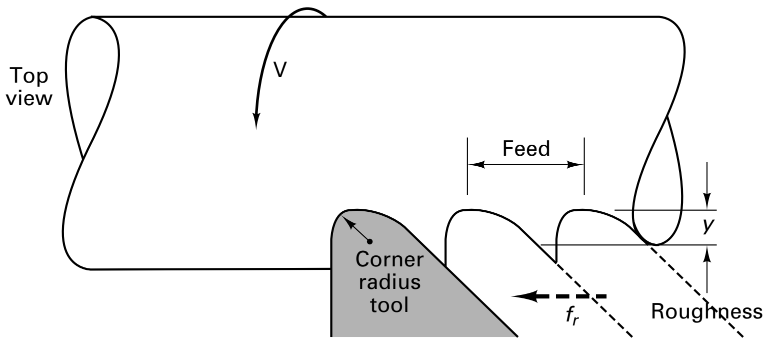
DIMENSIONAL ACCURACY

Dimensional accuracy in turning operations is controlled by many factors. Precision is influenced by deflection due to the cutting forces and surface roughness. Tool wear causes the workpiece dimension to change from the initial diameter when the tool is sharp to the diameter obtained after the tool has worn. The cutting forces increase as the tool wears, resulting in increased deflection between the workpiece and the cutting tool. A built-up edge (BUE) may form at the tip of the cutting tool. A BUE has the tendency to change the actual diameter of the workpiece. Thus, to hold close tolerances, the size of the wear land, the magnitude of the radial (thrust) force, and the elimination of the BUE should be taken into account. See Figure 22-7.

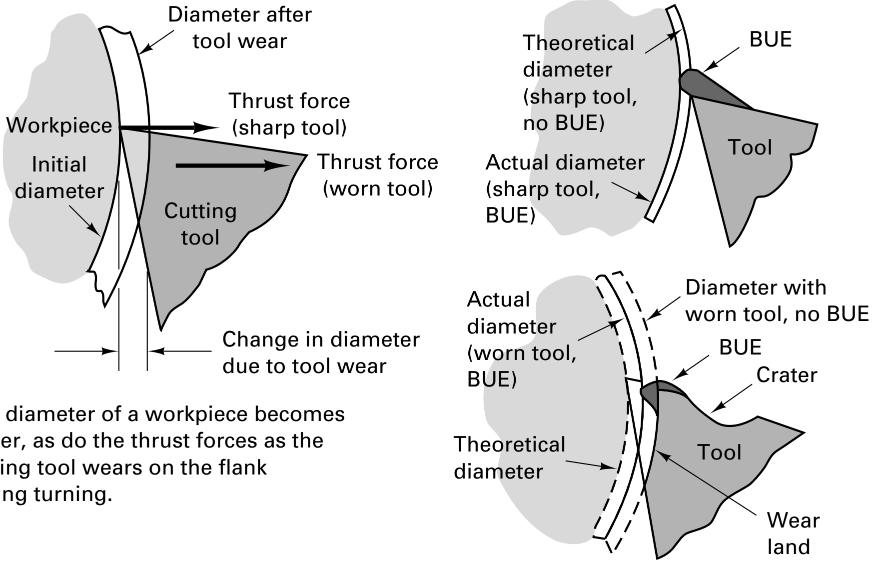
Dimensional accuracy will also be influenced by the workpiece shape, the material, the rigidity of all elements, the surface finish, and vibrations. For example, holding the dimensional accuracy of a boring operation on a deep hole is a problem, due to the deflection (rigidity) of the boring bar.

Turned surfaces display characteristic turning grooves that are produced by the feed and the tool tip corner radius, as shown in Figure 22-7. The roughness resulting from feed marks from a round-nosed tool can be approximated by the formula

$$y = \mathrm{CR} - \frac{\sqrt{\mathrm{CR}^2 - f_r^2}}{4} \cong \frac{f_r^2}{8\mathrm{CR}} \tag{22-10}$$



The feed and the corner radius (CR) of the cutting tool influence the surface roughness



The diameter of a workpiece becomes larger, as do the thrust forces as the cutting tool wears on the flank during turning.

Regardless of whether the tool is dull or sharp, a built-up edge (BUE) causes the diameter of the workpiece to be smaller than desired.

FIGURE 22-7 Accuracy and precision in turning is a function of many factors, including tool wear and BUE.

where y is the roughness height, CR the corner radius of insert, and f_r the feed rate (in./rev). To improve the surface finish, reduce the feed and increase the corner radius.

Other factors like BUE formations, cutting-edge sharpness, and tool wear grooves in the flank wear area also affect the surface finish in turning. Flank wear and BUE can combine to affect both surface finish and accuracy, as shown in Figures 22-1 and 22-7. Wear on the corner radius may cause grooves and nicks, which produce additional surface roughness on the finish-turned surfaces. Thus, to hold the surface roughness within specified limits, minimize tool wear and use small feeds and large-corner-radius tools. To minimize BUE formation, employ cutting speeds higher than those used in rough turning operations.

22.3 LATHE DESIGN AND TERMINOLOGY

Knowing the terminology of a machine tool is fundamental to understanding how it performs the basic processes, how the workholding devices are interchanged, and how the cutting tools are mounted and interfaced to the work. *Lathes* are machine tools designed primarily to do turning, facing, and boring. Very little turning is done on other types of machine tools, and none can do it with equal facility. Lathes also can do facing, drilling, and reaming, and recent designs permit milling and drilling operations using live (also called powered) spindles in multiple-tool turrets, so their versatility permits multiple operations to be done with a single setup of the workpiece. Consequently, the lathe is probably the most common machine tool, along with milling machines.

Lathes in various forms have existed for more than 2000 years, but modern lathes date from about 1797, when Henry Maudsley developed one with a leadscrew, providing controlled, mechanical feed of the tool. This ingenious Englishman also developed a change-gear system that could connect the motions of the spindle and leadscrew and thus enable threads to be cut.

LATHE DESIGN

The essential components of an *engine lathe* (Figure 22-8) are the bed, headstock assembly (which includes the spindle), tailstock assembly, carriage assembly, quick-change gearbox, and the leadscrew and feed rod. The *bed* is the base and backbone of a lathe.

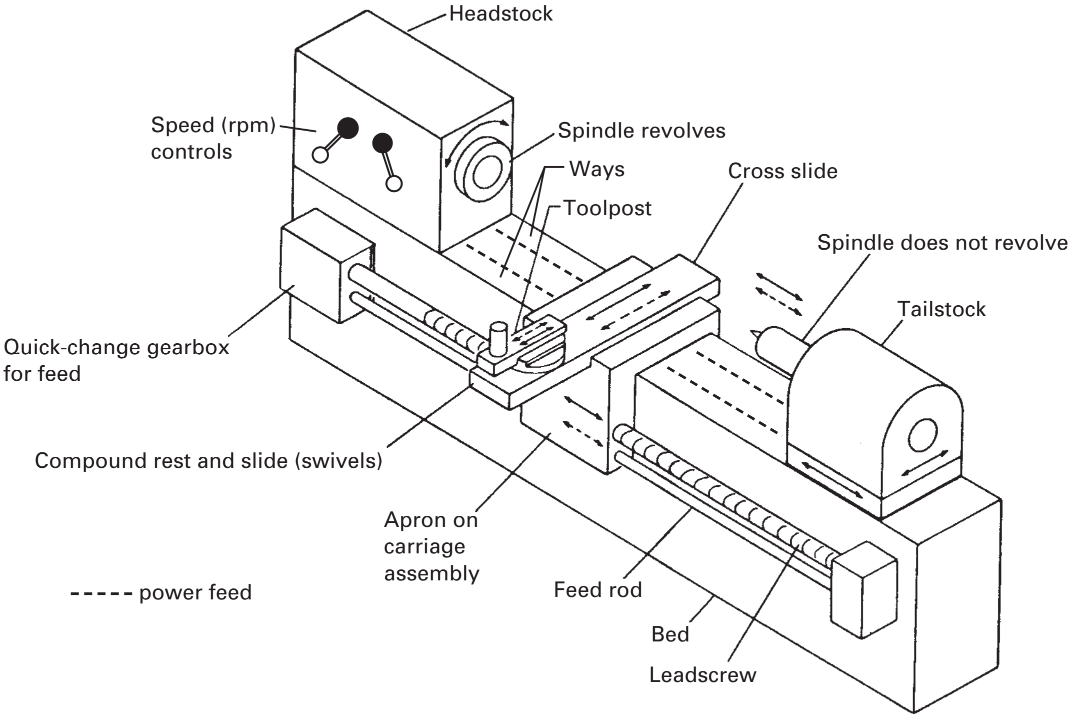


FIGURE 22-8 Schematic diagram of an engine lathe, showing basic components.

The bed is usually made of well-normalized or aged gray or nodular cast iron and provides a heavy, rigid frame on which all the other basic components are mounted. Two sets of parallel, longitudinal *ways*, inner and outer, are contained on the bed. On modern lathes, the ways are surface hardened and precision machined, and care should be taken to assure that the ways are not damaged. Any inaccuracy in them usually means that the accuracy of the entire lathe is destroyed.

The *headstock*, mounted in a fixed position on the inner ways, provides powered means to rotate the work at various rpm values. Essentially, it consists of a hollow *spindle*, mounted in accurate bearings, and a set of transmission gears—similar to a truck transmission—through which the spindle can be rotated at a number of speeds. Most lathes provide from 8 to 18 choices of rpm. On modern lathes all the rpm rates can be obtained merely by moving from two to four levers or the lathe has a continuously variable spindle rpm using electrical or mechanical drives.

The accuracy of a lathe is greatly dependent on the *spindle*. It carries the workholders and is mounted in heavy bearings, usually preloaded tapered roller or ball types. The spindle has a hole extending through its length, through which long bar stock can be fed. The size of this hole is an important dimension of a lathe because it determines the maximum size of bar stock that can be machined when the materials must be fed through the spindle.

The spindle protrudes from the gearbox and contains means for mounting various types of workholding devices (chucks, face and dog plates, collets). Power is supplied to the spindle from an electric motor through a V-belt or silent-chain drive. Most modern lathes have motors of from 5 to 25 hp to provide adequate power for carbide and ceramic tools cutting hard materials at high cutting speeds.

For the classic engine lathe, the *tailstock* assembly consists, essentially, of three parts. A lower casting fits on the inner ways of the bed, can slide longitudinally, and can be clamped in any desired location. An upper casting fits on the lower one and can be moved transversely upon it, on some type of keyed ways, to permit aligning the tailstock and headstock spindles (for turning tapers). The third major component of the assembly is the *tailstock quill*. This is a hollow steel cylinder, usually about 2 to 3 in. in diameter, that can be moved longitudinally in and out of the upper casting by means of a handwheel and screw. The open end of the quill hole has a Morse taper. Cutting tools or a *lathe center* are held in the quill. A graduated scale is usually engraved on the outside of the quill to aid in controlling its motion in and out of the upper casting. A locking device permits clamping the quill in any desired position. In recent years, dual-spindle NC turning centers have emerged, where a subspindle replaces the tailstock assembly. Parts can be automatically transferred from the spindle to the subspindle for turning the back end of the part. See Chapters 31 and 36 for more on NC turning centers.

The *carriage assembly*, together with the apron, provides the means for mounting and moving cutting tools. The *carriage*, a relatively flat H-shaped casting, rides on the outer set of ways on the bed. The *cross slide* is mounted on the carriage and can be moved by means of a feed screw that is controlled by a small handwheel and a graduated dial. The cross slide thus provides a means for moving the lathe tool in the facing or cutoff direction.

On most lathes, the tool post is mounted on a *compound rest*. See Figure 22-9. The compound rest can rotate and translate with respect to the cross slide, permitting further positioning of the tool with respect to the work. The *apron*, attached to the front of the carriage, has the controls for providing manual and powered motion for the carriage and powered motion for the cross slide. The carriage is moved parallel to the ways by turning a handwheel on the front of the apron, which is geared to a pinion on the back side. This pinion engages a rack that is attached beneath the upper front edge of the bed in an inverted position.

Powered movement of the carriage and cross slide is provided by a rotating *feed rod*. The feed rod, which contains a keyway, passes through the two reversing bevel pinions (Figure 22-10) and is keyed to them. Either pinion can be activated by means of the feed reverse lever, thus providing "forward" or "reverse" power to the carriage. Suitable clutches connect either the rack pinion or the cross-slide screw to provide longitudinal motion of the carriage or transverse motion of the cross slide.

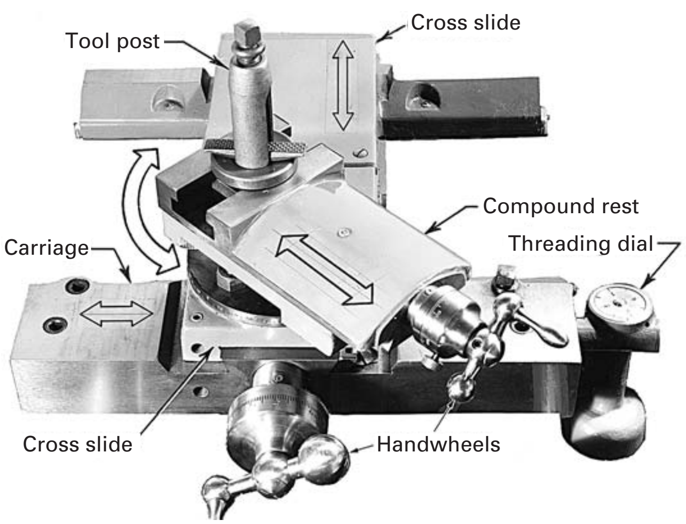

FIGURE 22-9 The cutting tools for lathe work are held in the tool post on the compound rest, which can translate and swivel.

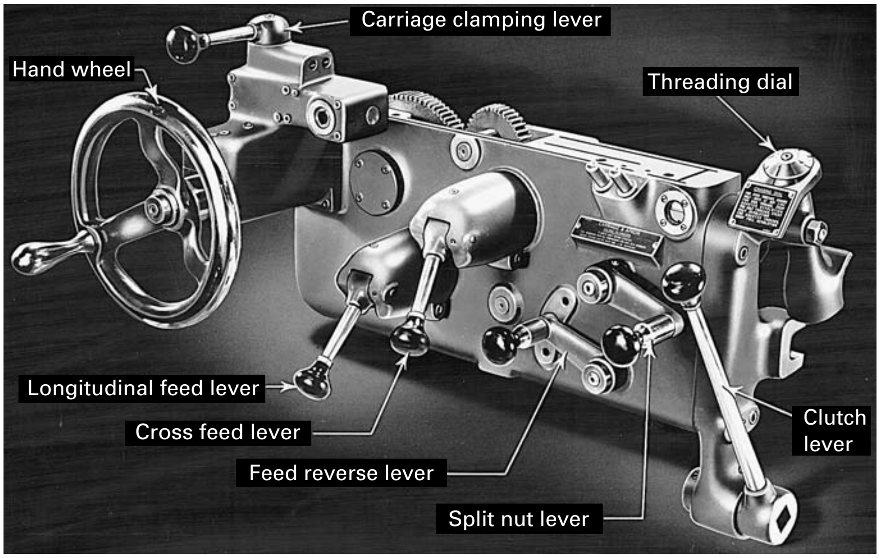
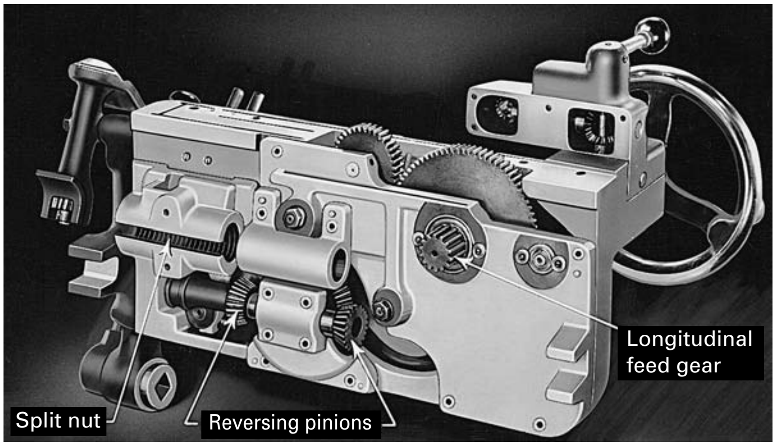


(a)



(b)

FIGURE 22-10 The carriage, cross slide, and apron assembly for an engine lathe.

For cutting threads, a *leadscrew* is used. When a friction clutch is used to drive the carriage, motion through the leadscrew is by a direct, mechanical connection between the apron and the leadscrew. A *split nut* is closed around the leadscrew by means of a lever on the front of the apron directly driving the carriage without any slippage.

Modern lathes have *quick-change gearboxes*, driven by the spindle, that connect the feed rod and leadscrew. Thus when the spindle turns a revolution, the tool (mounted on the carriage) translates (longitudinally or transversely) a specific distance in inches—that is, inches per revolution (ipr). This revolutions per minute, *rpm* or N_s, times the feed, f_r, gives the feed rate, f, in inches per minute that the tool is moving. In this way, the calculations for turning rpm and feed in inches per revolution are "mechanically related." Typical lathes may provide as many as 48 feeds, ranging from 0.002 to 0.118 in. (0.05 to 3 mm) per revolution of the spindle, and, through the leadscrew, leads from to 92 threads per inch.

SIZE DESIGNATION OF LATHES

The size of a lathe is designated by two dimensions. The first is known as the *swing*. This is the maximum diameter of work that can be rotated on a lathe. Swing is approximately twice the distance between the line connecting the lathe centers and the nearest point on the ways. The maximum diameter of a workpiece that can be mounted between centers is somewhat less than the swing diameter because the workpiece must clear the carriage assembly as well as the ways. The second size dimension is the *maximum distance between centers*. The swing thus indicates the maximum workpiece diameter that can be turned in the lathe, while the distance between centers indicates the maximum length of workpiece that can be mounted between centers.

TYPES OF LATHES

Lathes used in manufacturing can be classified as speed, engine, toolroom, turret, automatics, tracer, and numerical control turning centers. Speed lathes usually have only a headstock, a tailstock, and a simple tool post mounted on a light bed. They ordinarily have only three or four speeds and are used primarily for wood turning, polishing, or metal spinning. Spindle speeds up to about 4000 rpm are common.

Engine lathes are the type most frequently used in manufacturing. Figure 22-1 and Figure 22-8 are examples of this type. They are heavy-duty machine tools with all the components described previously and have power drive for all tool movements except on the compound rest. They commonly range in size from 12- to 24-in. swing and from 24- to 48-in. center distances, but swings up to 50 in. and center distances up to 12 ft are not uncommon. Very large engine lathes (36- to 60-ft-long beds) are therefore capable of performing roughing cuts in iron and steel at depths of cut of $^1/_2$ to 2 in. and at cutting speeds at 50 to 200 sfpm with WC tools run at 0.010 to 0.100 in./rev. To perform such heavy cuts requires rigidity in the machine tool, the cutting tools, the workholder, and the workpiece (using steady rests and other supports) and large horsepower (50 to 100 hp).

Most engine lathes are equipped with chip pans and a built-in coolant circulating system. Smaller engine lathes, with swings usually not over 13 in., also are available in *bench type*, designed for the bed to be mounted on a bench or table.

Toolroom lathes have somewhat greater accuracy and, usually, a wider range of speeds and feeds than ordinary engine lathes. Designed to have greater versatility to meet the requirements of tool and die work, they often have a continuously variable spindle speed range and shorter beds than ordinary engine lathes of comparable swing, since they are generally used for machining relatively small parts. They may be either bench or pedestal type.

Several types of special-purpose lathes are made to accommodate specific types of work. On a *gap-bed lathe*, for example, a section of the bed, adjacent to the headstock, can be removed to permit work of unusually large diameter to be swung. Another example is the *wheel lathe*, which is designed to permit the turning of railroad-car wheel-and-axle assemblies.

Figure 22-11 shows a CNC vertical turning lathe. Vertical lathes are an excellent alternative to large horizontal CNC lathes. Gravity-aided seating of large/heavy work-

FIGURE 22-11 This CNC vertical turning center is used for turning large circular parts rotated under vertically mounted tools.

pieces allows a high degree of process repeatability. A smaller footprint, lower initial cost, and increased productivity are all advantages when compared to traditional horizontal lathes.

Although engine lathes are versatile and very useful, the time required for changing and setting tools and for making measurements on the workpiece is often a large percentage of the cycle time. Often, the actual chip-production time is less than 30% of the total cycle time. Methods to reduce setup and tool-change time are now well known, reducing setups to minutes and unload/load steps to seconds. The placement of single-cycle machinetools into interim or lean manufacturing cells will increase the productivity of the workers because they can run more than one machine. Turret lathes, screw machines, and other types of semiautomatic and automatic lathes have been highly developed and are widely used in manufacturing as another means to improve cutting productivity.

Turret Lathes The basic components of a *turret lathe* are depicted in Figure 22-12. Basically, a longitudinally feedable, hexagon turret replaces the tailstock. The turret, on which six tools can be mounted, can be rotated about a vertical axis to bring each tool into operating position, and the entire unit can be translated parallel to the ways, either manually or by power, to provide feed for the tools. When the turret assembly is backed away from the spindle by means of a capstan wheel, the turret indexes automatically at the end of its movement, thus bringing each of the six tools into operating position in sequence.

The square turret on the cross slide can be rotated manually about a vertical axis to bring each of the four tools into operating position. On most machines, the turret can be moved transversely, either manually or by power, by means of the cross slide, and longitudinally through power or manual operation of the carriage. In most cases, a fixed tool holder also is added to the back end of the cross slide; this often carries a parting tool.

Through these basic features of a turret lathe, a number of tools can be set up on the machine and then quickly be brought successively into working position so that a complete part can be machined without the necessity for further adjusting, changing tools, or making measurements.

The two basic types of turret lathes are the ram-type turret lathe and the saddle-type turret lathe. In the *ram-type turret lathe*, the ram and turret are moved up to the cutting position by means of the capstan wheel, and the power feed is then engaged. As the ram is moved toward the headstock, the turret is automatically locked into position so that rigid tool support is obtained. Rotary stopscrews control the forward travel of

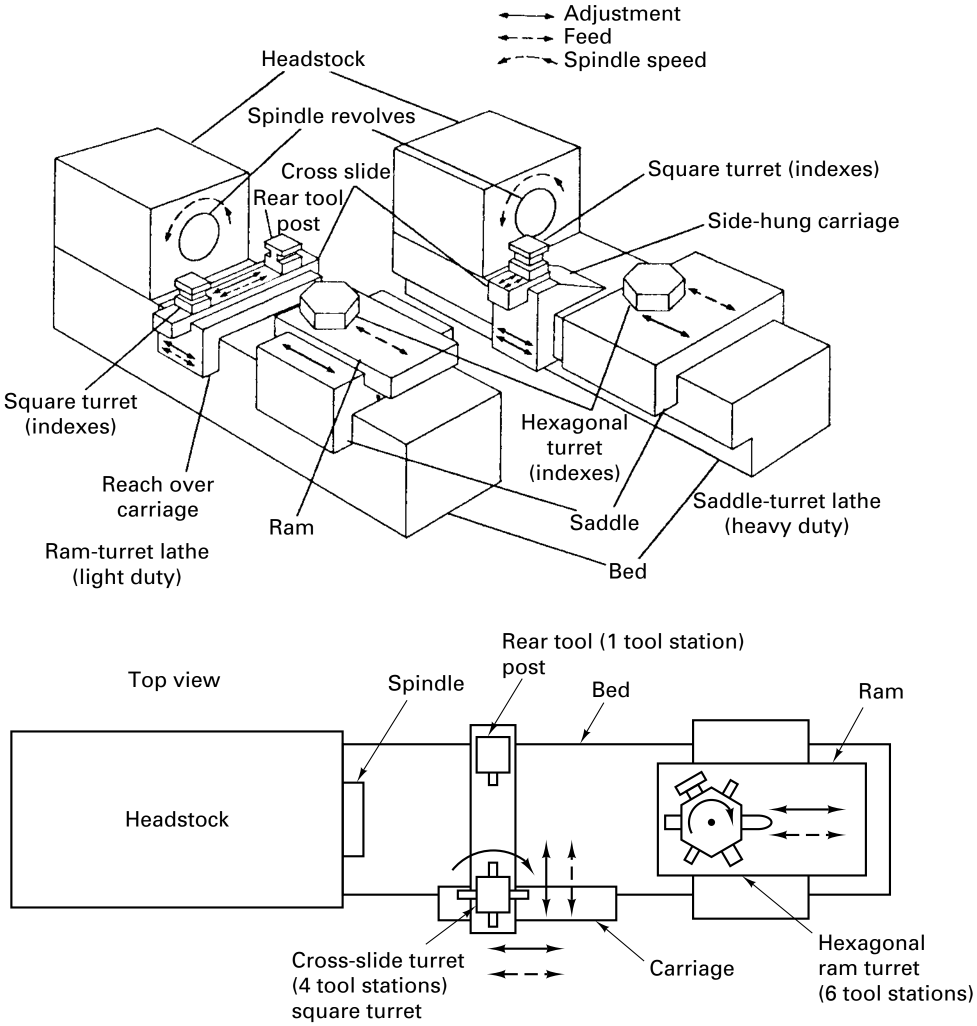


FIGURE 22-12 Block diagrams of ram- and saddle-turret lathe.

the ram, one stop being provided for each face on the turret. The proper stop is brought into operating position automatically when the turret is indexed. A similar set of stops is usually provided to limit movement of the cross slide. The *saddle-type turret lathe* provides a more rugged mounting for the hexagon turret than can be obtained by the ram-type mounting. In *saddle-type lathes*, the main turret is mounted directly on the saddle, and the entire saddle and turret assembly reciprocates. Larger turret lathes usually have this type of mounting. However, because the saddle-turret assembly is rather heavy, this type of mounting provides less rapid turret reciprocation. When such lathes are used with heavy tooling for making heavy or multiple cuts, a *pilot arm* attached to the headstock engages a pilot hole attached to one or more faces of the turret to give additional rigidity. Turret-lathe headstocks can shift rapidly between spindle speeds and brake rapidly to stop the spindle very quickly. They also have automatic stock-feeding for feeding bar stock through the spindle hole. If the work is to be held in a chuck, some type of air-operated chuck or a special clamping fixture is often employed to reduce the time required for part loading and unloading.

Single-Spindle Automatic Screw Machines. There are two common types of *single-spindle screw machines*. One, an American development and commonly called the turret type (Brown & Sharpe), is shown in Figure 22-13. The other is of Swiss origin and is referred to as the Swiss type. The *Brown & Sharpe screw machine* is essentially a small automatic turret lathe, designed for bar stock, with the main turret mounted in a vertical plane on a ram. Front and rear tool holders can be mounted on the cross slide. All motions of the turret, cross slide, spindle, chuck, and stock-feed mechanism are controlled

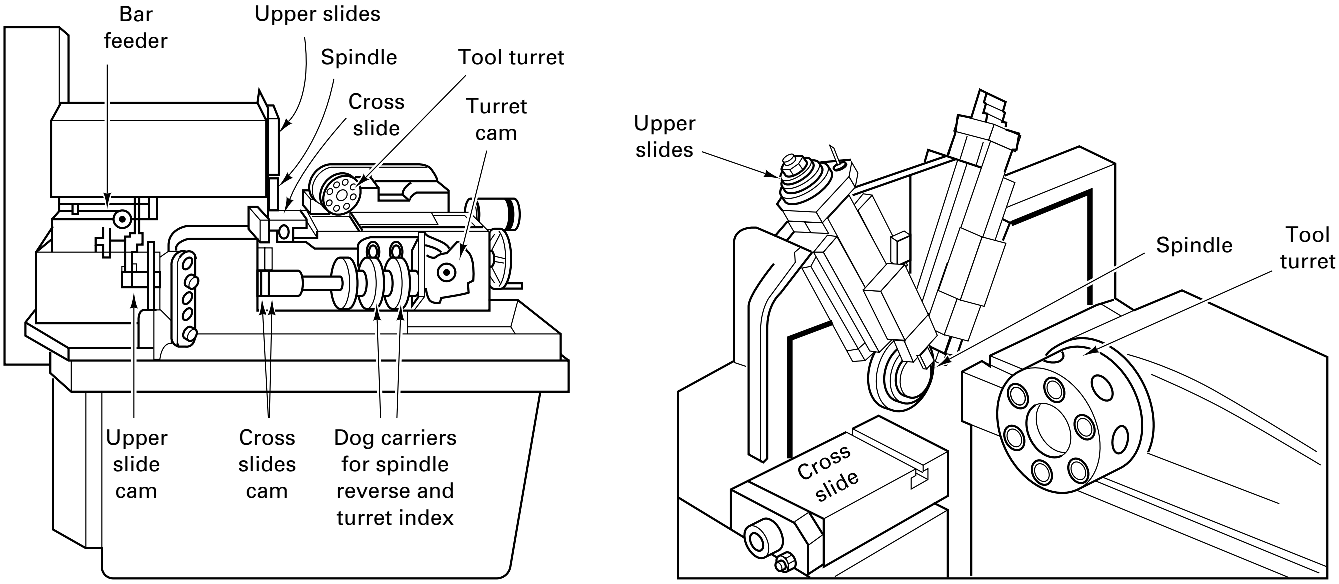

FIGURE 22-13 On the turret-type single-spindle automatic, the tools must take turns to make cuts.

by cams. The turret cam is essentially a program that defines the movement of the turret during a cycle. These machines are usually equipped with an automatic rod-feeding magazine that feeds a new length of bar stock into the collet (the workholding device) as soon as one rod is completely used.

Often, screw machines of the Brown & Sharpe type are equipped with a transfer or "picking" attachment. This device picks up the workpiece from the spindle as it is cut off and carries it to a position where a secondary operation is performed by a small, auxiliary power head. In this manner screwdriver slots are put in screw heads, small flats are milled parallel with the axis of the workpiece, or holes are drilled normal to the axis.

On the *Swiss-type automatic screw machine*, the cutting tools are held and moved in radial slides (Figure 22-14). Disk cams move the tools into cutting position and provide feed into the work in a radial direction only; they provide any required longitudinal feed by reciprocating the headstock.

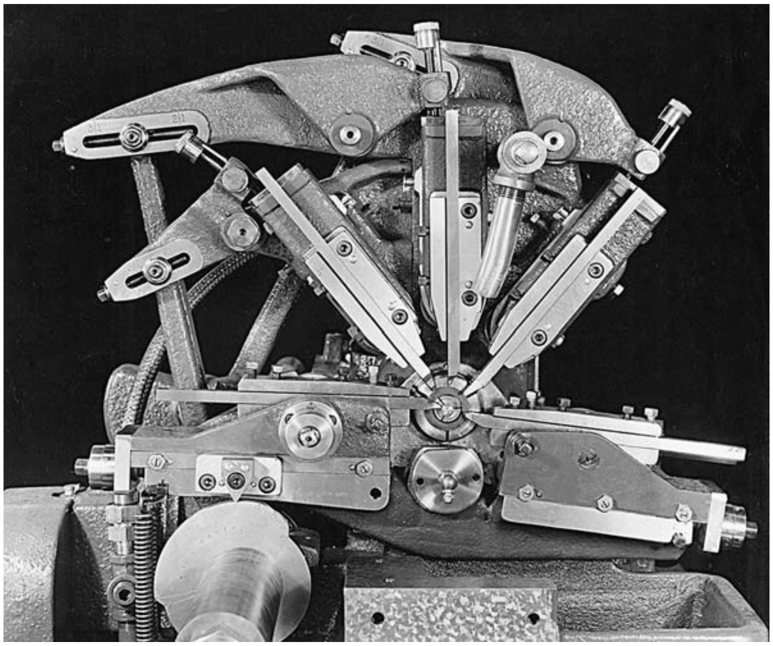

FIGURE 22-14 Close-up view of a Swiss-type screw machine, showing the tooling and radial tool sides, actuated by rocker arms controlled by a disk cam, shown in lower left. *(Courtesy of George Gorton Machine Corporation.)*

Most machining on Swiss-type screw machines is done with single-point cutting tools. Because they are located close to the spindle collet, the workpiece is not subjected to much deflection. Consequently, these machines are particularly well suited for machining very small parts.

Both types of single-spindle screw machines can produce work to close tolerances, the Swiss-type probably being somewhat superior for very small work. Tolerances of 0.0002 to 0.0005 in. are not uncommon. The time required for setting up the machine is usually an hour or two and can be much less. One person can tend many machines, once they are properly tooled. They have short cycle times, frequently less than 30 seconds per piece.

Multiple-Spindle Automatic Screw Machines. Single-spindle screw machines utilize only one or two tooling positions at any given time. Thus the total cycle time per workpiece is the sum of the individual machining and tool-positioning times. On *multiple-spindle screw machines*, sufficient spindles, usually four, six, or eight, are provided so that many tools can cut simultaneously. Thus, the cycle time per piece is equal to the maximum cutting time of a single tool position plus the time required to index the spindles from one position to the next.

The two distinctive features of multiple-spindle screw machines are shown in Figure 22-15. First, the six spindles are carried in a rotatable drum that indexes in order to bring each spindle into a different working position. Second, a nonrotating tool slide contains the same number of tool holders as there are spindles and thus provides and positions a cutting tool (or tools) for each spindle. Tools are fed by longitudinal reciprocating motion. Most machines have a cross slide at each spindle position so that an additional tool can be fed from the side for facing, grooving, knurling, beveling, and cutoff operations. These slides are also shown in Figure 22-15. All motions are controlled automatically.

Starting with the sixth position, follow the sequence of processing steps on the tooling sheet for making a part shown in Figure 22-15. With a tool position available on the end tool slide for each spindle (except for a stock-feed stop at position 6), when the slide moves forward, these tools cut essentially simultaneously. At the same time, the tools in the cross slides move inward and make their cuts. When the forward cutting motion of the end tool slide is completed, it moves away from the work, accompanied by the outward movement of the radial slides. The spindles are indexed one position, by rotation of the spindle carrier, to position each part for the next operation to be performed. At spindle position 5, finished pieces are cut off. Bar stock 1 in. in diameter is fed to correct length for the beginning of the next operation. Thus a piece is completed each time the tool slide moves forward and back. Multiple-spindle screw machines are made in a considerable range of sizes, determined by the diameter of the stock that can be accommodated in the spindles. There may be four, five, six, or eight spindles. The operating cycle of the end tool slide is determined by the operation that requires the longest time.

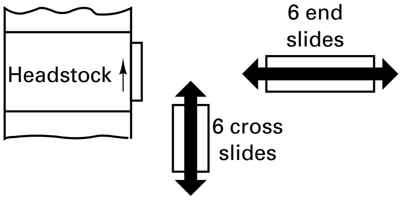
Once a multiple-spindle screw machine is set up, it requires only that the bar stock feed rack be supplied and the finished products checked periodically to make sure that they are within desired tolerances. One operator usually services many machines.

Most multiple-spindle screw machines use cams to control the motions. Setting up the cams and the tooling for a given job may require from 2 to 20 hours. However, once such a machine is set up, the processing time per part is very short. Often, a piece may be completed every 10 seconds. Typically, a minimum of 2000 to 5000 parts are required in a lot to justify setting up and tooling a multiple-spindle automatic screw machine. The precision of multiple-spindle screw machines is good, but seldom as good as that of single-spindle machines. However, tolerances from 0.0005 to 0.001 in. on the diameter are typical.

■ 22.4 CUTTING TOOLS FOR LATHES

LATHE CUTTING TOOLS

Most lathe operations are done using single-point *cutting tools*, such as the classic tool designs shown in Figure 22-16. On right-hand turning (and left-hand turning) and facing tools, the cutting usually takes place on the side of the tool; therefore, the side rake



All spindles on multiple-spindle automatic have the same tool path

FIGURE 22-15 The multiple-spindle, automatic screw machine makes all cuts simultaneously and then performs the noncutting functions (tool withdrawal, index, bar feed) at high speed.

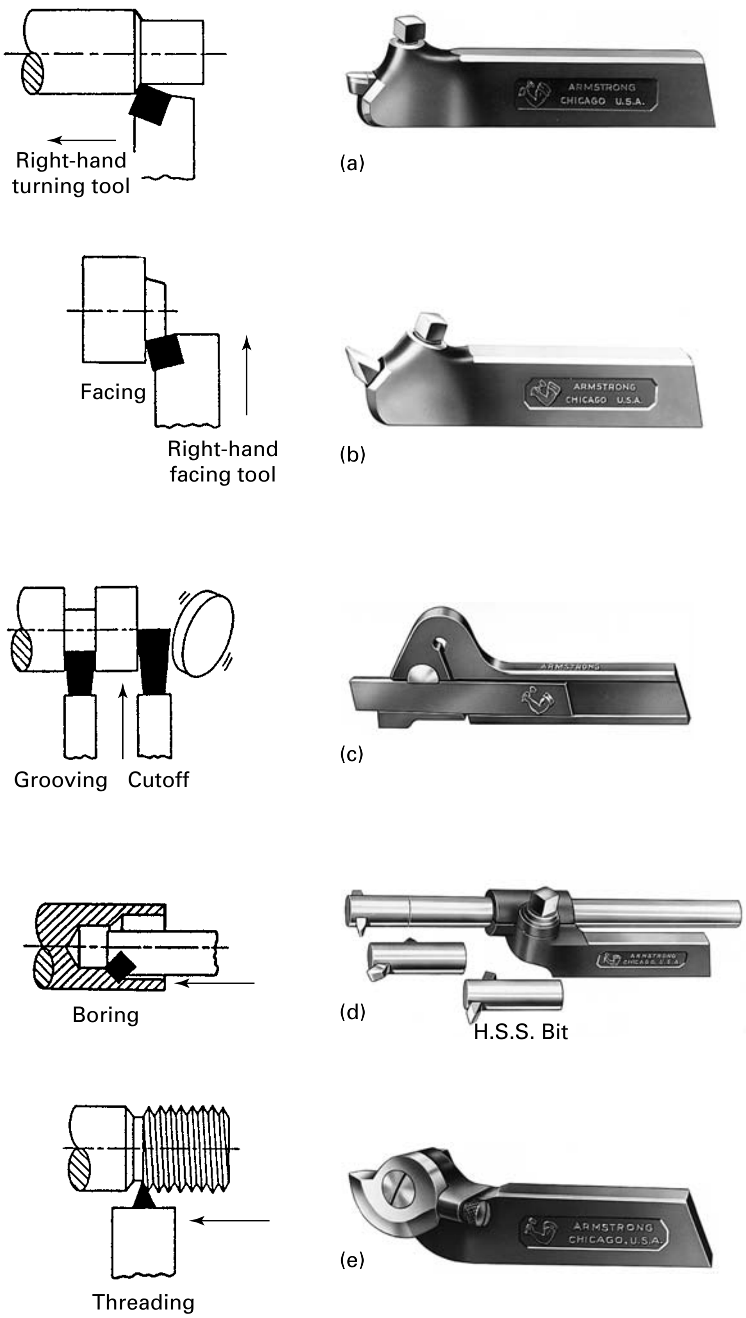

FIGURE 22-16 Common types of forged tool holders: (a) right-hand turning, (b) facing, (c) grooving cutoff, (d) boring, (e) threading. *(Courtesy of Armstrong Brothers Tool Company.)*

angle is of primary importance, particularly when deep cuts are being made. On the round-nose turning tools, cutoff tools, finishing tools, and some threading tools, cutting takes place on or near the tip of the tool, and the back rake is therefore of importance. Such tools are used with relatively light depths of cut.

Because tool materials are expensive, it is desirable to use as little as possible. At the same time, it is essential that the cutting tool be supported in a strong, rigid manner to minimize deflection and possible vibration. Consequently, lathe tools are supported in various types of heavy, forged steel tool holders, as shown in Figure 22-16. The high-speed steel (HSS) tool bit should be clamped in the tool holder with minimum overhang; otherwise tool chatter and a poor surface finish may result.

In the use of carbide, ceramic, or coated carbides for higher speed cutting, throwaway inserts are used that can be purchased in a great variety of shapes, geometrics (nose radius, tool angles, and groove geometry), and sizes (see Figure 22-17 for some examples).

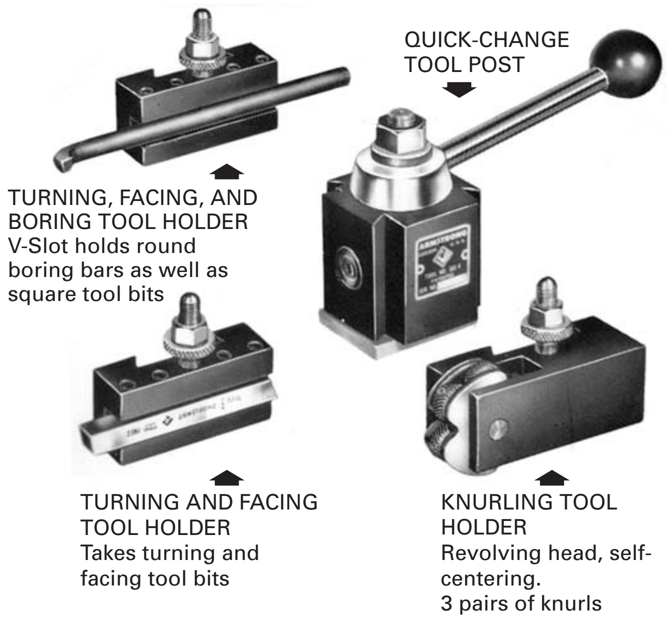

FIGURE 22-18 Quick-change tool post and accompanying toolholders. *(Courtesy of Armstrong Brothers Tool Company.)*

When several different operations on a lathe are performed repeatedly in sequence, the time required for changing and setting tools may constitute as much as 50% of the total cycle time. Quick-change tool holders (Figure 22-18) are used to reduce manual tool-changing time. The individual tools, preset in their holders, can be interchanged in the special tool post in a few seconds. With some systems, a second tool may be set in the tool post while a cut is being made with the first tool and can then be brought into proper position by rotating the post.

In lathe work, the nose of the tool should be set exactly at the same height as the axis of rotation of the work. However, because any setting below the axis causes the work to tend to "climb" up on the tool, most machinists set their tools a few thousandths of an inch above the axis, except for cutoff, threading, and some facing operations.

Form turning

FIGURE 22-19 Circular and block types of form tools. *(Courtesy of Speedi Tool Company, Incorporated.)*

FORM TOOLS

In Figure 22-15, the use of form tools was shown in automatic lathe work. Form tools are made by grinding the inverse of the desired work contour into a block of HSS or tool steel. A threading tool is often a form tool. Although form tools are relatively expensive to manufacture, it is possible to machine a fairly complex surface with a single inward feeding of one tool. For mass-production work, adjustable form tools of either flat or rotary types, such as are shown in Figure 22-19, are used. These are expensive to make initially but can be resharpened by merely grinding a small amount off the face and then raising or rotating the cutting edge to the correct position.

The use of form tools is limited by the difficulty of grinding adequate rake angles for all points along the cutting edge. A rigid setup is needed to resist the large cutting forces that develop with these tools. Light feeds with sharp, coated HSS tools are used on multiple-spindle automatics, turret lathes, and transfer line machines.

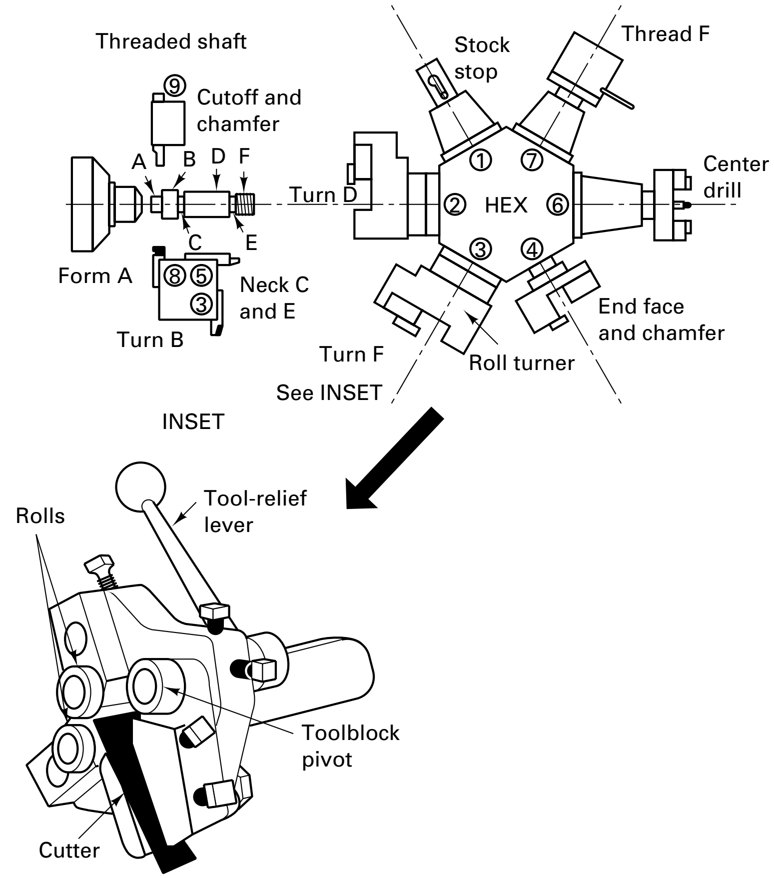
TURRET-LATHE TOOLS

In turret lathes, the work is generally held in collets and the correct amount of bar stock is fed into the machine to make one part. The tools are arranged in sequence at the tool stations with depths of cut all preset. The following factors should be considered when setting up a turret lathe.

1. *Setup time*: time required to install and set the tooling and set the stops. Standard tool holders and tools should be used as much as possible to minimize setup time. Setup time can be greatly reduced by eliminating adjustment in the setup.
2. *Workholding time:* time to load and unload parts and/or stock.
3. *Machine-controlling time:* time required to manipulate the turrets. Can be reduced by combining operations where possible. Dependent on the sequence of operations established by the design of the setup.
4. *Cutting time:* time during which chips are being produced. Should be as short as is economically practical and represent the greatest percentage of the total cycle time possible.
5. *Cost:* cost of the tool, setup labor cost, lathe operator labor cost, and the number of pieces to be made.

There are essentially eleven tooling stations, as shown in Figure 22-20, with six in the turret, four in the indexable tool post, and one in the rear tool post. The tooling is more rugged in turret lathes because heavy, simultaneous cuts are often made. Tools mounted in the hex turret that are used for turning are often equipped with pressure rollers set on the opposite side of the rotating workpiece from the tool to counter the cutting forces.

Turret lathes are most economical in producing lots too large for engine lathes but too small for automatic screw machines or automatic lathes. In recent years much of this work has been assumed by numerical control lathes or turning centers. For example, the component (threaded shaft) shown in Figure 22-20 could have also been made on an NC turret lathe with some savings in cycle time.



Roller turner has rolls to support the work against the cutting forces

FIGURE 22-20 Turret-lathe tooling setup for producing part shown. Numbers in circles indicate the sequence of the operations from 1 to 9. The letters A through F refer to the surfaces being machined. Operation 3 is a combined operation. The roll turner is turning surface F while tool 3 on the square post is turning surface B. The first operation stops the stock at the right length. The last operation cuts the finished bar off and puts a chamfer on the bar, which will next be advanced to the stock stop.

■ 22.5 WORKHOLDING IN LATHES

WORKHOLDING DEVICES FOR LATHES

Five methods are commonly used for supporting workpieces in lathes:

1. Held between centers
2. Held in a chuck
3. Held in a collet
4. Mounted on a faceplate
5. Mounted on the carriage

In the first four of these methods, the workpiece is rotated during machining. In the fifth method, which is not used extensively, the tool rotates while the workpiece is fed into the tool.

A general discussion of workholding devices is found in Chapter 25, and the student involved in designing working devices should study the reference materials under *Tool Design*. For lathes, workholding is a matter of selecting from standard tooling.

LATHE CENTERS

Workpieces that are relatively long with respect to their diameters are usually machined between centers. See Figure 22-21. Two *lathe centers* are used, one in the spindle hole and the other in the hole in the tailstock quill. Two types are used, called *dead* and *live*. Dead centers are *solid*, that is, made of hardened steel with a Morse taper on one end so that it will fit into the spindle hole. The other end is ground to a taper. Sometimes the tip of this taper is made of tungsten carbide to provide better wear resistance. Before a center

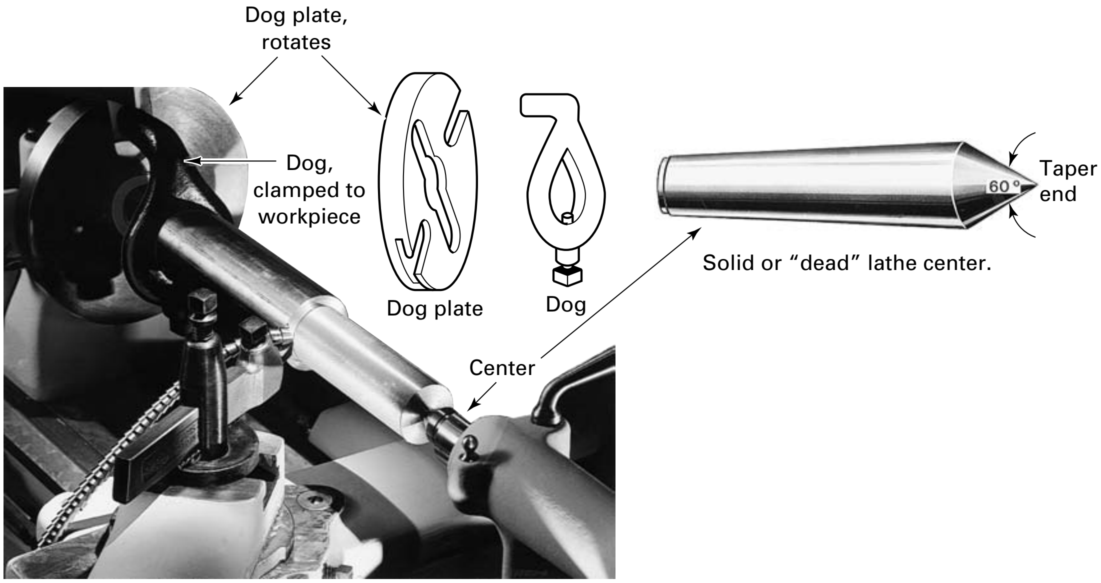


FIGURE 22-21 Work being turned between centers in a lathe, showing the use of a dog and dog plate. *(Courtesy of South Bend Lathe.)*

FIGURE 22-22 Live lathe center can rotate with the part.

is placed in position, the spindle hole should be carefully wiped clean. The presence of foreign material will prevent the center from seating properly, and it will not be aligned accurately.

Live centers are shown in Figure 22-22. A mechanical connection must be provided between the spindle and the workpiece to provide rotation. This is accomplished by a *lathe dog* and *dog plate*. The dog is clamped to the work. The *tail* of the dog enters a slot in the dog plate, which is attached to the lathe spindle in the same manner as a lathe chuck. For work that has a finished surface, a piece of soft metal, such as copper or aluminum, can be placed between the work and the dog setscrew clamp to avoid marring. Live centers are designed so that the end that fits into the workpiece is mounted on ball or roller bearings. It is free to rotate. No lubrication is required. Live centers may not be as accurate as the solid type and therefore are not often used for precision work.

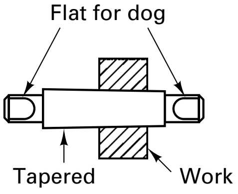
Before a workpiece can be mounted between lathe centers, a center hole must be drilled in each end. This is typically done in a drill press or on the lathe with a tool held in the rear turret. A combination center drill and countersink ordinarily is used, with care taken that the center hole is deep enough so that it will not be machined away in any facing operation and yet is not drilled to the full depth of the tapered portion of the center drill (see Chapter 23).

Because the work and the center of the headstock end rotate together, no lubricant is needed in the center hole at this end. The center in the tailstock quill does not rotate; adequate lubrication must be provided. A mixture of white lead and oil is often used. Failure to provide proper lubrication at all times will result in scoring of the workpiece center hole and the center, and inaccuracy and serious damage may occur. Live centers are often used in the tailstock to overcome these problems.

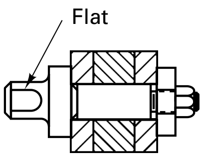
The workpiece must rotate freely, yet no looseness should exist. Looseness will usually be manifested in chattering of the workpiece during cutting. The setting of the centers should be checked after cutting for a short time. Heating and thermal expansion of the workpiece will reduce the clearances in the setup.

MANDRELS

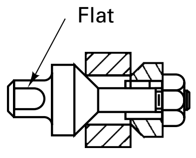
Workpieces that must be machined on both ends or are disk-shaped are often mounted on *mandrels* for turning between centers. Three common types of mandrels are shown in Figure 22-23. *Solid mandrels* usually vary from 4 to 12 in. in length and are accurately ground with a 1:2000 taper (0.006 in./ft). After the workpiece is drilled and/or bored, it is pressed on the mandrel. The mandrel should be mounted between centers so that the



Plain solid mandrel



Gang mandrel



Cone mandrel

FIGURE 22-23 Three types of mandrels, which are mounted between centers for lathe work.

cutting force tends to tighten the work on the mandrel taper. Solid mandrels permit the work to be machined on both ends as well as on the cylindrical surface. They are available in stock sizes but can be made to any desired size.

Gang (or disk) mandrels are used for production work because the workpieces do not have to be pressed on and thus can be put in position and removed more rapidly. However, only the cylindrical surface of the workpiece can be machined when this type of mandrel is used. *Cone mandrels* have the advantage that they can be used to center workpieces having a range of hole sizes.

LATHE CHUCKS

Lathe chucks are used to support a wider variety of workpiece shapes and to permit more operations to be performed than can be accomplished when the work is held between centers. Two basic types of chucks are used (Figure 22-24).

Three-jaw self-centering chucks are used for work that has a round or hexagonal cross section. The three jaws are moved inward or outward simultaneously by the rotation of a spiral cam, which is operated by means of a special wrench through a bevel gear. If they are not abused, these chucks will provide automatic centering to within about 0.001 in. However, they can be damaged through use and will then be considerably less accurate.

Each jaw in a *four-jaw independent chuck* can be moved inward and outward independent of the others by means of a chuck wrench. Thus they can be used to support a wide variety of work shapes. A series of concentric circles engraved on the chuck face aid in adjusting the jaws to fit a given workpiece. Four-jaw chucks are heavier and more rugged than the three-jaw type, and because undue pressure on one jaw does not destroy the accuracy of the chuck, they should be used for all heavy work. The jaws on both three- and four-jaw chucks can be reversed to facilitate gripping either the inside or the outside of workpieces.

Combination four-jaw chucks are available in which each jaw can be moved independently or can be moved simultaneously by means of a spiral cam. Two-jaw chucks are also available. For mass-production work, special chucks are often used in which the jaws are actuated by air or hydraulic pressure, permitting very rapid clamping of

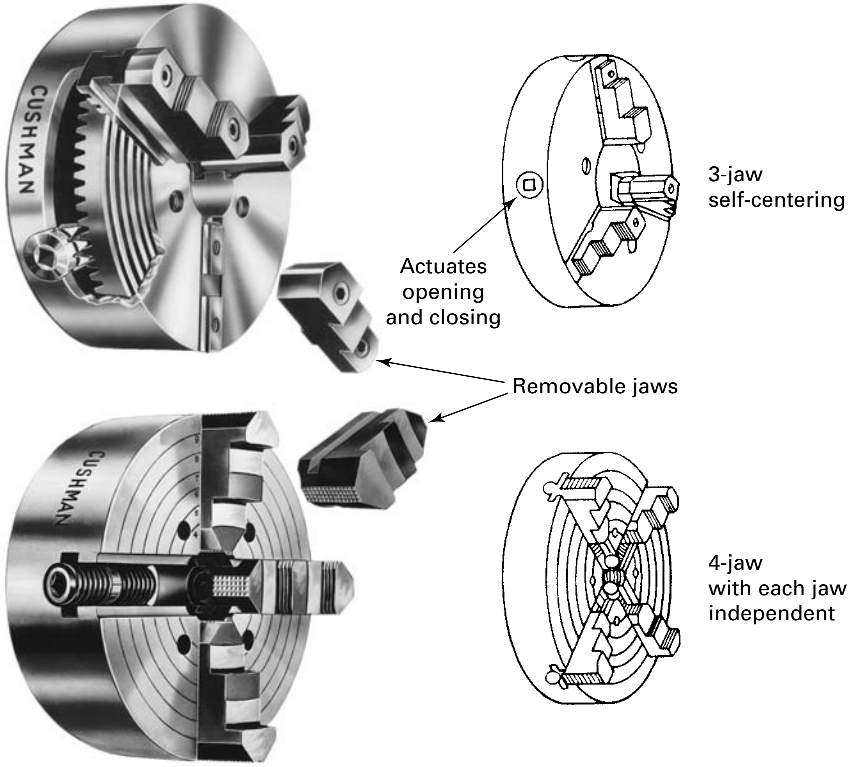


FIGURE 22-24 The jaws on chucks for lathes (four-jaw independent or three-jaw self-centering) can be removed and reversed.

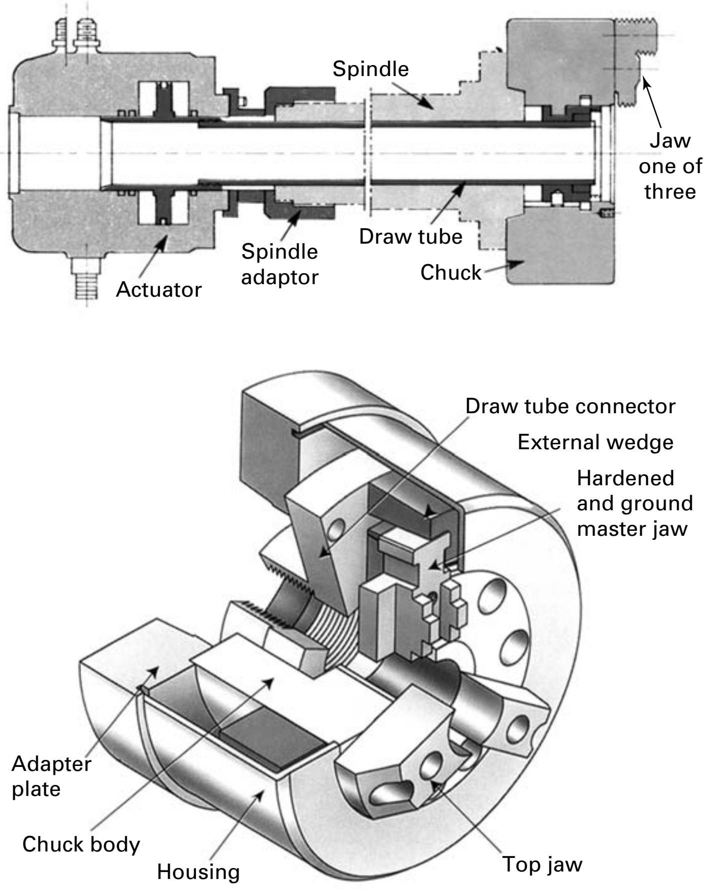

FIGURE 22-25 Hydraulically actuated through-hole three-jaw power chuck shown in section view to left and in the spindle of the lathe above connected to the actuator.

the work. See Figure 22-25 for a schematic. The rapid exchange of tooling is a key manufacturing strategy in manufacturing cells. Chuck jaw sets are dedicated and customized for specific parts. The first time a chuck jaw set is used, each jaw is marked with the number of the jaw slot where it was installed and an index mark that corresponds with the alignment of the jaw serrations and the first tooth on the chuck master jaw. The jaws can now be reinstalled on the chuck exactly where they were bored. The adjustability of the chuck body lets the operator dial in part concentrically without resetting the jaw.

COLLETS

Collets are used to hold smooth cold-rolled bar stock or machined workpieces more accurately than with regular chucks. As shown in Figure 22-26, collets are relatively thin tubular steel bushings that are split into three longitudinal segments over about two-thirds of their length. At the split end, the smooth internal surface is shaped to fit the piece of stock that is to be held. The external surface of the collet is a taper that mates with an internal taper of a collet sleeve that fits into the lathe spindle. When the collet is pulled inward into the spindle (by means of the draw bar), the action of the two mating tapers squeezes the collet segments together, causing them to grip the workpiece.

Collets are made to fit a variety of symmetrical shapes. If the stock surface is smooth and accurate, good collets will provide very accurate centering, with runout less than 0.0005 in. However, the work should be no more than 0.002 in. larger or 0.005 in. smaller than the nominal size of the collet. Consequently, collets are used only on drill-rod, cold-rolled, extruded, or previously machined stock.

Collets that can open automatically and feed bar stock forward to a stop mechanism are commonly used on automatic lathes and turret lathes. An example of a collet chuck is shown in Figure 22-27. Another type of collet similar to a Jacobs drill chuck has a greater size range than ordinary collets; therefore, fewer are required.

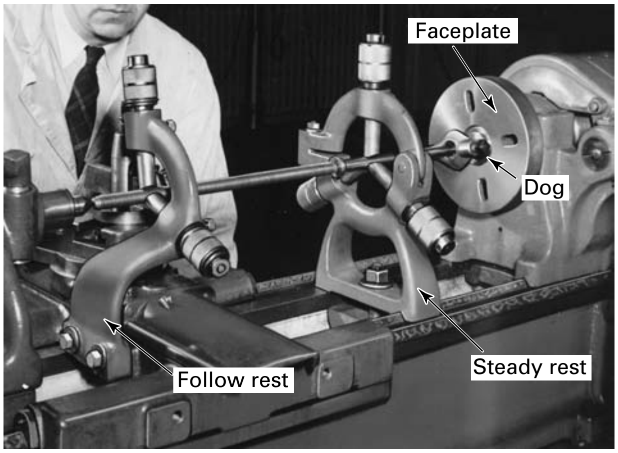

FIGURE 22-28 Cutting a thread on a long, slender workpiece, using a follow rest (left) and a steady rest (right) on an engine lathe. Note the use of a dog and face plate to drive the workpiece. *(Courtesy of South Bend Lathe.)*

FACEPLATES

Faceplates are used to support irregularly shaped work that cannot be gripped easily in chucks or collets. The work can be bolted or clamped directly on the faceplate or can be supported on an auxiliary fixture that is attached to the faceplate. The latter procedure is time saving when identical pieces are to be machined.

MOUNTING WORK ON THE CARRIAGE

When no other means is available, boring occasionally is done on a lathe by mounting the work on the carriage, with the boring bar mounted between centers and driven by means of a dog.

STEADY AND FOLLOW RESTS

If one attempts to turn a long, slender piece between centers, the radial force exerted by the cutting tool or the weight of the workpiece itself may cause it to be deflected out of line. Steady rests and follow rests (Figure 22-28) provide a means for supporting such work between the headstock and the tailstock. The steady rest is clamped to the lathe ways and has three movable fingers that are adjusted to contact the work and align it. A light cut should be taken before adjusting the fingers to provide a smooth contact-surface area.

A steady rest also can be used in place of the tailstock as a means of supporting the end of long pieces, pieces having too large an internal hole to permit using a regular dead center, or work where the end must be open for boring. In such cases the headstock end of the work must be held in a chuck to prevent longitudinal movement. Tool feed should be toward the headstock.

The follow rest is bolted to the lathe carriage. It has two contact fingers that are adjusted to bear against the workpiece, opposite the cutting tool, in order to prevent the work from being deflected away from the cutting tool by the cutting forces.

Review Questions

1. How is the tool–work relationship in turning different from that in facing?
2. What different kinds of surfaces can be produced by turning versus facing?
3. How does form turning differ from ordinary turning?
4. What is the basic difference between facing and a cutoff operation?
5. Which machining operations shown in Figure 22-2 do not form a chip?
6. Why is it difficult to make heavy cuts if a form turning tool is complex in shape?
7. Show how equation 22-5 is an approximate equation.
8. Why is the spindle of the lathe hollow?
9. What function does a lathe carriage have?
10. Why is feed specified for a boring operation typically less than that specified for turning if the MRR equations are the same?
11. What function is provided by the leadscrew on a lathe that is not provided by the feed rod?
12. How can work be held and supported in a lathe?
13. How is a workpiece that is mounted between centers on a lathe driven (rotated)?
14. What will happen to the workpiece when turned, if held between centers, and the centers are not exactly in line?
15. Why is it not advisable to hold hot-rolled steel stock in a collet?
16. How does a steady rest differ from a follow rest?
17. What are the advantages and disadvantages of a four-jaw independent chuck versus a three-jaw chuck?
18. Why should the distance a lathe tool projects from the tool holder be minimized?
19. What is the difference between a ram- and a saddle-turret lathe?
20. How can a tapered part be turned on a lathe?
21. Why might it be desirable to use a heavy depth of cut and a light feed at a given speed in turning rather than the opposite?
22. If the rpm for a facing cut (assuming given work and tool materials) is being held constant, what is happening during the cut to the speed? To the feed?
23. Why is it usually necessary to take relatively light feeds and depths of cut when boring on a lathe?
24. How does the corner radius of the tool influence the surface roughness?
25. What effect does a BUE have on the diameter of the workpiece in turning?
26. How does the multiple-spindle screw machine differ from the single-spindle machine?
27. Why does boring ensure concentricity between the hole axis and the axis of rotation of the workpiece (for boring tool), whereas drilling does not?
28. Why are vertical spindle machines better suited for machining large workpieces than horizontal lathes?
29. What is the principal advantage of a horizontal boring machine over a vertical boring machine for large workpieces?
30. In which figures in this chapter is a workpiece being held in a three-jaw chuck?
31. How is the workpiece in Figure 22-14 being held?
32. In which figures in this chapter is a dead center shown?
33. In which figures in this chapter is a live center shown?
34. In which figures in this chapter showing setups do you find the following being used as a workholding device?
    a. Three-jaw chuck
    b. Collet
    c. Faceplate
    d. Four-jaw chuck
35. How many form tools are being utilized in the process shown in Figure 22-15 to machine the part?
36. From the information given in Figure 22-20, start with a piece of round bar stock and show how it progresses, operation by operation, into a finished part—a threaded shaft.

Problems

1. A cutting speed of 100 sfpm has been selected for a turning cut. At what rpm should a 3-in.-diameter bar be rotated?
2. Assume that the workpiece in Problem 1 is 8 in. (203.2 mm) long and a feed of 0.020 in. (0.51 mm) per revolution is used. What is the machining time for a cut across its entire length? Don't forget to add an allowance.
3. If the depth of cut in Problem 2 is 0.25 in., what is the metal removal rate (MRR) exactly? What is the MRR approximately?
4. Using the same recommended cutting speeds and feeds, calculate the machining time to cut off the bar in Problem 2.
5. The following data apply for machining a part on a turret lathe and on an engine lathe:

	Engine Lathe	Turret Lathe
Times, in minutes, to machine part	30 min	5 min
Cost of special tooling	0	$300
Time to set up the machine	30 min	3 hr
Labor rates	$8/hr	$8/hr
Machine rates (overhead)	$10/hr	$12/hr

   a. How many pieces would have to be made for the cost of the engine lathe to just equal the cost of the turret lathe? This is the BEQ.
   b. What is the cost per unit at the BEQ?
6. A finish cut for a length of 10 in. on a diameter of 3 in. is to be taken in 1020 steel with a speed of 100 fpm and a feed of 0.005 ipr. What is the machining time?
7. A workpiece 10 in. in diameter is to be faced down to a diameter of 2 in. on the right end. The CNC lathe (see Chapter 26) controls the spindle speed and maintains the cutting speed at 100 fpm throughout the cut by changing the rpm. What should be the time for the cut? Now suppose the spindle rpm for the workpiece is set to give a speed of 100 fpm for the 10-in. diameter and is not changed during the cut. What is the machining time for the cut now? The feed rate is 0.005 ipr.
8. A hole 89 mm in diameter is to be drilled and bored through a piece of 1340 steel that is 200 mm long, using a horizontal boring, drilling, and milling machine. High-speed tools will be used. The sequence of operations will be center drilling; drilling with an 18-mm drill followed by a 76-mm drill; then boring to size in one cut, using a feed of 0.50 mm/rev. Drilling feeds will be 0.25 mm/rev for the smaller drill and 0.64 mm/rev for the

larger drill. The center drilling operation requires 0.5 min. To set or change any given tool and set the proper machine speed and feed requires 1 min. Select the initial cutting speeds, and compute the total time required for doing the job. (Neglect setup time for the fixture.) This is often referred to as the run time or the cycle time. (*Hint:* Check in Chapter 21 for recommended speeds for turning.)

9. Figure 22-A shows the fixed and variable costs for a part being produced on an engine lathe. Figure 22-B has three plots of unit production cost ($/unit) versus production volume (Q = build quantity). (Note that this plot is made on log-log paper.) Cost per unit for a particular process decreases with increased volume as fixed costs are spread out over more units. For a particular process there is no minimum cost but rather production volumes within which particular processes are most economical.

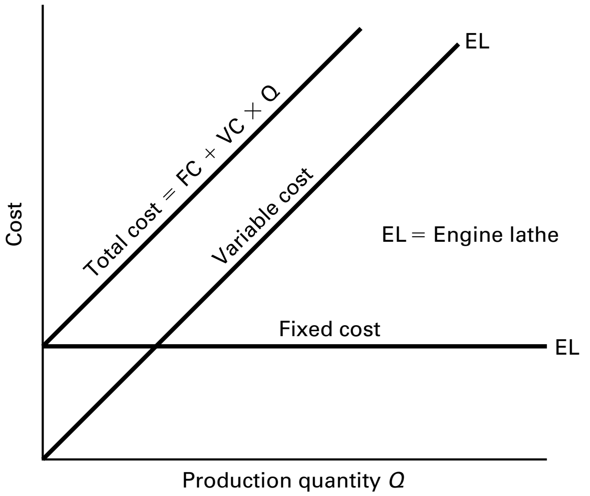

FIGURE 22-A

   a. Each of these curves is a plot of the equation for total cost divided by quantity, which means each is the sum of the fixed cost per unit (mainly setup and tooling costs) and the variable costs per unit (direct labor, direct material). From the data on the plots, estimate the fixed costs for the engine lathe, the NC lathe, and the single-spindle automatic.
   b. For what build quantities is the NC lathe most economical (approximately)?
   c. What cost per unit does the NC lathe approach as the build quantity becomes very large?
   d. Explain how to go from a cost vs. quantity plot to a cost/unit vs. quantity plot?
   e. What happens to these plots if you plot them on regular Cartesian coordinates? Try it and comment on what you find.
   f. Many Japanese manufacturers have found innovative ways to eliminate setup time in many of their processes. What is the impact of this on these kinds of plots, on cost per unit economics, and on job shop inventories?

10. The derivation of the approximate equation 22-5 for the MRR for turning process requires an assumption regarding the diameters of the parts being turned. Determine the error in the equation for Problem 3. What is the assumption?

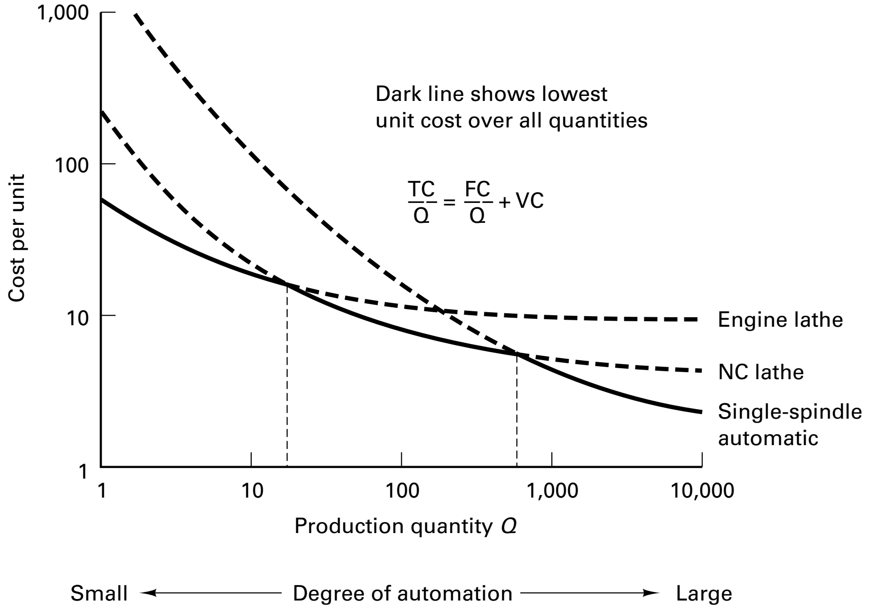

FIGURE 22-B

Chapter 22 CASE STUDY

Estimating the Machining Time for Turning

As the plant manufacturing engineer at **BRC**, Inc., Jay Strom has been called into the production department to provide an expert opinion on a machining problem. Unfortunately, the only tool or instrument you have available at the time is a 1-inch micrometer.

Katrin Zachary, the production manager, would like to know the minimum time required to machine a large forging. The 8-foot-long forging is to be turned down from an original diameter of 10 in. to a final diameter of 6 in. The forging has a BHN of 300 to 400. The turning is to be performed on a heavy-duty lathe, which is equipped with a 50 HP motor and a continuously variable speed drive on the spindle. The work will be held between centers, and the overall efficiency of the lathe has been determined to be 75%. See **Chapter 21**.

The forging (or log) is made from medium-carbon, 4345 alloy steel. The steel manufacturer, some basic experimentation, and established knowledge of the product and its manufacture have provided the following information:

1. A tool-life equation developed for the most suitable type of tool material at a feed of 0.020 ipr and a rake angle of $\alpha = 10$ degrees. The equation $VT^n = C$ generally fits the data, with V = cutting speed and T = the time in minutes to tool failure. Two test cuts were run, one at $V = 60$ sfpm where $T = 100$ minutes and another at $V = 85$ sfpm, where $T = 10$ minutes.
2. According to the vendor, the dynamic shear strength of the material is on the order of 125,000 psi.
3. Jay decides to make two test cuts at the standard feed of 0.020 ipr. He assumes that the chip thickness ratio varies almost linearly between the speeds of 20 and 80 fpm, the values being 0.4 at the speed of 20 fpm and 0.6 at 80 fpm. The chip thickness values were determined by micrometer measurement in order to determine the value of r_C.
4. The machined forging (log) will be used as a roller in a newspaper press and must be precisely machined. If the log deflects during the cutting more than 0.005 in., the roll will end up barrel-shaped after final grinding and polishing.

How should Jay proceed to estimate the minimum time required to machine this forging, assuming that one finishing pass will be needed when the log has been reduced to 6 in. in diameter? The deflection due to cutting forces must be kept below 0.005 in. at the mid-log location.

You can assume that $F_C \times 0.5 = F_f$ and $F_f \times 0.5 = F_R$ and that F_R causes the deflection.

CHAPTER 23

DRILLING AND RELATED HOLE-MAKING PROCESSES

23.1 INTRODUCTION

In manufacturing it is probable that more holes are produced than any other shape, and a large proportion of these are made by *drilling*. Of all the machining processes performed, drilling makes up about 25%. Consequently, drilling is a very important process. Although drilling appears to be a relatively simple process, it is really a complex process. Most drilling is done with a tool having two cutting edges, or *lips*, as shown in Figure 23-1. This is a twist drill, the most common drill geometry. The cutting edges are at the end of a relatively flexible tool. Cutting action takes place inside the workpiece. The only exit for the chips is the hole that is mostly filled by the drill. Friction between the margin and the hole wall produces heat that is additional to that due to chip formation. The counterflow of the chips in the flutes makes lubrication and cooling difficult. There are four major actions taking place at the point of a drill.

1. A small hole is formed by the web—chips are not cut here in the normal sense.
2. Chips are formed by the rotating lips.

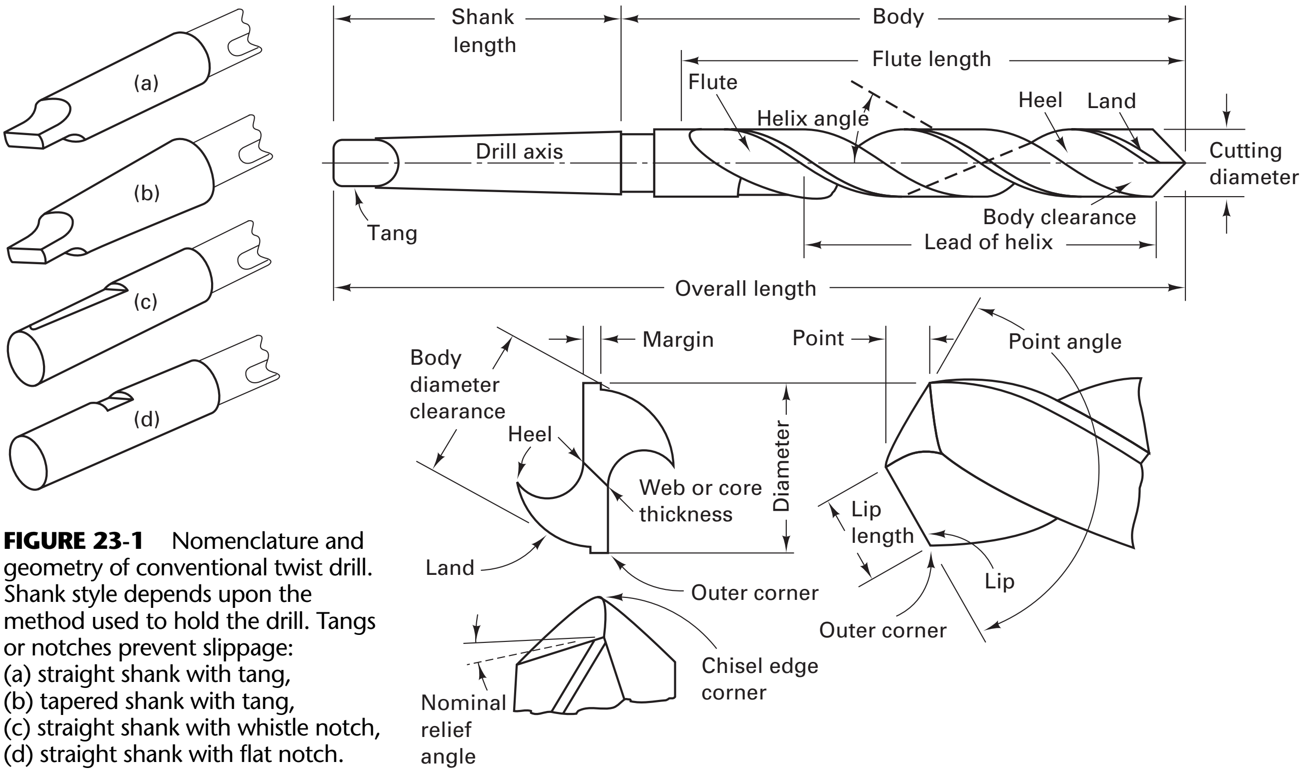

FIGURE 23-1 Nomenclature and geometry of conventional twist drill. Shank style depends upon the method used to hold the drill. Tangs or notches prevent slippage:
(a) straight shank with tang,
(b) tapered shank with tang,
(c) straight shank with whistle notch,
(d) straight shank with flat notch.

3. Chips are removed from the hole by the screw action of the helical flutes.
4. The drill is guided by lands or margins that rub against the walls of the hole.

In recent years, new drill-point geometries and TiN coatings have resulted in improved hole accuracy, longer life, self-centering action, and increased feed-rate capabilities. However, the great majority of drills manufactured are twist drills. One estimate has U.S. manufacturing companies consuming 250 million twist drills per year.

When high-speed steel (HSS) drills wear out, the drill can be reground to restore its original geometry. If regrinding is not done properly, the original drill geometry may be lost, and so will drill accuracy and precision. Drill performance also depends on the drilling machine tool, the workholding device, the drill holder, and the surface of the workpiece. Poor surface conditions (sand pockets and/or chilled hard spots on castings, or hard oxide scale on hot-rolled metal) can accelerate early tool failure and degrade the hole-drilling process.

23.2 Fundamentals of the Drilling Process

The process of drilling creates two chips. A conventional two-flute drill, with drill of diameter D, has two principal cutting edges rotating at an rpm rate of N and feeding axially. The rpm of the drill is established by the selected cutting velocity or cutting speed

$$N_s = \frac{12V}{\pi D} \tag{23-1}$$

with V in surface feet per minute and D in inches (mm). This equation assumes that V is the cutting speed at the outer corner of the cutting lip (point X in Figure 23-2).

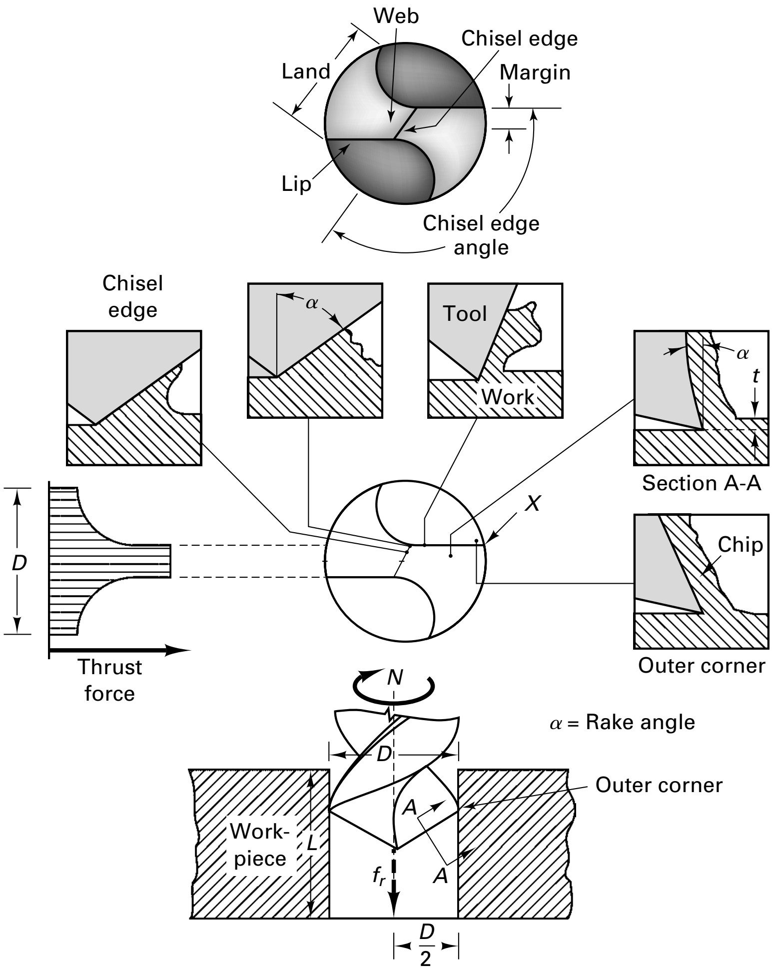

FIGURE 23-2 Conventional drill geometry viewed from the point showing how the rake angle varies from the chisel edge to the outer corner along the lip. The thrust force increases as the web is approached.

The feed, f_r, is given in inches per revolution. The depth of cut in drilling is equal to half the feed rate, or $t = f_r/2$ (see section A–A in Figure 23-2). The feed rate in inches per minute, f_m, is $f_r N_s$. The length of cut in drilling equals the depth of the hole, L, plus an allowance for approach and for the tip of drill, usually $A = D/2$. In drilling, the speed and feed depend upon the material being machined, the cutting tool material, and the size of drill. Table 23-1 gives some typical values for V and for carbide indexable insert drills, a type of drill shown later in the chapter.

After selecting the cutting speed and feed for drilling the hole, the rpm value of the spindle of the machine is determined from equation 23-1, the maximum velocity occurring at the extreme ends of the drill lips. The velocity is very small near the center of the chisel end of the drill. For drilling, cutting time is

$$T_m = \frac{(L + A)}{f_r N_s} = \frac{L + A}{f_m} \tag{23-2}$$

TABLE 23-1 Recommended Speeds and Feeds for Indexable-Insert Drills

Material Group	Size Range	Cutting Speed sfpm	Feed Rate (in./rev.)[a]
Cast iron: modular, ductile, or malleable	$\frac{13}{16}$–$1\frac{1}{8}$	165–300	0.004–0.008
	1–$1\frac{3}{8}$	165–300	0.005–0.010

	$2\frac{3}{8}$–$3\frac{1}{2}$	135–190	0.006–0.010

[a] Ultimate speeds and feeds may differ from recommended speeds and feeds depending on materials, rigidity of machine and setup, workpiece, and depth of cut.

Example of Drilling

A cast iron plate is 2 in. thick and needs 4-in.-diameter holes drilled in it. An indexable-insert drill has been selected. Looking at Table 23-1, we select a cutting speed of 200 fpm and a feed of 0.005 ipr.

The spindle rpm = $12V/\pi D = 12 \times 200 / 3.14 \times 1 = 764$ rpm.

What if the machine does not have this specific rpm? Pick the closest value: Let's say it is 750 rpm.

The penetration rate or feed rate (in./min) = feed (ipr). The rpm = $0.005 \times 750 = 3.75$ in./min. The maximum chip load = feed (ipr)/2 = 0.005/2 = 0.0025in./rev.

What if the machine does not have the specific feed rate? Pick the next lowest value as a starting value. Let's say it is 3.5 in./min.

The material removal rate (in.^{3}/min) = $(\pi/4) \times (D)^2 \times$ feed (ipr) $\times$ rpm = $(\pi/4)\ 1^2 \times$ feed rate = $3.14/4 \times 1^2 \times 3.50 = 2.75$ in.^{3}/min.

The MRR can be used with the unit power for cast iron (see Chapter 20) to estimate the HP needed to drill the hole. Let $HP_s = 0.33$ for this Cl:

$$HP = HP_s \times MRR = 0.33 \times 2.75 = .90$$

This value would typically represent 80% of the total motor horsepower (HP) needed, so in this case, a horsepower motor greater than 1.5 or 2 would be sufficient.

In estimating the cost of a job, it is often necessary to determine the time to drill a hole.

$$\text{drill time/hole} = \frac{\text{length drilled} + \text{allowance}}{\text{feed rate (in./min)}} + \frac{\text{rapid traverse length of withdrawal}}{\text{rapid traverse rate}} + \text{prorated downtime to change drills per hole}$$

The last term prorated downtime is

$$\frac{\text{drill change downtime}}{\text{holes drilled per drill (tool life)}}$$

And the cost/hole is

$$\text{drilling time/holes} \times (\text{labor} + \text{machine rate}) + \text{prorated cost of drill/hole}$$

The metal removal rate is

$$MRR = \frac{\text{volume}}{T_m} = \frac{\pi D^2 L/4}{L/f_r N_s} \text{(omitting allowances)} \qquad (23\text{-}3)$$

which reduces to

$$MRR = (\pi D^2/4) f_r N_s \text{ in.}^3 \qquad (23\text{-}4)$$

Substituting for N with equation 23-1, we obtain an approximate form

$$MRR \cong 3DVf_r \qquad (23\text{-}5)$$

23.3 TYPES OF DRILLS

The most common types of drills are *twist drills*. These have three basic parts: the *body*, the *point*, and the *shank*, shown in Figures 23-1 and 23-2. The body contains two or more spiral or helical grooves, called *flutes*, separated by *lands*. To reduce the friction between the drill and the hole, each land is reduced in diameter except at the leading edge, leaving a narrow *margin* of full diameter to aid in supporting and guiding the drill and thus aiding in obtaining an accurate hole. The lands terminate in the point, with the leading edge of each land forming a cutting edge. The flutes serve as channels through which the chips are withdrawn from the hole and coolant gets to the cutting edges. Although most drills have two flutes, some, as shown in Figure 23-3, have three, and some have only one.

FIGURE 23-3 Types of twist drills and shanks. Bottom to top: Straight-shank, three-flute core drill; straight-shank; taper-shank; bit-shank; straight-shank, high-helix angle; straight-shank, straight-flute; taper-shank, subland drill.

The principal rake angles behind the cutting edges are formed by the relation of the flute *helix angle* to the work. This means that the rake angle of a drill varies along the cutting edges (or lips), being negative close to the point and equal to the helix angle out at the lip. Because the helix angle is built into the twist drill, the primary rake angle cannot be changed by normal grinding. The helix angle of most drills is 24°, but drills with larger helix angles—often more than 30°—are used for materials that can be drilled very rapidly, resulting in a large volume of chips. Helix angles ranging from 0° to 20° are used for soft materials, such as plastics and copper. Straight-flute drills (zero helix and rake angles) are also used for drilling thin sheets of soft materials. It is possible to change the rake angle adjacent to the cutting edge by a special grinding procedure called *dubbing*.

The cone-shaped point on a drill contains the cutting edges and the various clearance angles. This cone angle affects the direction of flow of the chips across the tool face and into the flute. The 118° cone angle that is used most often has been found to provide good cutting conditions and reasonable tool life when drilling mild steel, thus making it suitable for much general-purpose drilling. Smaller cone angles—from 90° to 118°—are sometimes used for drilling more brittle materials, such as gray cast iron and magnesium alloys. Cone angles from 118° to 135° are often used for the more ductile materials, such as aluminum alloys. Cone angles less than 90° frequently are used for drilling plastics. Many methods of grinding drills have been developed that produce point angles other than 118°.

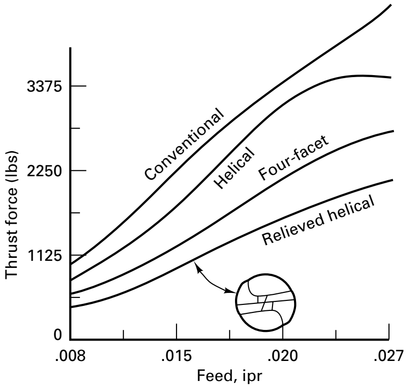
The drill produces a thrust force T and a torque M. Drill torque increases with feed (in./rev) and drill diameter, while the thrust force is influenced greatly by the web or chisel end design, as shown in Figures 23-2 and 23-4.

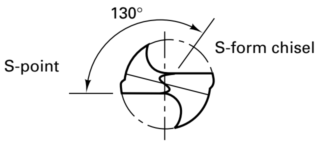
The relatively thin *web* between the flutes forms a metal column or backbone. If a plain conical point is ground on the drill, the intersection of the web and the cone produces a straight-line *chisel end*, which can be seen in the end view of Figure 23-2. The chisel point, which also must act as a cutting edge, forms a 56° negative rake angle with the conical surface. Such a large negative rake angle does not cut efficiently, causing excessive deformation of the metal. This results in high thrust forces and excessive heat being developed at the point. In addition, the cutting speed at the drill center is low, approaching zero. As a consequence, drill failure on a standard drill occurs both at the center, where the cutting speed is lowest, and at the outer tips of the cutting edges, where the speed is highest.

When the rotating, straight-line chisel point comes in contact with the workpiece, it has a tendency to slide or "walk" along the surface, thus moving the drill away from the desired location. The conventional point drill, when used on machining centers or high-speed automatics, will require additional supporting operations like center drilling, burr removal, and tool change, all of which increase total production time and reduce productivity.

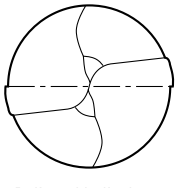
Many special methods of grinding drill points have been developed to eliminate or minimize the difficulties caused by the chisel point and to obtain better cutting action and tool life (see Figure 23-4 for some examples).

The center core or slot-point drill shown in Figure 23-5 has twin carbide tips brazed on a steel shank and a hole (or slot) in the center. The work material in the slot is not machined but, rather, fractured away. The center core drill has a self-centering action and greatly relieves the thrust force produced by the chisel edge of conventional twist drills. This drill operates at about 30 to 50% less thrust than that of

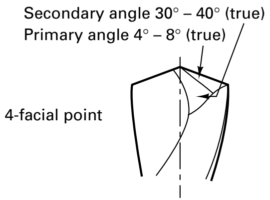




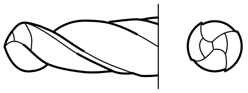
Helical (S-shape chisel point)
Can eliminate center drilling on NC machining centers
Excellent hole geometry
Close relationship between drill size and hole size
Increased tool life
Lower thrust requirements
Leaves burr on breakthrough



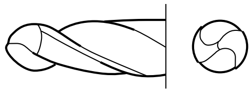
Relieved helical
Reduces thrust force
Eliminates chisel end
Equal, rake angle



Four-facet
Good self-centering ability
Breaks up chips for deep-hole drilling
Can be generated in a single grinding operation: reduces thrust.
Eliminates center drilling in NC

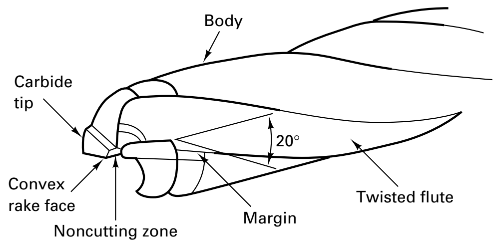


Bickford
Combination of helical and Racon point features
Self-centering and reduced burrs
Excellent hole geometry
Increased tool life



Racon (radiused conventional point)
Increased feed rates
Increased tool life (8–10 times in C.I.)
Reduced burrs at breakthrough
Not self-centering

FIGURE 23-4 As the drill advances, it produces a thrust force. Variations in the drill-point geometry are aimed at reducing the thrust force.



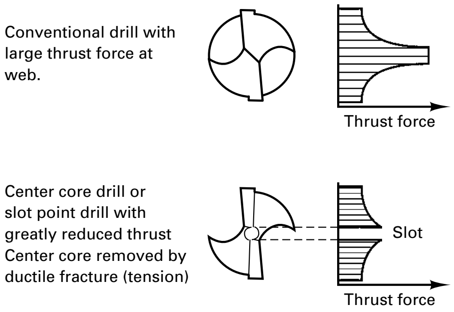


FIGURE 23-5 Center core drills can greatly reduce the thrust force.

conventional drills. All rake angles of the cutting edge are positive, which further reduces the cutting force.

The conventional point also has a tendency to produce a burr on the exit side of a hole. Some type of chip breaker is often incorporated into drills. One procedure is to grind a small groove in the rake face, parallel with and a short distance back from the cutting edge. Drills with a special chip-breaker rib as an integral part of the flute are available. The rib interrupts the flow of the chip, causing it to break into short lengths.

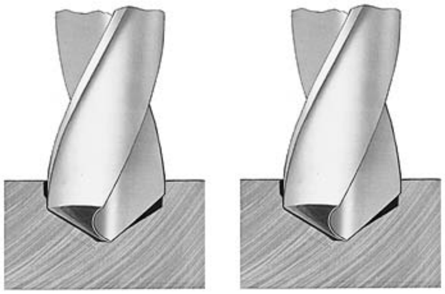
The split-point drill is a form of *web thinning* to shorten the chisel edge. This design reduces thrust and allows for higher feed rates. Web thinning uses a narrow grinding wheel to remove a portion of the web near the point of the drill. Such methods have had varying degrees of success, and they require special drill-grinding equipment.

Also shown in Figure 23-4 is a four-facet self-centering point that works well in tougher materials. The facets refer to the number of edges on the clearance surfaces exposed to the cutting action. The self-centering drill lasts longer and saves machining time on numerical control (NC) centers as they can eliminate the need for center drills. A common aspect in drill-point terminology is total indicator runout (TIR). This is a measure of the cutting lips' relative side-to-side accuracy. The original drill point produced by the manufacturer lasts only until the first regrind; thereafter performance and life depend upon the quality of regrind. Proper regrinding (reconditioning) of a drill is a complex and important operation. If satisfactory cutting and hole size are to be achieved, it is essential that the point angle, lip clearance, lip length, and web thinning be correct. As illustrated in Figure 23-6, incorrect sharpening often results in unbalanced cutting forces at the tip, causing misalignment and oversized holes. Drills, even small drills, should always be machine ground, never hand ground. Drill grinders, often computer controlled, should be used to ensure exact reproduction of the geometry established by the manufacturer of the drill. This is extremely important when drills are used on mass-production or numerically controlled machines. Companies invest huge sums in NC machining centers but overlook the value of a top-quality drill-grinding machine.

Drill shanks are made in several types. The two most common types are the straight and the taper. *Straight-shank* drills are usually used for sizes up to $\frac{3}{8}$-in. diameter and must be held in some type of drill chuck. *Taper shanks* are available on larger drills and are common on drills above 1 in. Morse tapers are used on taper-shank drills, ranging from a number 1 taper to a number 6.

Taper-shank drills are held in a female taper in the end of the machine tool spindle. If the taper on the drill is different from the spindle taper, adapter sleeves are available. The taper assures the drill's being accurately centered in the spindle. The *tang* at the end

FIGURE 23-6 Typical causes of drilling problems.



(a) Angle unequal (b) Length unequal

Outer corners break down: Cutting speed too high; hard spots in material; no cutting compound at drill point; flutes clogged with chips

Cutting lips chip: Too much feed; lip relief too great

Checks or cracks in cutting lips: Overheated or too quickly cooled while sharpening or drilling

Chipped margin: Oversize jig bushing

Drill breaks: Point improperly ground; feed too heavy; spring or backlash in drill press, fixture, or work; drill is dull; flutes clogged with chips

Tang breaks: Imperfect fit between taper shank and socket caused by dirt or chips or by burred or badly worn sockets

Drill breaks when drilling brass or wood: Wrong type drill; flutes clogged with chips

Drill spilts up center: Lip relief too small; too much feed

Drill will not enter work: Drill is dull; web too heavy; lip relief too small

Hole rough: Point improperly ground or dull; no cutting compounds at drill point; improper cutting compound; feed too great; fixture not rigid

Hole oversize: Unequal angle of the cutting edges; unequal length of the cutting edges; see part (a)

Chip shape changes while drilling: Dull drill or cutting lips chipped

Large chip coming from one flute, small chip from the other: Point improperly ground, one lip doing all the cutting

of the taper shank fits loosely in a slot at the end of the tapered hole in the spindle. The drill may be loosened for removal by driving a metal wedge, called a *drift*, through a hole in the side of the spindle and against the end of the tang. It also acts as a safety device to prevent the drill from rotating in the spindle hole under heavy loads. However, if the tapers on the drill and in the spindle are proper, no slipping should occur. The driving force to the drill is carried by the friction between the two tapered members. Standard drills are available in four size series, the size indicating the diameter of the drill body:

- *Millimeter series:* 0.01- to 0.50-mm increments, according to size, in diameters from 0.015 mm
- *Numerical series:* no. 80 to no. 1 (0.0135 to 0.228 in.)
- *Lettered series: A* to *Z* (0.234 to 0.413 in.)
- *Factional series:* to 4 in. (and over) by 64ths.

TiN coating of conventional drills greatly improves drilling performance. The increase in tool life of TiN-coated drills over uncoated drills in machining steel is more than 200 to 1000%.

DEPTH-TO-DIAMETER RATIO

The depth of the hole to be drilled divided by the diameter of the drill is the depth-to-diameter ratio. Most machinists consider a ratio of 3 to 1 to be deep-hole drilling, after which hole accuracy (location) drilling speed and tool life will be reduced. The bores of rifle barrels were once drilled using conventional drills. Today, *deep-hole drills*, or *gundrills*, are used when deep holes are to be drilled.

The oldest of these deep-hole techniques is *gundrilling*. The original *gundrills* were very likely half-round drills, drilled axially with a coolant hole to deliver cutting fluids to the cutting edge (see Figure 23-7). Modern gundrills typically consist of an alloy-steel-tubing shank with a solid carbide or carbide-edged tip brazed or mechanically fixed to it. Guide pads following the cutting edge by about 90° to 180° are also standard.

The gundrill is a single-lipped tool, and its major feature is the delivery of coolant through the tool at extremely high pressures—typically from 300 psi to 1800 psi, depending on diameter—to force chips back down the flute. Successful application of a gundrill depends almost entirely on the formation of small chips that can be effectively evacuated by the flow of cutting fluids.

Standard gundrills are made in diameters from 0.0078 in. (2 mm) to 2 in. or more. Depth-to-diameter ratios of 100 to 1 or more are possible.

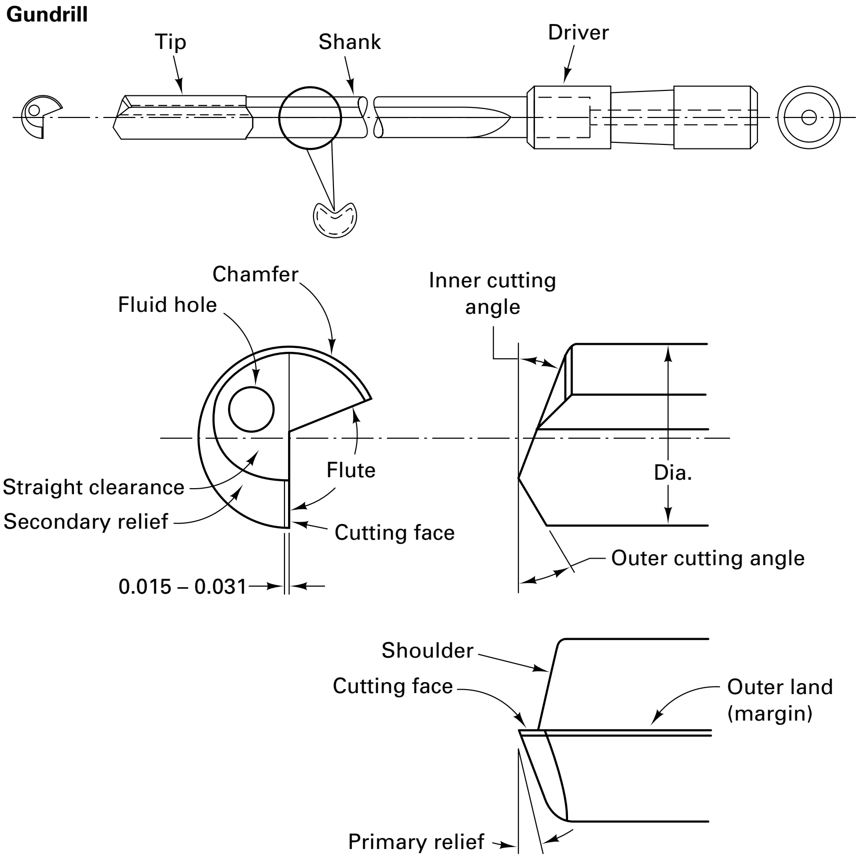


FIGURE 23-7 The gundrill geometry is very different from that of conventional drills.

In gundrilling tolerances for diameters of drilled holes under 1 in. can be held to 0.0005-in. total tolerance, and, should not exceed 0.001 in. over all. According to one source, "roundness accuracies of 0.00008 inch can be attained." Because of the burnishing effect of the guide pads, excellent surface finishes can be produced.

Hole straightness is affected by a number of variables, such as diameter, depth, uniformity of workpiece material, condition of the machine, sharpness of the gundrill, feeds and speeds used, and the specific technique used (rotation of the tool, of the work, or both), but deviation should not exceed about 0.002 in. TIR in a 4-in. depth at any diameter, and it can be held to 0.002 in. per foot.

Basic setup for a gundrilling operation, which is generally horizontal, requires a drill bushing very close to the work entry surface and may involve rotating the work or the tool, or both. Best concentricity and straightness are achieved by the work and the tool rotating in opposite directions.

Other deep-hole drills are called *BTA* (Boring Trepanning Association) *drills* and *ejector drills*. A deep hole is one in which the length (or depth) of the hole is three or more times the diameter. Coolants can be fed internally through these drills to the cutting edges. See Figure 23-8 for schematic of an ejector drill and the machine tool used for gundrilling. The coolants flush the chips out the flutes. The special design of these drills reduces the tendency of the drill to drift, thus producing a more accurately aligned hole. The typical BTA deep-hole drilling tools are designed for single-lip end cutting of a hole in a single pass. Solid-deep-hole drills have alloy-steel shanks with a carbide-edged tip that is fixed to it mechanically. The cutting edge cuts through the center on one side of the hole, leaving no area of material to be extruded. The cutting is done by the outer and inner cutting angles, which meet at a point. Theoretically, the depth of the hole has no limit, but practically, it is restricted by the torsional rigidity of the shank.

Gundrills have a single-lip cutting action. Bearing areas and lifting forces generated by the coolant pressure counteract the radial and tangential loads. The single-lip construction forces the edge to cut in a true circular pattern. The tip thus follows the direction of its own axis. The *trepanning gundrill* leaves a solid core.

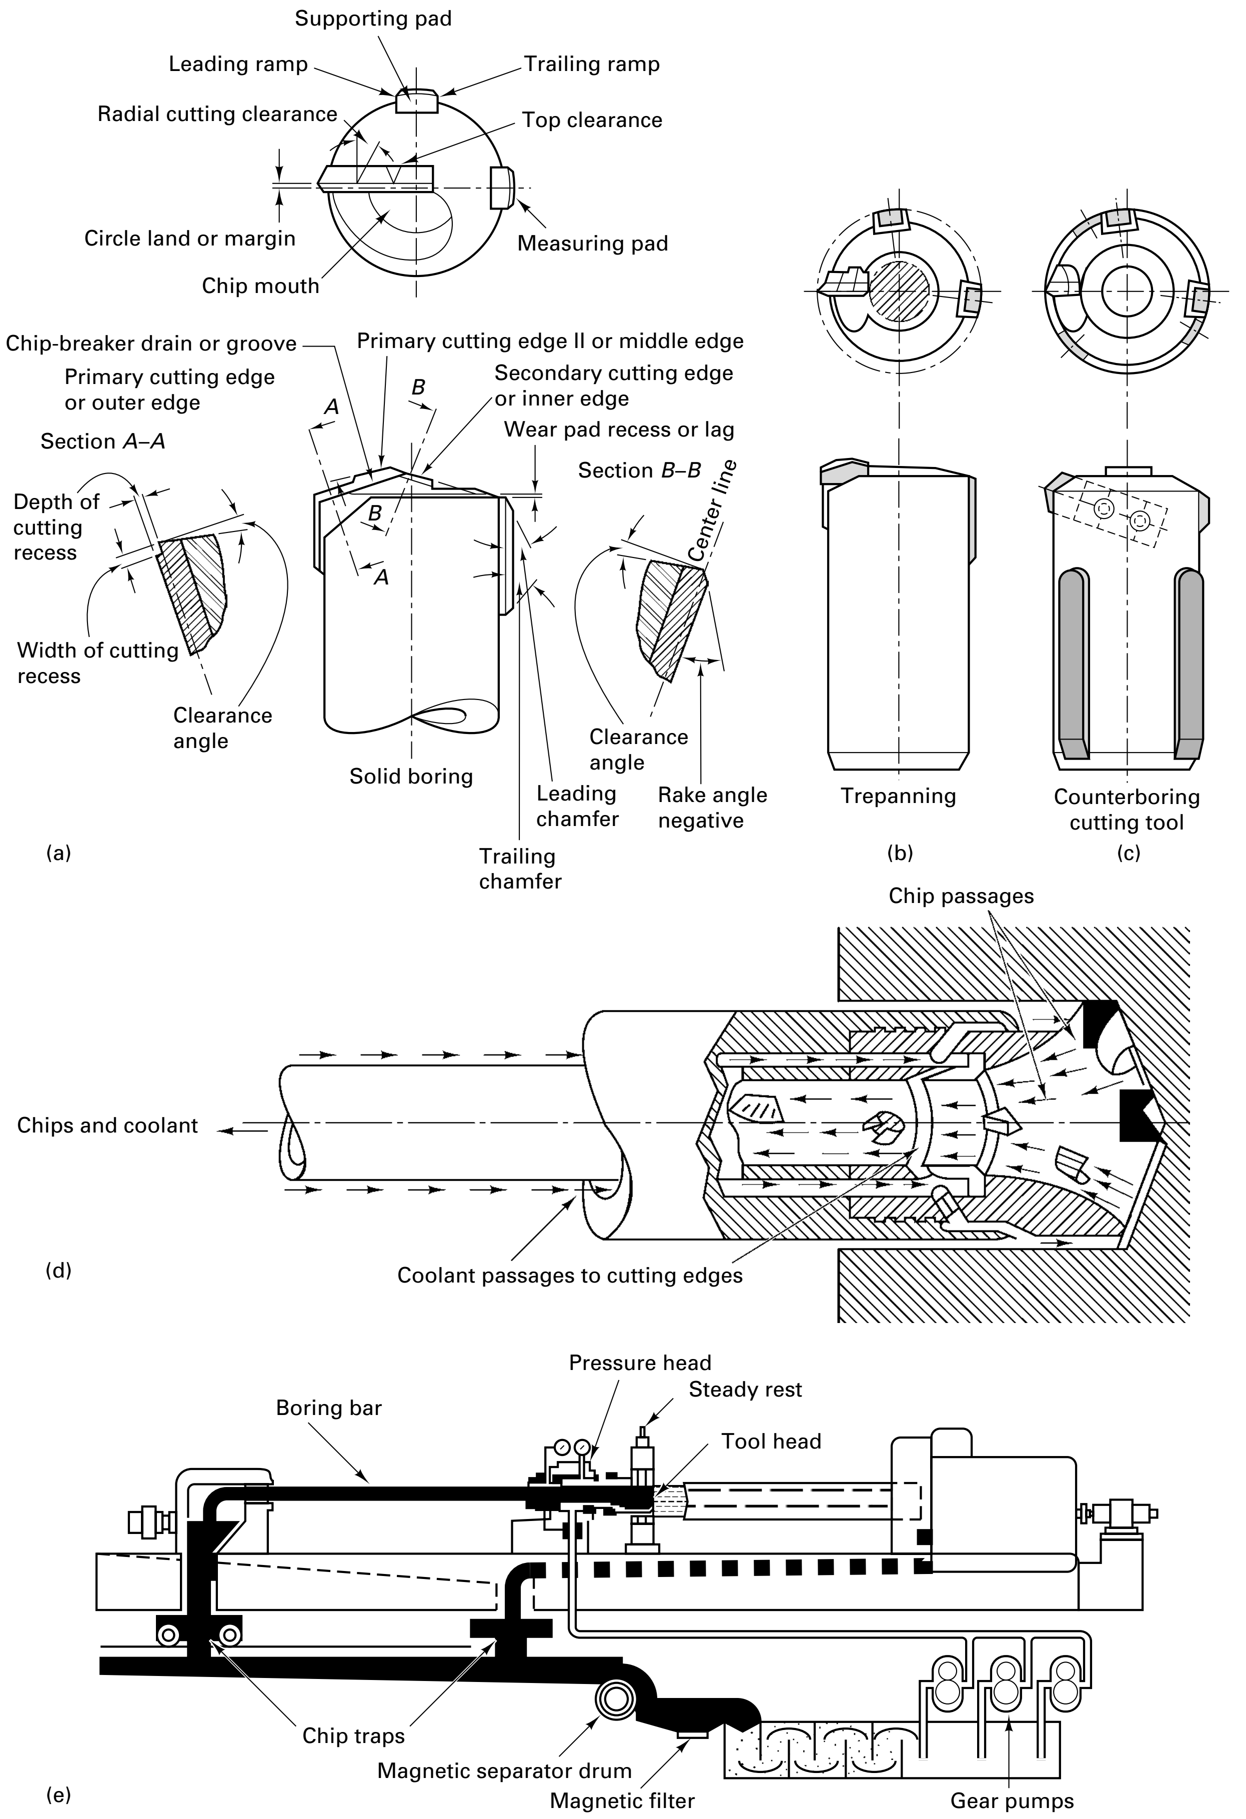

FIGURE 23-8 BTA drills for (a) boring, (b) trepanning, (c) counterboring, (d) deep-hole drilling with ejector drill, (e) horizontal deep-hole-drilling machine. *(S. Azad and S. Chandeashekar,* Mechanical Engineering, *Sept. 1985, pp. 62, 63.)*

TABLE 23-2 Drilling Processes Compared

	Twist Drill	Pivot (micro)	Spade (inserted blade)	Indexable-Insert Drill	Gundrill	BTA System	Ejector Drill	Trepanning
Diameter, in.	0.020–2	0.001–0.020	1–6	$^{5}/_{8}-3$	0.078–1	$^{7}/_{16}-8$	$^{3}/_{4}-2^{1}/_{2}$	$1^{3}/_{4}-10$

Ultimate	>50	20	10 (vert)	—	200	>100	>50	>100
			>100 (horz)					

[a] Maximum depth/diameter ratios in this table are estimates of what can be achieved with special attention and under ideal conditions. Equality of tolerances should not be assumed for the different processes.

Hole straightness is affected by variables such as diameter, depth, uniformity of the workpiece material, condition of the machine, sharpness of cutting edges, feeds and speeds used, and whether the tool or the workpiece is rotated or counterrotated.

Two-flute drills are available that have holes extending throughout the length of each land to permit coolant to be supplied, under pressure, to the point adjacent to each cutting edge. These are helpful in providing cooling and also in promoting chip removal from the hole in drilling to moderate depths. They require special fittings through which the coolant can be supplied to the rotating drill, and they are used primarily on automatic and semiautomatic machines. See Table 23-2 for comparison of drilling processes.

Larger holes in thin material may be made with a *hole cutter* (Figure 23-9), whereby the main hole is produced by the thin-walled, multiple-tooth cutter with saw teeth. Hole cutters are often called *hole saws*.

When starting to drill a hole, a drill can deflect rather easily because of the "walking" action of the chisel point. Hole location accuracy is lost. Consequently, to ensure that a hole is started accurately, a *center drill* (Figure 23-10) is used prior to a regular chisel-point twist drill. The center drill and countersink tool have a short, straight drill section extending beyond a 60° taper portion. The heavy, short body provides rigidity so that a hole can be started with little possibility of tool deflection. The hole should be drilled only partway up on the tapered section of countersink. The conical portion of the hole serves to guide the drill being used to make the main hole. Combination center drills are made in four sizes to provide a starting hole of proper size for any drill. If the drill is sufficiently

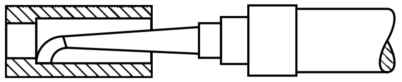
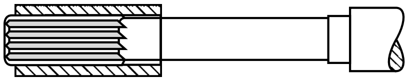
Step 2 Drilling with a standard twist drill.



Step 3 Truing hole by boring.



Step 4 Final sizing and finishing with a reamer.

FIGURE 23-10 To obtain a hole that is accurate as to size and aligned on center (located), this four-step sequence of operations is usual.

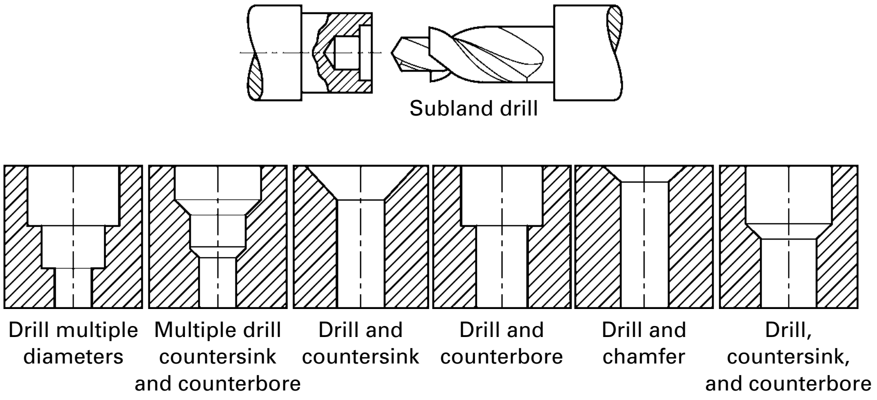


FIGURE 23-11 Special-purpose subland drill (above), and some of the operations possible with other combination drills (below).

large in diameter, or if it is sufficiently short, satisfactory accuracy may often be obtained without center drilling. Special drill holders are available that permit drills to be held with only a very short length protruding.

Because of its flexibility and endpoint geometry, a drill may start or drift off centerline during drilling. The use of a center (start) drill will help to ensure that a drill will start drilling at the desired location. Nonhomogeneities in the workpiece and imperfect drill geometries may also cause the hole to be oversize or off-line. For accuracy, it is necessary to follow center drilling and drilling by boring and reaming. Boring corrects the hole alignment, and reaming brings the hole to accurate size and improves the surface finish.

Special *combination drills* can drill two or more diameters, or drill and countersink and/or counterbore, in a single operation (Figure 23-11). Countersinking and counterboring usually follow drilling. These operations are described in more detail later in this chapter. A *step drill* has a single set of flutes and is ground to two or more diameters. *Subland drills* have a separate set of flutes on a single body for each diameter or operation; they provide better chip flow, and the cutting edges can be ground to give proper cutting conditions for each operation. Combination drills are expensive and may be difficult to regrind but can be economical for production-type operations if they reduce work handling, setups, or separate machines and operations.

Spade drills (Figure 23-12) are widely used for making holes 1 in. or larger in diameter at low speeds or with high feeds (Table 23-3). The workpiece usually has an

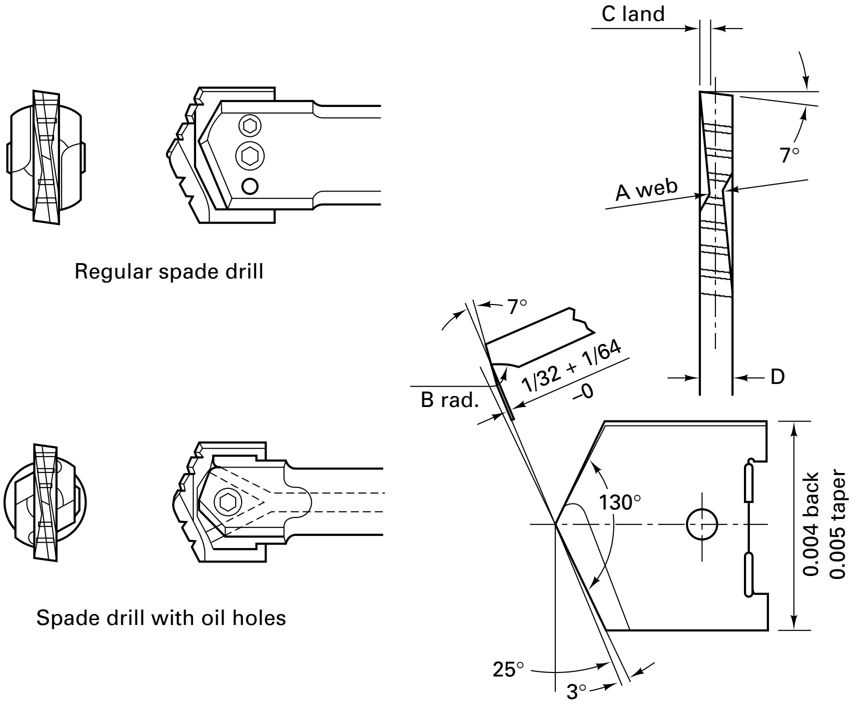

FIGURE 23-12 (Top) Regular spade drill; (middle) spade drill with oil holes; (bottom) spade drill geometry, nomenclature.

TABLE 23-3 Recommended Surface Speeds and Feeds for High-Speed Steel Spade Drills for Various Materials

Material	Surface Speed (ft per min)
Mild machinery steel 0.2 and 0.3 carbon	65–110
Steel, annealed 0.4 to 0.5 carbon	55–80
Tool steel, 1.2 carbon	45–60
Steel forging	35–50
Alloy steel	45–70
Stainless steel, free machining	50–70
Stainless steel, hard	25–40
Cast iron, soft	80–150
Cast iron, medium hard	55–100
Cast iron, hard, chilled	25–40
Malleable iron	79–90
Brass and bronze, ordinary	200–300
Bronze, high tensile	70–150
Monel metal	35–50
Aluminum and its alloys	200–300
Magnesium and its alloys	250–400

Feed Rates for Spade Drilling (inches per revolution)

Drill Size (inches)	Cast Iron Malleable Iron Brass Bronze	Medium Steel Stainless Steel Monel Metal Drop-Forged Alloys Tool Steel (annealed)	Tough Steel Drop Forging Aluminum
1 to $1^{1}/_{4}$	0.010–0.020	0.008–0.014	0.006–0.012
$1^{1}/_{4}$ to $^{3}/_{4}$	0.010–0.024	0.008–0.018	0.008–0.017
$1^{3}/_{4}$ to $2^{1}/_{2}$	0.010–0.030	0.010–0.024	0.010–0.017
$2^{1}/_{2}$ to 4	0.012–0.032	0.012–0.030	0.010–0.017
4 to 6	0.012–0.032	0.010–0.024	0.008–0.017

existing hole, but a spade drill can drill deep holes in solids or stacked materials. Spade drills are less expensive because the long supporting bar can be made of ordinary steel. The drill point can be ground with a minimum chisel point. The main body can be made more rigid because no flutes are required, and it can have a central hole through which a fluid can be circulated to aid in cooling and in chip removal. The cutting blade is easier to sharpen; only the blades need to be TiN-coated.

Spade drills are often used to machine a shallow locating cone for a subsequent smaller drill and at the same time to provide a small bevel around the hole to facilitate later tapping or assembly operations. Such a bevel also frequently eliminates the need for deburring. This practice is particularly useful on mass-production and numerically controlled machines.

Carbide-tipped drills and drills with indexable inserts are also available (see Figure 23-13) with one- and two-piece inserts for drilling shallow holes in solid workpieces. *Indexable insert drills* can produce a hole four times faster than a spade drill because they run at high speeds/low feeds and are really more of a boring operation than a drilling process.

However, to use indexable drills, you must have an extremely rigid machine tool and setup, adequate horsepower, and lots of cutting fluid. Indexable drills are roughing tools generating hole tolerances of and surface finish of 250 rpms or greater. The tool is designed for the inboard insert to cut past the centerline of the tool so the inboard tool is positioned radially below the center. See Table 23-4 for an indexable drilling troubleshooting guide.

FIGURE 23-13 One- and two-lipped indexable insert drills are widely used for holes over 1 inch in diameter. *(Courtesy of Waukesha.)*

TABLE 23-4 Indexable Drilling Troubleshooting Guide[a]

Problem	Source	Solution
Insert chipping or breakage[b]	Off-center drill, caused by misalignment	Maintain proper alignment. Concentricity not to exceed ±0.005 TIR.
	Improper seating of tool in tool holder, spindle, or turret	Check tool shank and socket for nicks and dirt. Check parting line between tool shank and socket with feeler gage. Check to see if tool is locked tightly.
	Deflection because of too much overhand and lack of rigidity	With indicator, check if tool can be moved by hand. Check if tool can be held shorter.
	Improper seating of inserts in pockets	Clean pockets whenever indexing or changing inserts. Check pockets for nicks and burrs. Check if inserts rest completely on pocket bottoms.
	Damaged insert screws	Check head and thread for nicks and burns. Do not overtorque screws.
	Improper speeds and feeds	Check recommended guidelines for given materials.
	Insufficient coolant supply	Check coolant flow.
	Improper carbide grade in inboard station	Recommend straight grade for multiple-insert drills.
Grooving on back stroke; drill body rubbing hole wall; over- or undersize holes	Off-center drill	Maintain proper alignment and concentricity. Check bottom of hole or disk for center stub.
	Deflection	Check setup rigidity. Check speed and feed guidelines.
Poor hole surface finish	Vibrations	Check setup and part rigidity. Check seat in spindle or tool holder. Check speeds and feeds.
	Insufficient coolant pressure and volume	Increase coolant pressure and flow. Is coolant flow constant? Make sure coolant reaches inserts at all times.
	Recutting chips, causing drill to jump	Increase coolant flow. Add coolant grooves.
	Poor chip control; chips trapped in hole	Mostly speed or feed.
	Chatter	Mostly feed rate.
Very short, thick, flat chips	Feed rate too high in relation to cutting speed	Lower feed or increase speed.
Long and stringy chips	Feed rate too low in relation to cutting speed	Increase feed rate or decrease speed. Use dimple inserts.
Unable to loosen insert locking screws	Seized threads, caused by coolant or heat	Apply water and heat-resistant lubricant to threads.

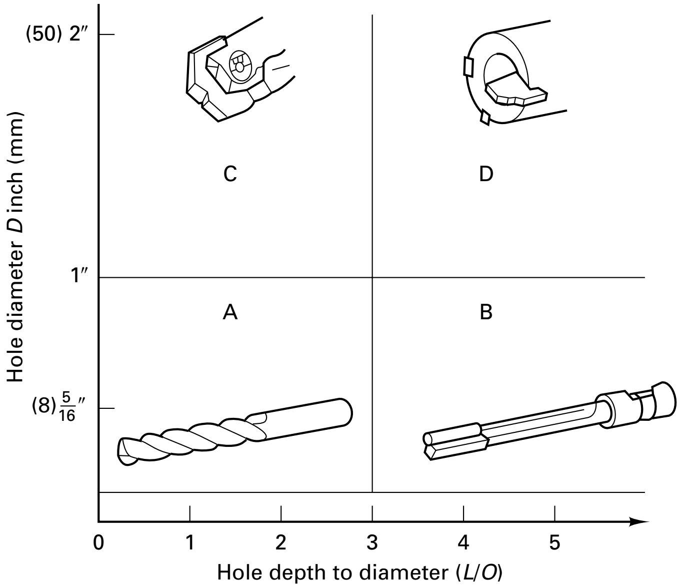
[b] If constant chipping occurs, especially on an inner insert, and conditions are optimum, try an uncoated-carbide insert or a grade with higher transverse rapture strength.



Sector	Typical drill types
A	Twist drill (HSS) Center core drill
B	Twist drill Gundrill BTA Ejector drill
C	Twist drill Indexable insert drill Spade drill Center core drill
D	BTA Ejector drill

FIGURE 23-14 Drill selection depends on hole diameter and hole depth.

A high-pressure, pulsating coolant system can generate pressures up to 300 psi and works well with indexable drilling. It can have disadvantages, however. High pressure with pulsating action can decrease chip control and cause drill deflection. A high-pressure coolant stream can flatten chips at the point of forming and forces them into the cut, causing recutting, insert chipping, and poor hole finishes. The pressure can force chips between the drill body and hole diameter, wrapping them around the drill. Friction then will weld the chips to the tool body or hole.

The diameter of the hole and the length/diameter ratio usually determine what kind of drill to use. Figure 23-14 explores how drill selection depends on the depth of the hole and the diameter of the drill: Section A shows the drilling areas of relatively shallow holes and small diameters. About half of all the drilling process falls within the category of this section. It is the section for which the majority of the work is done by twist drills and a very few cemented carbide drills. Section B is the drilling of deep holes for which cemented carbide gundrills are used. Section C is that of shallow holes having large diameters, for which spade drills are used. Section D is that of deep holes having large diameters, for which BTA tools are used.

MICRODRILLING

As the term suggests, microdrilling involves very-small-diameter cutting tools, including drills, end mills, routers, and other special tools. Drills from 0.002 in. (0.05 mm) and mills to 0.005 in. in diameter are used to produce geometries involving dimensions at which many workpiece materials no longer exhibit uniformity and homogeneity. Grain borders, inclusions, alloy or carbide segregates, and microscopic voids are problems in microdrilling, where holes of 0.02 to 0.0001 in. have been drilled using pivot drills, as shown in Figure 23-15.

Pivot drills are two-lipped (two-fluted), end-cutting tools of relatively simple geometry. Web thickness tapers toward the point, and a generous back-taper is incorporated. For softer workpiece materials, point angles are typically 118° and lip clearance is 15°. For steels and general use in harder metals, 135° points and 8° clearance are recommended. The chisel edge is similar to that of a twist drill. Pivot drills are made of tungsten-alloy tool steel in standard sizes from 0.0001 in. to 0.125 in. and of sintered tungsten carbide from 0.001 in. to 0.125 in.

Small drills easily deflect, and getting accurate and precise holes requires a machine with a high-quality spindle and very sensitive feeding pressure. In the medical components field, much of this machining work is performed on Computer Numerical Control (CNC) Swiss-type turning machines. Speeds and feeds are greatly reduced with frequent pecking to clear the chips. Use a light, lard-based, sulfurized cutting oil.

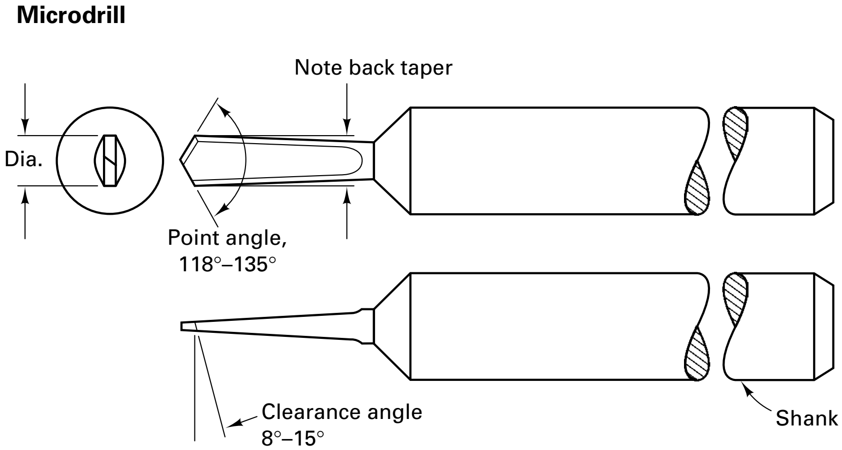


FIGURE 23-15 Pivot microdrill for drilling very-small-diameter holes.

23.4 TOOL HOLDERS FOR DRILLS

Straight-shank drills must be held in some type of drill *chuck* (Figure 23-16). Chucks are adjustable over a considerable size range and have radial steel fingers. When the chuck is tightened by means of a chuck key, these fingers are forced inward against the drill. On smaller drill presses, the chuck often is permanently attached to the machine

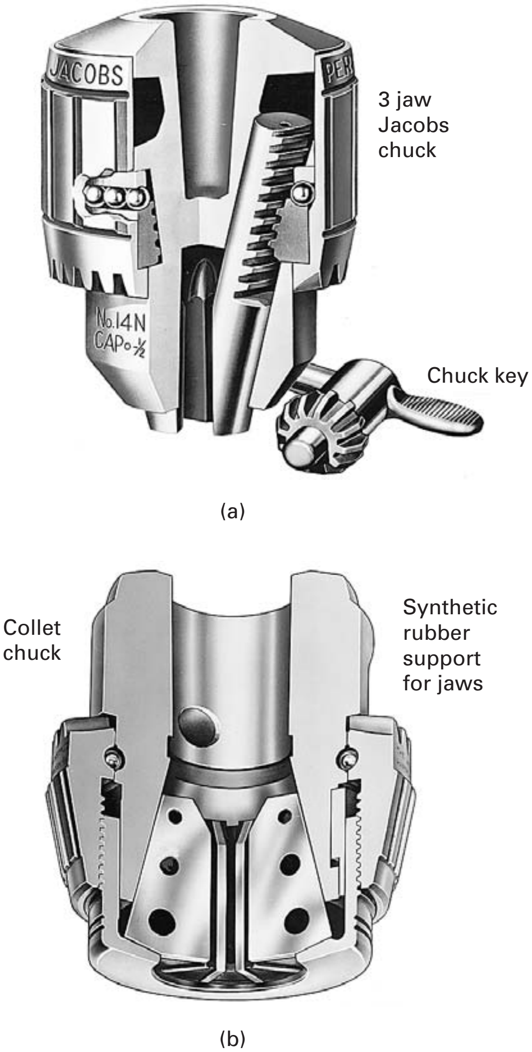

FIGURE 23-16 Two of the most commonly used types of drill chucks are the 3-jaw Jacobs chuck (above) and the collet chuck with synthetic rubber support for jaws. *(Courtesy of Jacobs Manufacturing Company.)*

spindle, whereas on larger drilling machines the chucks have a tapered shank that fits into the female Morse taper of the machine spindle. Special types of chucks in semiautomatic or fully automatic machines permit quite a wide range of sizes of drills to be held in a single chuck.

Chucks using chuck keys require that the machine spindle be stopped in order to change a drill. To reduce the downtime when drills must be changed frequently, *quick-change chucks* are used. Each drill is fastened in a simple round collet that can be inserted into the chuck hole while it is turning by merely raising and lowering a ring on the chuck body. With the use of this type of chuck, center drills, drills, counterbores, reamers, and so on can be manually changed in quick succession. For carbide drills, collet-type holders with thrust bearings are recommended (Figure 23-17). For drills using an internal coolant supply, a very rigid chuck with either an inducer or through-spindle coolant source is recommended.

Conventional holders such as keyless chucks cannot be used because the gripping strength is limited. Collet holders should be cleaned periodically with oil to remove small chips.

The entire flute length must protrude from the chuck. At maximum hole depth, the length of flute protruding from the hole must be at least 1 to 1.5 times the drill diameter. Radial runout at the drill tip must not exceed 0.001 in.

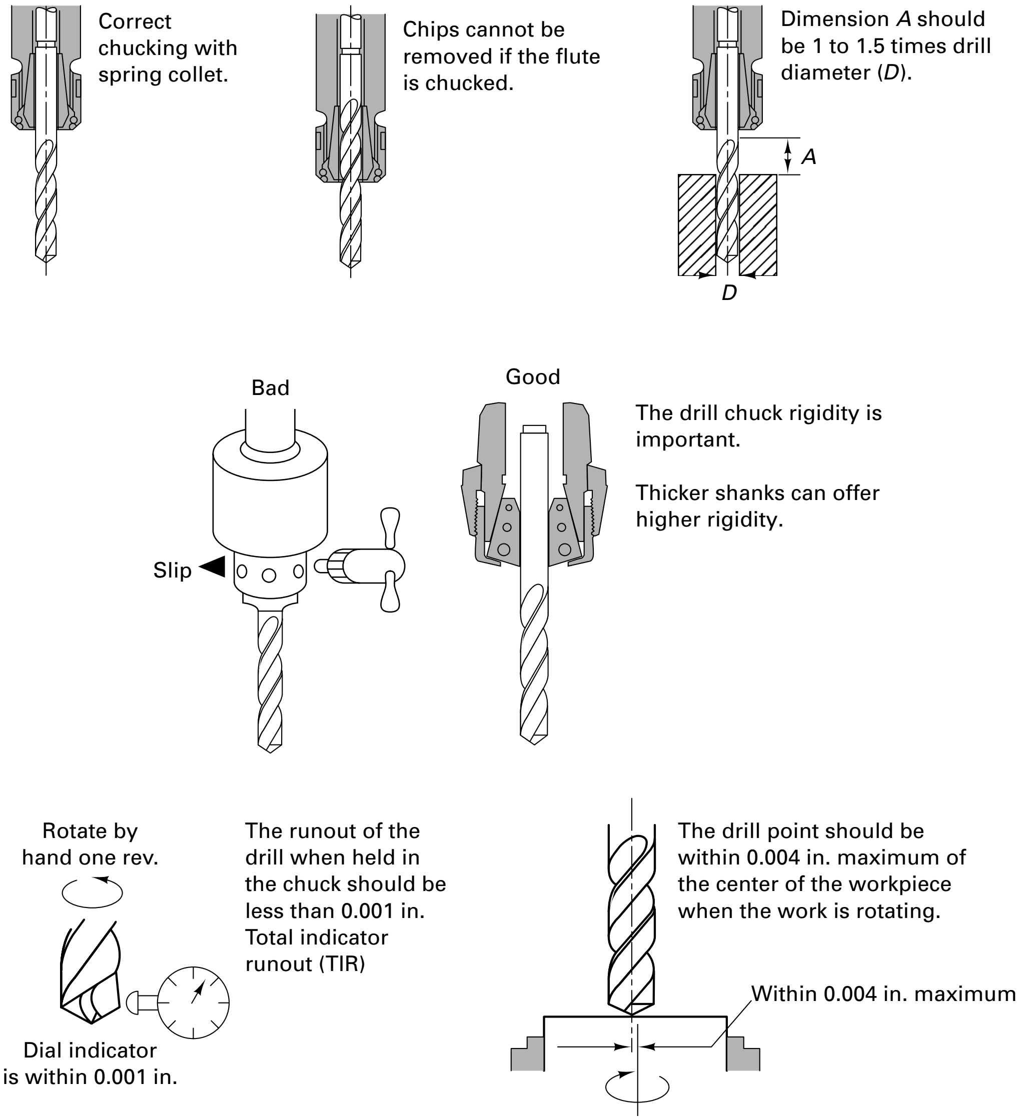

FIGURE 23-17 Here are some suggestions for correct chucking of carbide drills.

23.5 WORKHOLDING FOR DRILLING

Work that is to be drilled is ordinarily held in a vise or in specially designed workholders called *jigs*. Workholding devices are the subject of Chapter 25, where the design of workholding devices is discussed. Many examples of drill jigs are shown.

With regard to safety, the work should not be held on the table by hand unless adequate leverage is available, even in light drilling operations. This is a dangerous practice and can lead to serious accidents, because the drill has a tendency to catch on the workpiece and cause it to rotate, especially when the drill exits the workpiece. Work that is too large to be held in a jig can be clamped directly to the machine table using suitable bolts and clamps and the slots or holes in the table. Jigs and workholding devices on indexing machines must be free from play and firmly seated.

23.6 MACHINE TOOLS FOR DRILLING

The basic work and tool motions required for drilling—relative rotation between the workpiece and the tool, with relative longitudinal feeding—also occur in a number of other machining operations. Thus drilling can be done on a variety of machine tools such as lathes, horizontal and vertical milling machines, boring machines, and machining centers. This section will focus on those machines that are designed, constructed, and used primarily for drilling.

First of all, the machine tools must have sufficient power (torque) and thrust to perform the cut. It is the task of the engineer to select the correct machine or select the cutting parameters (speed and feed) based on the drill diameter, drill material, and work material (hardness). Because of the complex geometry of the drill, empirical equations are widely used. Figure 23-18 shows the type of information provided by cutting-tool manufacturers to calculate (estimate) thrust in drilling. Data with K_s (specific cutting force) and X and Y (empirical constants) are obtained from cutting-tool manufacturers. Much of this kind of data has been developed for high-speed-steel tools. When using solid carbide tools, rigid machines such as machining centers or NC turning machines are recommended, whereas a radial drilling machine is not recommended (not rigid enough).

Rigidity is especially important in avoiding chatter. A lack of rigidity in the cutting tool, the workpiece, or the machine tool permits the affected members to deflect due to the cutting forces developing the conditions for chatter (see Chapter 20), with the result that the cutting lips have a hammering action against the work. So, use the shortest tool possible.

In addition, backlash in the feed mechanism should be kept at a minimum to reduce strain on the drill when it breaks through the bottom of the hole.

The common name for the machine tool used for drilling is the *drill press*. Drill presses consist of a *base*, a *column* that supports a *powerhead*, a *spindle*, and a *worktable*. On small machines, the base rests on a workbench, whereas on larger machines it rests on the floor (Figure 23-19). The column may be either round or of box-type construction, the latter being used on larger, heavy-duty machines, except in radial types. The powerhead contains an electric motor and means for driving the spindle in rotation at several speeds. On small drilling machines this may be accomplished by shifting a belt on a step-cone pulley, but on larger machines a geared transmission is used.

The heart of any drilling machine is its spindle. In order to drill satisfactorily, the spindle must rotate accurately and also resist whatever side forces result from the drilling process. In virtually all machines the spindle rotates in preloaded ball or taper-roller bearings. In addition to powered rotation, provision is made so that the spindle can be moved axially to feed the drill into the work. On small machines the spindle is fed by hand, using the handles extending from the capstan wheel; on larger machines power feed is provided. Except for some small bench types, the spindle contains a hole with a Morse taper in its lower end into which taper-shank drills or drill chucks can be inserted.

The worktables on drilling machines may be moved up and down on the column to accommodate work of various sizes. On round-column machines the table can usually

Axial Thrust Force

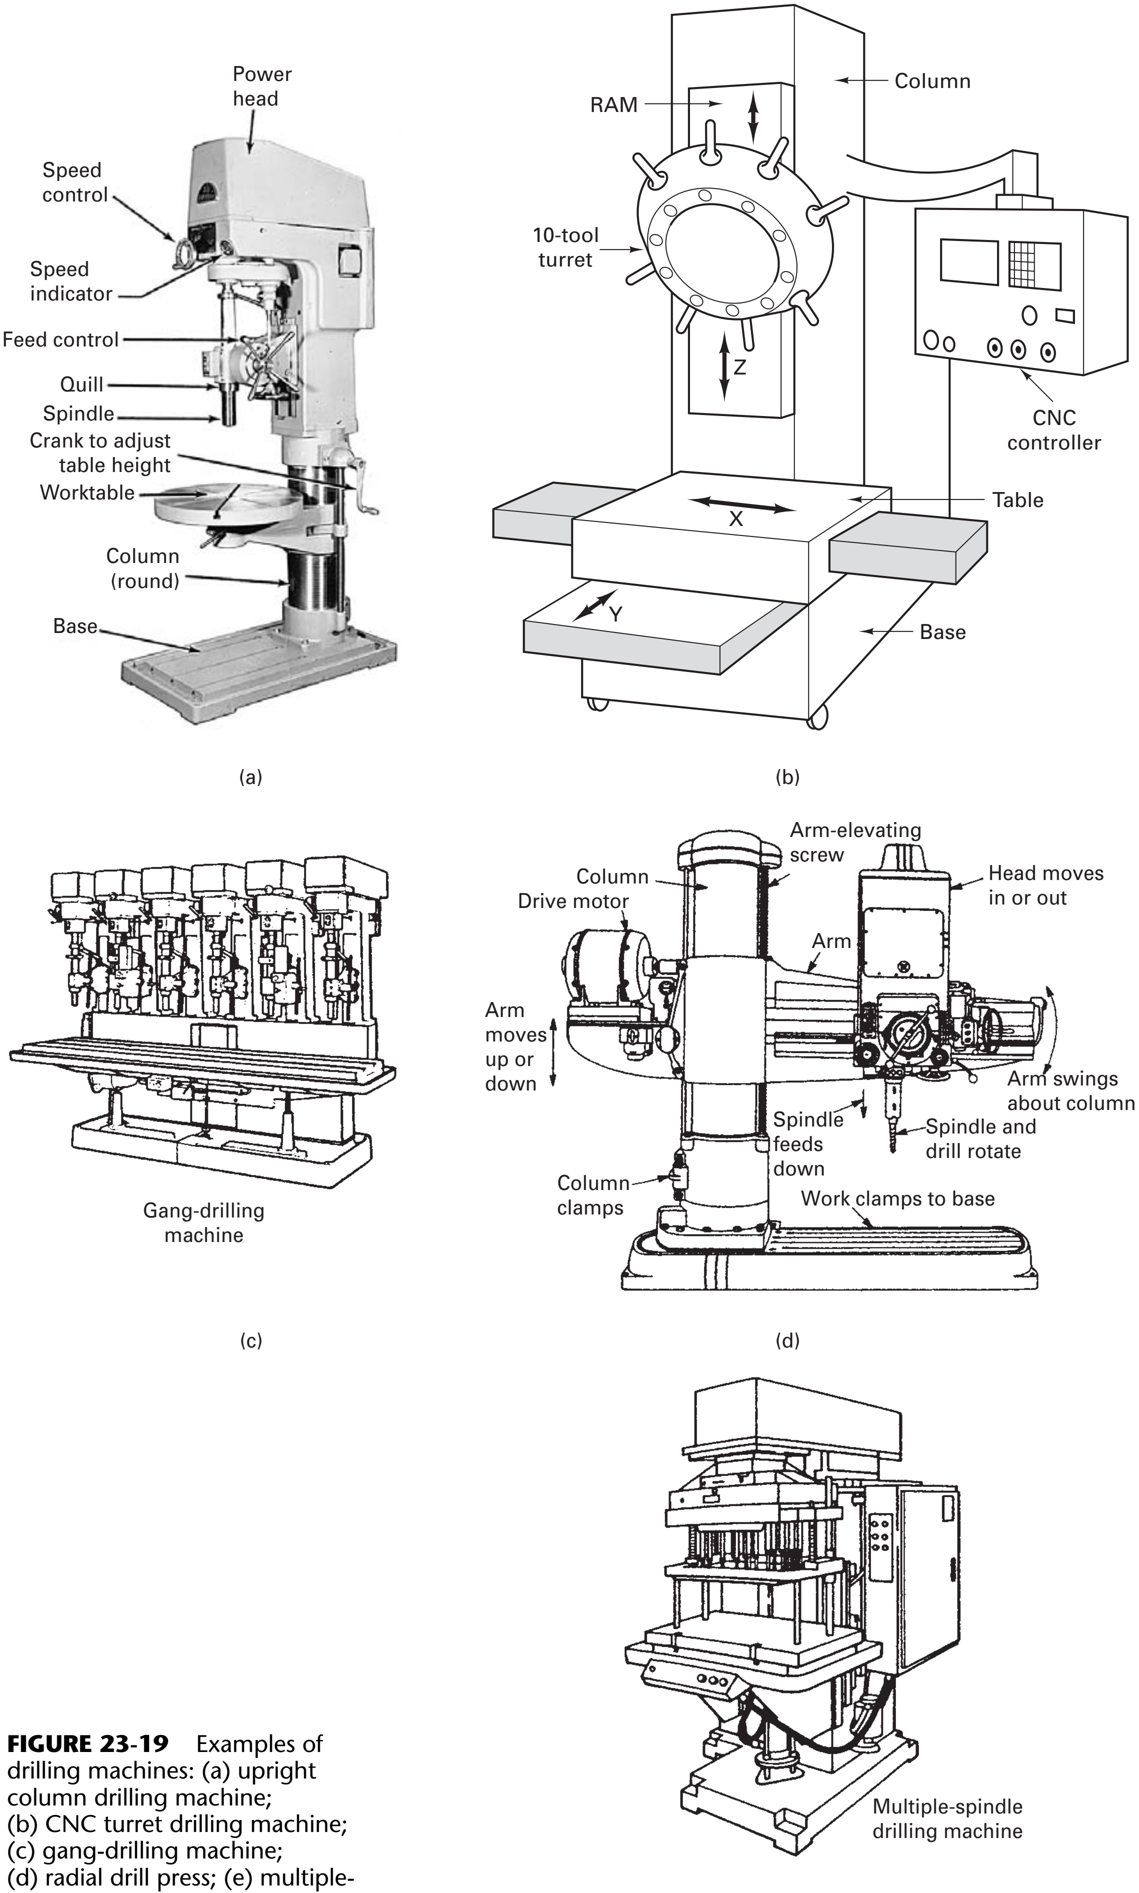
be rotated out of the way so that workpieces can be mounted directly on the base. On some box-column machines the table is mounted on a subbase so that it can be moved in two directions in a horizontal plane by means of feed screws.

Figure 23-19 shows examples of common types of drilling machines used in production environments. Drilling machines usually are classified as bench, upright with single spindle, turret or NC turret, gang, multispindle, deep-hole, and transfer.



(a) (b) (c) (d) (e)

FIGURE 23-19 Examples of drilling machines: (a) upright column drilling machine; (b) CNC turret drilling machine; (c) gang-drilling machine; (d) radial drill press; (e) multiple-spindle drilling machine.

With bench drill presses, holes up to $^1/_2$ in. in diameter can be drilled. The same type of machine can be obtained with a long column so that it can stand on the floor. The size of bench and upright drilling machines is designated by *twice* the distance from the centerline of the spindle to the nearest point on the column, this being an indication of the maximum size of the work that can be drilled in the machines. For example, a 15-in. drill press will permit a hole to be drilled at the center of a workpiece 15 in. in diameter.

Sensitive drilling machines are essentially smaller, plain bench-type machines with more accurate spindles and bearings. They are capable of operating at higher speeds, up to 30,000 rpm. Very sensitive hand-operated feeding mechanisms are provided for use in drilling small holes. Such machines are used for tool and die work and for drilling very small holes, often less than a few thousandths of an inch in diameter, when high spindle speeds are necessary to obtain proper cutting speed and sensitive feel to provide delicate feeding to avoid breakage of the very small drills.

Upright drilling machines usually have spindle speed ranges from 60 to 3500 rpm and power feed rates, from 4 to 12 steps, from about 0.004 to 0.025 in. rev. Most modern machines use a single-speed motor and a geared transmission to provide the range of speeds and feeds. The feed clutch disengages automatically when the spindle reaches a preset depth.

Worktables on most upright drilling machines contain holes and slots for use in clamping work and nearly always have a channel around the edges to collect cutting fluid, when it is used. On box-column machines, the table is mounted on vertical ways on the front of the column and can be raised or lowered by means of a crank-operated elevating screw.

In mass production *gang-drilling machines* are often used when several related operations, such as drilling holes of different sizes, reaming, or counterboring, must be done on a single part. These consist essentially of several independent columns, heads, and spindles mounted on a common base and having a single table. The work can be slid into position for the operation at each spindle. They are available with or without power feed. One or several operators may be used. This machine would be an example of a simple small cell except that the machines are usually not single-cycle automatics.

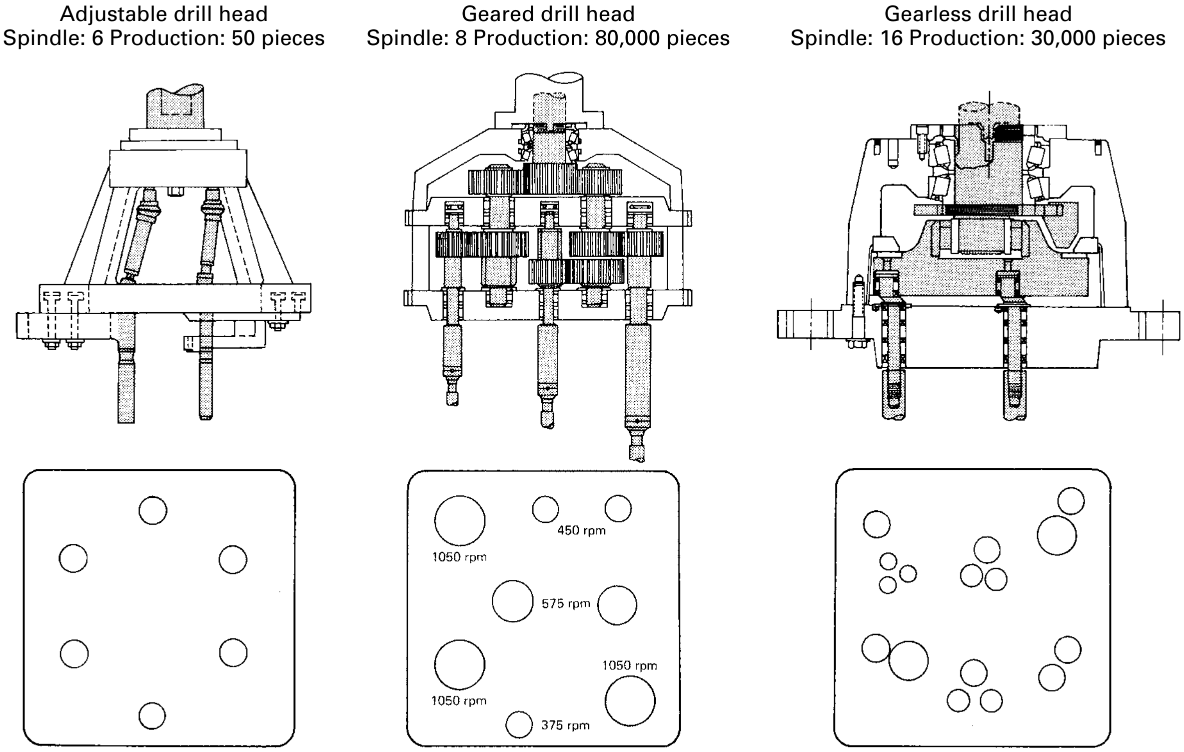
Turret-type, *upright drilling machines* are used when a series of holes of different sizes, or a series of operations (such as center drilling, drilling, reaming, and spot facing), must be done repeatedly in succession. The selected tools are mounted in the turret. Each tool can quickly be brought into position merely by rotation of the turret. These machines automatically provide individual feed rates for each spindle and are often numerically controlled.

Radial drilling machine tools are used on large workpieces that cannot be easily handled manually. As shown in Figure 23-19, these machines have a large, heavy, round, vertical column supported on a large base. The column supports a radial arm that can be raised and lowered by power and rotated over the base. The spindle head, with its speed- and feed-changing mechanism, is mounted on the radial arm. It can be moved horizontally to any desired position on the arm. Thus the spindle can quickly be positioned properly for drilling holes at any point on a large workpiece mounted either on the base of the machine or even sitting on the floor.

Plain radial drilling machines provide only a vertical spindle motion. On *semiuniversal machines*, the spindle head can be pivoted at an angle to a vertical plane. On *universal machines*, the radial arm is rotated about a horizontal axis to permit drilling at any angle.

Radial drilling machines are designated by the radius of the largest disk in which a center hole can be drilled when the spindle head is at its outermost position. Sizes from 3 to 12 ft are available. Radial drilling machines have a wide range of speeds and feeds, can do boring, and include provisions for tapping (internal threading) (see Chapter 29).

Multiple-spindle drilling machines (Figure 23-19) are mass-production machines with as many as 50 spindles driven by a single powerhead and fed simultaneously into the work. Figure 23-20 shows an adjustable multiple-spindle head that can be mounted on a regular single spindle-drill press. Figure 23-20 shows the methods of driving and positioning the spindles, which permit them to be adjusted so that holes can be drilled



Adjustable drill head
Spindle: 6 Production: 50 pieces

Geared drill head
Spindle: 8 Production: 80,000 pieces

Gearless drill head
Spindle: 16 Production: 30,000 pieces

An adjustable drill head should be considered for low-production jobs. However, many short-run jobs such as this would be required to justify a multiple-spindle head.

A geared drill head is most appropriate in this situation, where there is a large difference in sizes and a high daily production.

Only a gearless head can perform this operation in one pass, due to the close proximity of the spindle centers.

FIGURE 23-20 Three basic types of multiple-spindle drill heads: (left) adjustable; (middle) geared; (right) gearless. *(Courtesy of Zagar Incorporated.)*

at any location within the overall capacity of the head. Special drill jigs are often designed and built for each job to provide accurate guidance for each drill. Although such machines and workholders are quite costly, they can be cost-justified when the quantity to be produced will justify the setup cost and the cost of the jig. Reducing setup on these machines is difficult. Numerically controlled drill presses other than turret drill presses are not common because drilling and all its related processes can be done on vertical or horizontal NC machining centers equipped with automatic tool changers (see Chapter 31).

Special machines are used for drilling long (deep) holes, such as are found in rifle barrels, connecting rods, and long spindles. High cutting speeds, very light feeds, and a copious flow of cutting fluid ensure rapid chip removal. Adequate support for the long, slender drills is required. In most cases horizontal machines are used. The work is rotated in a chuck with steady rests providing support along its length, as required. The drill does not rotate and is fed into the work. Vertical machines are also available for shorter workpieces. Notice the similarity between this process and boring.

■ 23.7 CUTTING FLUIDS FOR DRILLING

For shallow holes, the general rules relating to cutting fluids, as given in Chapter 21, are applicable. When the depth of the hole exceeds one diameter, it is desirable to increase the lubricating quality of the fluid because of the rubbing between the drill margins and the wall of the hole. The effectiveness of a cutting fluid as a coolant is quite variable in drilling. While the rapid exit of the chips is a primary factor in heat removal, this action

TABLE 23-5 Cutting Fluids for Drilling

Work Material	Cutting Fluid
Aluminum and its alloys	Soluble oil, kerosene, and lard-oil compounds; light, nonviscous neutral oil; kerosene and soluble oil mixtures
Brass	Dry or a soluble oil; kerosene and lard-oil compounds; light, nonviscous neutral oil
Copper	Soluble oil, strained lard oil, oleic-acid compounds
Cast iron	Dry or with a jet of compressed air for cooling
Malleable iron	Soluble oil, nonviscous neutral oil
Monel metal	Soluble oil, sulfurized mineral oil
Stainless steel	Soluble oil, sulfurized mineral oil
Steel, ordinary	Soluble oil, sulfurized oil, high extreme-pressure-value mineral oil
Steel, very hard	Soluble oil, sulfurized oil, turpentine
Wrought iron	Soluble oil, sulfurized oil, mineral-animal oil compound

- Neat oil can be used effectively with the solid carbide drills for low-speed drilling (up to 130 sfpm).
- If the work surface becomes hard or blue in color, decrease the rpm and use neat oil.
- For heavy-duty cutting, emulsion-type oil containing some extreme pressure additive is recommended.
- A volume of 3.0 gal/min at a pressure of 37–62 lb/in.^{2} is recommended.
- A double stream supply of fluid is recommended.

also tends to restrict entry of the cutting fluid. This is of particular importance in drilling materials that have poor heat conductivity. Recommendations for cutting fluids for drilling are given in Table 23-5.

If the hole depth exceeds two or three diameters, it is usually advantageous to withdraw the drill each time it has drilled about one diameter of depth, to clear chips from the hole. Some machines are equipped to provide this “pecking” action automatically.

Where cooling is desired, the fluid should be applied copiously. For severe conditions, drills containing coolant holes have a considerable advantage. Not only is the fluid supplied near the cutting edges, but the coolant flow aids in flushing the chips from the hole. Where feasible, drilling horizontally has distinct advantages over drilling vertically downward.

23.8 COUNTERBORING, COUNTERSINKING, AND SPOT FACING

Drilling is often followed by *counterboring*, *countersinking*, or *spot facing*. As shown in Figure 23-21, each provides a bearing surface at one end of a drilled hole. They are usually done with a special tool having from three to six cutting edges.

Counterboring provides an enlarged cylindrical hole with a flat bottom so that a bolt head, or a nut, will have a smooth bearing surface that is normal to the axis of the hole; the depth may be sufficient so that the entire bolt head or nut will be below the surface of the part. The pilot on the end of the tool fits into the drilled hole and helps to ensure concentricity with the original hole. Two or more diameters may be produced in a single counterboring operation. Counterboring also can be done with a single-point tool, although this method ordinarily is used only on large holes and essentially is a boring operation. Some counterboring tools are shown in Figure 23-21b.

Countersinking makes a beveled section at the end of a drilled hole to provide a proper seat for a flat-head screw or rivet. The most common angles are 60°, 82°, and 90°. Countersinking tools are similar to counterboring tools except that the cutting edges are elements of a cone, and they usually do not have a pilot because the bevel of the tool causes them to be self-centering.

Spot facing is done to provide a smooth bearing area on an otherwise rough surface at the opening of a hole and normal to its axis. Machining is limited to the minimum depth that will provide a smooth, uniform surface. Spot faces thus are somewhat easier and more economical to produce than counterbores. They are usually made with a multiedged end-cutting tool that does not have a pilot, although counterboring tools are frequently used.

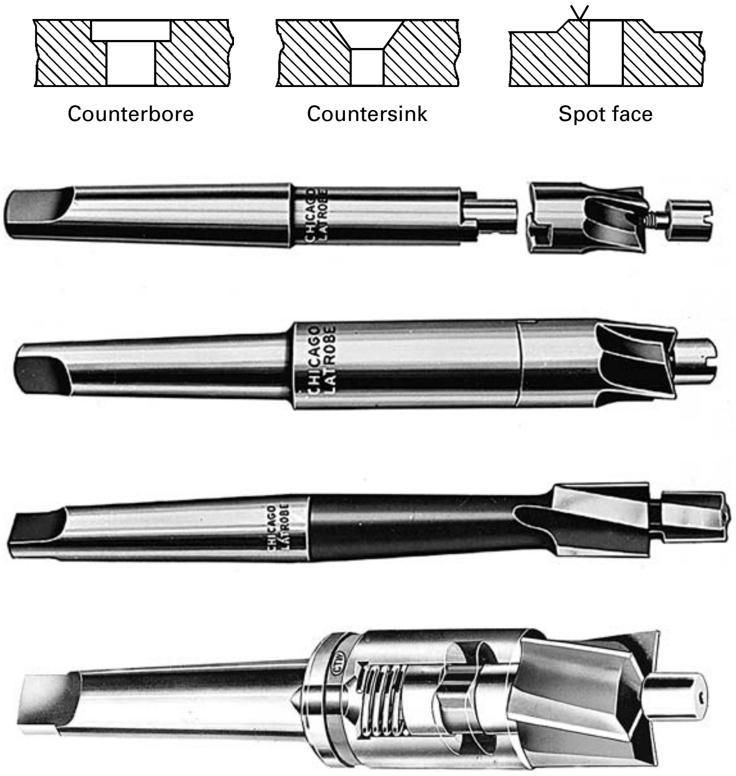


FIGURE 23-21 (a) Surfaces produced by counterboring, countersinking, and spot facing. (b) Counterboring tools: (bottom to top) interchangeable counterbore; solid, taper-shank counterbore with integral pilot; replaceable counterbore and pilot; replaceable counterbore, disassembled. *(Courtesy of Ex-Cell-O Corporation and Chicago Latrobe Twist Drill Works.)*

■ 23.9 REAMING

Reaming removes a small amount of material from the surface of holes. It is done for two purposes: to bring holes to a more exact size and to improve the finish of an existing hole. Multiedge cutting tools are used, as shown in Figure 23-22. No special machines are built for reaming. The same machine that was employed for drilling the hole can be used for reaming by changing the cutting tool.

To obtain proper results, only a minimum amount of materials should be left for removal by reaming. As little as 0.005 in. is desirable, and in no case should the amount exceed 0.015 in. A properly reamed hole will be within 0.001 in. of correct size and have a fine finish.

The principal types of reamers are shown in Figures 23-22 and 23-23. *Hand reamers* are intended to be turned and fed by hand and to remove only a few thousandths of an inch of metal. They have a straight shank with a square tang for a wrench. They can have straight or spiral flutes and be solid or expandable. The teeth have relief along their edges and thus may cut along their entire length. However, the reamer is tapered from 0.005 to 0.010 in. in the first third of its length to assist in starting it in the hole, and most of the cutting therefore takes place in this portion.

Machine or *chucking reamers* are for use with various machine tools at slow speeds. The best feed is usually two to three times the drilling feed. Machine reamers have chamfers on the front end of the cutting edges. The chamfer causes the reamer to seat firmly and concentrically in the drilled hole, allowing the reamer to cut at full diameter. The longitudinal cutting edges do little or no cutting. Chamfer angles are usually 45°. Reamers have straight or tapered shanks and straight or spiral flutes. *Rose-chucking reamers* are ground cylindrical and have no relief behind the outer edges of the teeth. All cutting is done on the beveled ends of the teeth. *Fluted-chucking reamers*, on the other hand, have relief behind the edges of the teeth as well as beveled ends. They can therefore cut on all portions of the teeth. Their flutes are relatively short, and they are intended for light finishing cuts. For best results they should not be held rigidly but permitted to float and be aligned by the hole.

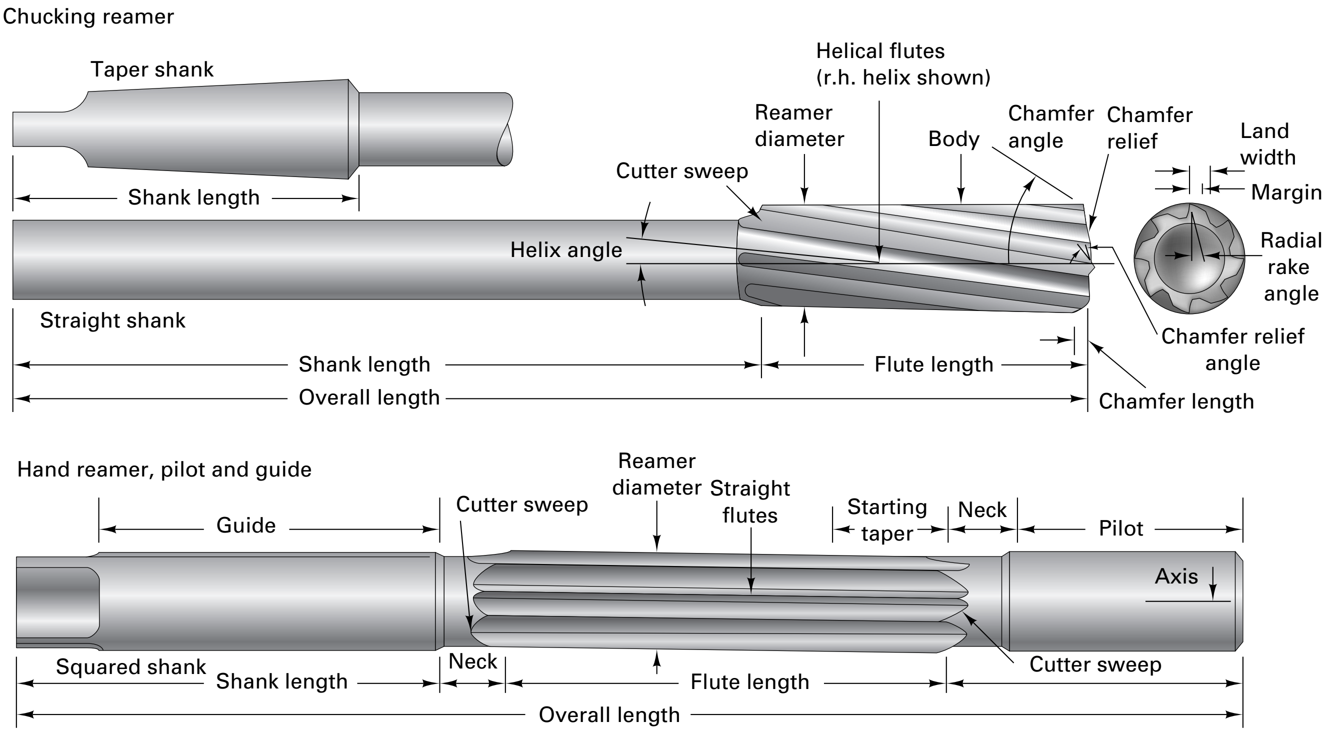

FIGURE 23-22 Standard nomenclature for hand and chucking reamers.

Shell reamers often are used for larger sizes in order to save cutting-tool material. The shell, made of tool steel for smaller sizes and with carbide edges for larger sizes or for mass-production work, is held on an arbor that is made of ordinary steel. One arbor may be used with any number of shells. Only the shell is subject to wear and needs to be replaced when worn. They may be ground as rose or fluted reamers.

Expansion reamers can be adjusted over a few thousandths of an inch to compensate for wear or to permit some variation in hole size to be obtained. They are available in both hand and machine types.

FIGURE 23-23 Types of reamers: (top to bottom) Straight-fluted rose reamer, straight-fluted chucking reamer, straight-fluted taper reamer, straight-fluted hand reamer, expansion reamer, shell reamer, adjustable insert-blade reamer.

Adjustable reamers have cutting edges in the form of blades that are locked in a body. The blades can be adjusted over a greater range than expansion reamers. This permits adjustment for size and to compensate for regrinding. When the blades become too small from regrinding, they can be replaced. Both tool steel and carbide blades are used.

Taper reamers are used for finishing holes to an exact taper. They may have up to eight straight or spiral flutes. Standard tapers, such as Morse, Jarno, or Brown & Sharpe, come in sets of two. The *roughing reamer* has nicks along the cutting edge to break up the heavy chips that result as a cylindrical hole is cut to a taper. The *finishing reamer* has smooth cutting edges.

REAMING PRACTICE

If the material to be removed is free-cutting, reamers of fairly light construction will give satisfactory results. However, if the material is hard, then tough, solid-type reamers are recommended, even for fairly large holes.

To meet quality requirements, including both finish and accuracy (tolerances on diameter, roundness, straightness, and absence of bell-mouth at ends of holes), reamers must have adequate support for the cutting edges, and reamer deflection must be minimal. Reaming speed is usually two-thirds the speed for drilling the same materials. However, for close tolerances and fine finish, speeds should be slower.

Feeds are usually much higher than those for drilling and depend upon material. A feed of between 0.0015 and 0.004 in. per flute is recommended as a starting point. Use the highest feed that will still produce the required finish and accuracy. Recommended cutting fluids are the same as those for drilling. Reamers, like drills, should not be allowed to become dull. The chamfer must be reground long before it exhibits excessive wear. Sharpening is usually restricted to the starting taper or chamfer. Each flute must be ground exactly even, or the tool will cut oversize.

Reamers tend to chatter when not held securely, when the work or workholder is loose, or when the reamer is not properly ground. Irregularly spaced teeth may help reduce chatter. Other cures for chatter in reaming are to reduce the speed, vary the feed rate, chamfer the hole opening, use a piloted reamer, reduce the relief angle on the chamfer, or change cutting fluid. Any misalignment between the workpiece and the reamer will cause chatter and improper reaming.

■ Review Questions

1. What functions are performed by the flutes on a standard twist drill?
2. What determines the rake angle of a drill? See Figure 23-2.
3. Basically, what determines what helix angle a drill should have?
4. When a large-diameter hole is to be drilled, why is a smaller-diameter hole often drilled first?
5. Equation 23-4 for the MRR for drilling can be thought of as ____ times ____ where $f_r N_s$ is the feed rate of the drill bit.
6. Are the recommended surface speeds for spade drills given in Table 23-3 typically higher or lower than those recommended for twist drills? How about the feeds? Why?
7. What can happen when an improperly ground drill is used to drill a hole?
8. Why are most drilled holes oversize with respect to the nominally specified diameter?
9. What are the two primary functions of a combination center drill?
10. What is the function of the margins on a twist drill?

11. What factors tend to cause a drill to "drift" off the centerline of a hole?
12. The drills shown in Figure 23-13 have coolant passages in the flutes. What is the purpose of these holes?
13. In drilling, the deeper the hole, the greater the torque. Why?
14. Why do cutting fluids for drilling usually have more lubricating qualities than those for most other machining operations?
15. How does a gang-drilling machine differ from a multiple-spindle drilling machine?
16. How does a multiple-spindle drilling machine differ from a NC drilling machine with a tool changer that would hold all the drills found in the multiple-spindle machine?
17. How does the thrust force vary with feed? Why?
18. Holding the workpiece by hand when drilling is not a good idea. Why?
19. What is the rationale behind the operation sequence shown in Figure 23-10?
20. In terms of thrust, what is unusual about the slot-point drill compared to other drills?
21. What is the purpose of spot facing?
22. How does the purpose of counterboring differ from that of spot facing?
23. What are the primary purposes of reaming?
24. What are the advantages of shell reamers?
25. A drill that operated satisfactorily for drilling cast iron gave very short life when used for drilling a plastic. What might be the reason for this?
26. What precautionary procedures should be used when drilling a deep, vertical hole in mild steel when using an ordinary twist drill?
27. What is the advantage of a spade drill? Is it really a drill?
28. What is a "pecking" action in drilling?
29. Why does drill feed increase with drill size?
30. Suppose you specified a drilling feed rate that was too large. What kinds of problems do you think this might cause? See Figure 23-6 and Table 23-4 for help.

Problems

1. Suppose you wanted to drill a 1.5-in.-diameter hole through a piece of 1020 cold-rolled steel that is 2 in. thick, using an indexable insert drill. What values of feed and cutting speed will you specify, along with an appropriate allowance. Is this the correct tool? What other drill types could be used?
2. How much time will be required to drill the hole in Problem 1 using the insert drill?
3. What is the metal removal rate when a 1.5-in.-diameter hole, 2 in. deep, is drilled in 1020 steel at a cutting speed of 200 fpm with a feed of 0.010 ipr? What is the cutting time?
4. If the specific horsepower for the steel in Problem 3 is 0.9, what horsepower would be required, assuming 80% efficiency in the machine tool?
5. If the specific power of an AISI 1020 steel of 0.9, and 80% of the output of the 1.0-kW motor of a drilling machine is available at the tool, what is the maximum feed that can be used in drilling a 1-in.-diameter hole with a carbide drill? (Use the cutting speed suggested in Problem 3.)
6. Show how the approximate equation 23-5 for MRR in drilling was obtained. What assumption was needed?
7. A workpiece must have 10 holes finished in it. Manual layout time is $^1/_2$ hr/piece. To drill and ream all the holes requires 1 hour on the machine for each piece, not counting layout or setup. The labor rate is \$10/hr and the machine rate is \$20/hr. If a jig is used, the labor cost to lay out each piece can be saved. Both methods give the same-quality product, but this jig saves 40 min in processing time on the machine. How large a lot justifies the use of a jig that costs \$150 to make (labor and materials)?
8. A part has two holes located for drilling by manual layout. If a drill jig is used, 0.5 min in processing time is saved for each piece. The labor rate is \$9/hr. The overhead rate on the labor saved is 100%. Setup time is no more with than without the jig. The combined rate for interest, insurance, taxes, and maintenance is 35%. The cost of the jig is \$500.
   a. How many pieces must be made in one lot to make the jig worthwhile?
   b. How many pieces must be made on the jig in one lot each month to earn the cost of the jig in two years?
9. Manufacturer's charts will help determine the best feed and speed to run the drills. For example, a 1.5-in hole is to be drilled in 4140 steel annealed to Bhn 275. For the spade drill, speed is 80 sfm; feed, 0.009 ipr; and spindle rotation, 204 rpm. For the indexable insert drill, speed is 358 sfm; feed, 0.007 ipr; and spindle rotation, 891 rpm. Typically, an indexable insert drill can produce a hole four times faster than a spade drill but may cost (with inserts) 50% to 75% more than the equivalent spade blade and holder. For making only a couple of holes, the extra cost is not usually justified. Determine the number of holes needed to justify the extra cost of the indexable insert drill. Some additional cost data are given below.

   Ignore tool life and assume that the blades and the indexable drills make about the same number of holes. (Why is this a reasonable assumption?) The holes are 3 in. deep, with no allowance needed. Cost of drills:

Spade drill	Indexable-insert Drill
\$139.00 holder	\$273.00 drill
+21.90 per blade	+12.80 per two inserts
\$160.90	\$285.80

   Assume for this example that a machine rate of \$45/hr includes the cost of labor and machine burden.
10. Assume that you are drilling eight holes, equally spaced in a bolt-hole circle. That is, there would be holes at 12, 3, 6, and 9 o'clock and four more holes equally spaced between them. The diameter of the bolt hole circle is 6 in. The designer says that the holes must be 45° ± 1° from each other around the circle.
    a. Compute the tolerance between hole centers.
    b. Do you think a typical multiple-spindle drill setup could be used to make this bolt circle—using eight drills all at once? Why or why not?
    c. Do you think that the use of a jig may help improve the situation?
    d. Do you think a CNC drilling process could do the holes best?
11. A part with seven holes can be machined on a numerically controlled turret drill press in 3 min (estimated time based on

similar parts). The rate on the CNC machine for labor is \$34/hr. Currently, the part is being machined on a gang drill press with a special jig in 10 minutes per piece. The jig for the gang drill costs \$300; the combined rate for depreciation, interest, insurance, and taxes is 135%; and the hourly rate for the gang drill and operator is \$16. Setup time is about the same for both machines. For how many pieces is it economical to switch to the CNC?

12. It is estimated that a jig for machining a part with three holes costs \$400 and with it the operation takes 15 min per part. The operation can be done without a jig on a numerically controlled drill press in 5 min. Assume that any other conditions are the same as in Problem 11. How many pieces are needed to cost-justify the use of a jig?

Chapter 23 CASE STUDY

Bolt-down Leg on a Casting

Steve Hunter is a consulting engineer and has just received the drawing shown in Figure CS-23. This is one of four legs on a casting made by the CRS Company. These legs are used to attach the device to the floor. The section drawing to the right shows the typical loading to which the leg is subjected. The company is currently drilling the bolt hole and then counterboring the land, but manufacturing has experienced some difficulty in machining the four holes. They report a lot of drill breakage. Quality control reports that distances between the four holes are frequently too large. Sales has recently reported that a substantial number of in-service failures have occurred with these legs. Steve has obtained a sketch from sales showing where the legs typically fail. This casting is manufactured from gray cast iron using the sand casting process.

1. What machining difficulties should Steve suspect this leg to have?
2. Why were the distances between the holes too large?
3. What should Steve recommend for solving these problems in the future in terms of materials, design, and manufacturing methods?
4. What should Steve recommend be done with the units in the field to stop the failures?

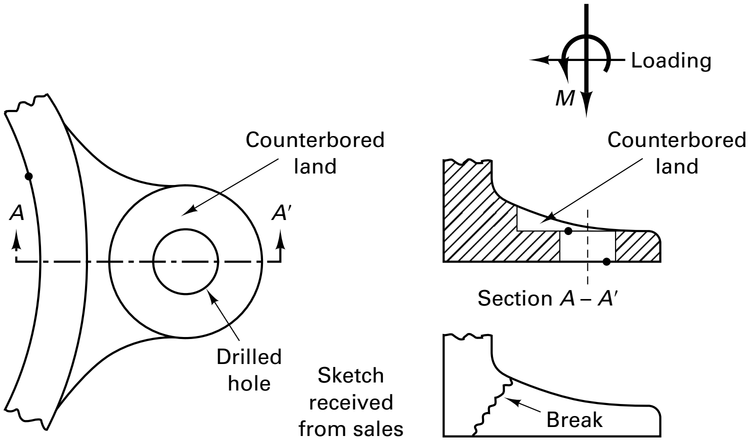

Figure CS-23 shows the design of one of four legs on a casting made by the BRC Company.

CHAPTER 24

MILLING

24.1 INTRODUCTION

Milling is a basic machining process by which a surface is generated by progressive chip removal. The workpiece is fed into a rotating cutting tool. Sometimes the workpiece remains stationary, and the cutter is fed to the work. In nearly all cases, a multiple-tooth cutter is used so that the material removal rate is high. Often the desired surface is obtained in a single pass of the cutter or work and, because very good surface finish can be obtained, milling is particularly well suited and widely used for mass-production work. Many types of milling machines are used, ranging from relatively simple and versatile machines that are used for general-purpose machining in job shops and tool and die work (these are NC or CNC machines) to highly specialized machines for mass production. Unquestionably, more flat surfaces are produced by milling than by any other machining process.

The cutting tool used in milling is known as a *milling cutter*. Equally spaced peripheral teeth will intermittently engage and machine the workpiece. This is called *interrupted cutting*. The workpieces are typically held in fixtures, as described in Chapter 25.

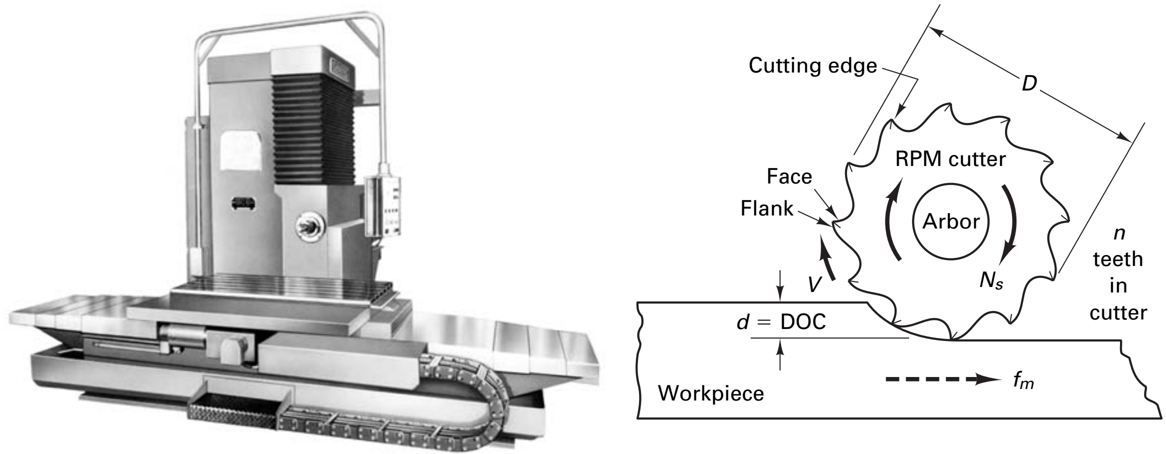
24.2 FUNDAMENTALS OF MILLING PROCESSES

Milling operations can be classified into two broad categories called peripheral milling and face milling. Each has many variations. In *peripheral milling* the surface is generated by teeth located on the periphery of the cutter body (Figure 24-1). The surface is parallel with the axis of rotation of the cutter. Both flat and formed surfaces can be produced by this method, the cross section of the resulting surface corresponding to the axial contour of the cutter. This process, often called *slab milling*, is usually performed on horizontal spindle milling machines. In slab milling, the tool rotates (mills) at some rpm (N_s) while the work feeds past the tool at a table feed rate f_m in inches per minute, which depends on the feed per tooth, f_t.

As in the other processes, the cutting speed V and feed per tooth are selected by the engineer or the machine tool operator. As before, these variables depend upon the work material, the tool material, and the specific process. The cutting velocity is that which occurs at the cutting edges of the teeth in the milling center. The rpm of the spindle is determined from the surface cutting speed, where D is the cutter diameter in inches according to

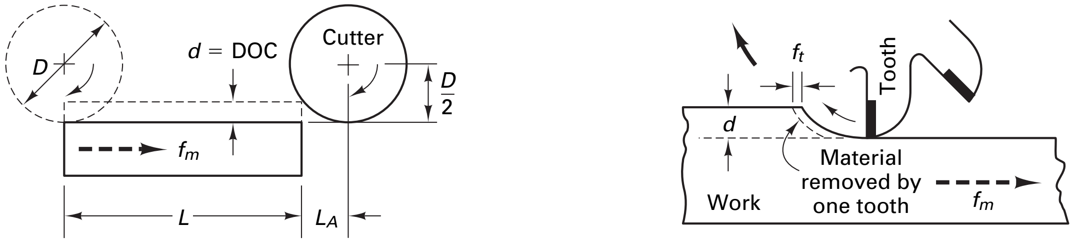
$$N_s = \frac{12V}{\pi D} \tag{24-1}$$

The depth of cut, called DOC or d in Figure 24-1, is simply the distance between the old and new machined surface.



(a) Horizontal-spindle milling machine

(b) Slab milling—multiple tooth



(c) Allowances for cutter approach

(d) Feed per tooth

FIGURE 24-1 Peripheral milling can be performed on a horizontal-spindle milling machine. The cutter rotates at rpm N_s, removing metal at cutting speed *V*. The allowance for starting and finishing the cut depends on the cutter diameter and depth of cut, *d*. The feed per tooth, f_t and cutting speed are selected by the operator or process planner.

The width of cut is the width of the cutter or the work, in inches, and is given the symbol W. The length of the cut L is the length of the work plus some allowance L_A for approach and overtravel. The feed of the table f_m, in inches per minute, is related to the amount of metal each tooth removes during a revolution, the feed per tooth f_t, according to

$$f_m = f_t N_s n \tag{24-2}$$

where n is the number of teeth in the cutter (teeth rev.).

The *cutting time is*

$$T_m = \frac{L + L_A}{f_m} \tag{24-3}$$

The length of approach is

$$L_A = \sqrt{\frac{D^2}{4} - \left(\frac{D}{2} - \text{DOC}\right)^2} = \sqrt{d(D - d)} \tag{24-4}$$

The metal removal rate is

$$\text{MRR} = \frac{\text{volume}}{T_m} = \frac{LWd}{T_m} = Wf_m d \text{ in.}^3/\text{min} \tag{24-5}$$

ignoring L_A. Values for f_t are given in Table 24-1, along with recommended cutting speeds in feet per minute.

TABLE 24-1 Suggested Starting Feeds and Speeds Using High-Speed Steel and Carbide Cutters[a]

		Carbide Cutters						High-Speed-Steel Cutters

[a] Generally, lower end of range used for inserted blade cutters, higher end of range for indexable insert cutters.

In *face milling* and *end milling*, the generated surface is at right angles to the cutter axis (Figure 24-2). Most of the cutting is done by the peripheral portions of the teeth, with the face portions providing some finishing action. Face milling is done on both horizontal- and vertical-spindle machines.

The tool rotates (face mills) at some rpm (N_s) while the work feeds past the tool. The rpm is related to the surface cutting speed V and the cutting tool diameter D, according to equation 24-1. The depth of cut is d, in inches, as shown in Figure 24-2b. The width of cut is W, in inches, and may be width of the workpiece or width of the cutter, depending on the setup. The length of cut is the length of the workpiece L plus an allowance L_A for approach and overtravel L_O, in inches. The feed rate of the table f_m, in inches per minute, is related to the amount of metal each tooth removes during a pass over the work, called the feed per tooth f_t, so $f_m = f_t N_s n$ where the number of teeth in the cutter is n. The cutting time is

$$T_m = \frac{L + L_A + L_O}{f_m} \text{ min} \tag{24-6}$$

The *metal removal rate* is

$$\text{MRR} - \frac{\text{volume}}{T_m} = \frac{LWd}{T_m} = f_m W d \text{ in.}^3/\text{min}$$

When calculating the MRR, ignore L_O and L_A. The length of approach is usually equal to the length of overtravel, which usually equals *D/2* in. For a setup where the tool does not completely pass over the workpiece,

$$L_O = L_A = \sqrt{W(D - W)} \text{ for } W < \frac{D}{2} \tag{24-7}$$

$$L_O = L_A = \frac{D}{2} \text{ for } W \geq \frac{D}{2} \tag{24-8}$$

FACE MILLING EXAMPLE

A 4-in.-diameter, six-tooth face mill is selected, using carbide inserts (Figure 24-3). The material being machined is low-alloy steel, annealed. Using cutting data recommendations, the cutting speed chosen is 400 sfpm with a feed of 0.008 in./tooth at a d of 0.12 inches. Determining rpm at the spindle,

$$N_s = \frac{12V}{\pi D} = \frac{12 \times 400}{3.14 \times 4} = 392 \text{ rpm}$$

Determining the feed rate of the table, $f_m = nN_s f_t$,

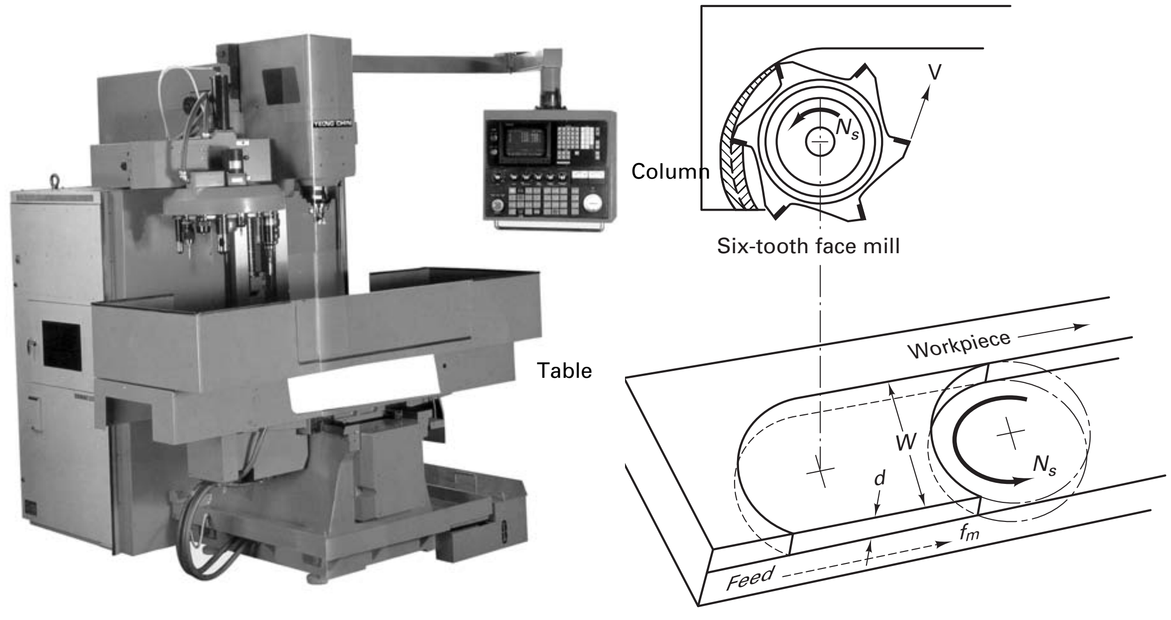
$$f_m = 0.008 \times 6 \times 392 = 19 \text{ in./min}$$

If slab or side milling were being performed, as shown in Figure 24-4, with the same parameters being selected as above, the setup would be different but the spindle rpm and table feed rate the same. The cutting time would be different because the allowances for face milling are greater than for slab milling. In milling, power consumption is usually the limiting factor. A thick chip is more power efficient than a thin chip.

END MILLING EXAMPLE

End milling is a very common operation performed on both vertical- and horizontal-spindle milling machines or machining centers. Figure 24-5 shows a vertical spindle end milling process, cutting a step in the workpiece. This cutter can cut on both the sides and ends of the tool. If you were performing this operation on a block of metal (for example, 430F stainless steel), you (the manufacturing engineer) would select a specific machine tool. You would have to determine how many passes (rough and finish cuts) were needed to produce the geometry specified in the design. Why? The number of passes determines the total cutting time for the job.

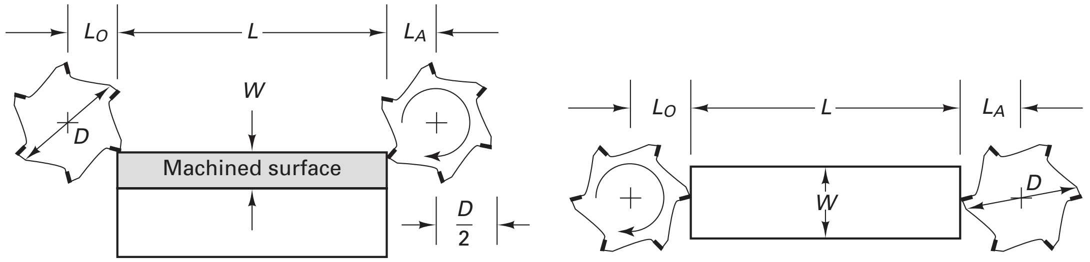
Using a vertical-spindle milling machine, an end mill can produce a step in the workpiece. In Figure 24-5, an end mill with six teeth on a 2-in. diameter is used to cut a step in



(a) Vertical-spindle milling machine

(b) Face milling over part of surface

Top views



(c) Allowance for partial coverage

(d) Allowance for full coverage

FIGURE 24-2 Face milling is often performed on a spindle milling machine using a multiple-tooth cutter ($n = 6$ teeth) rotating N_s at rpm to produce cutting speed V. The workpiece feeds at rate f_m in inches per minute past the tool. The allowance depends on the tool diameter and the width of cut.

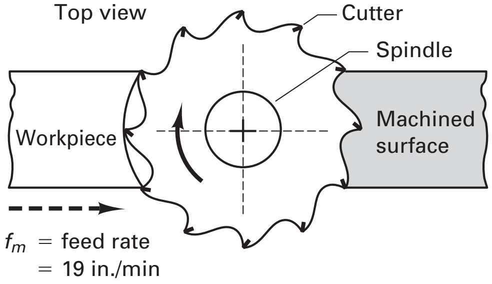


FIGURE 24-3 Face milling viewed from above with vertical spindle-machine.

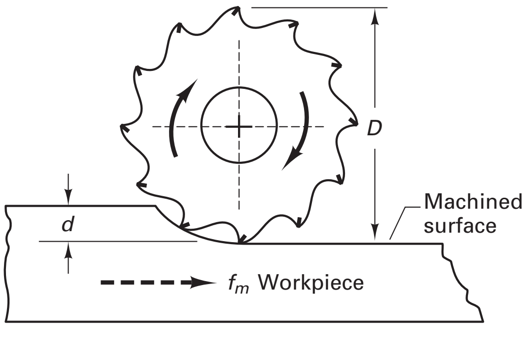

FIGURE 24-4 Slab or side milling being done as a down milling process with horizontal spindle-machine.

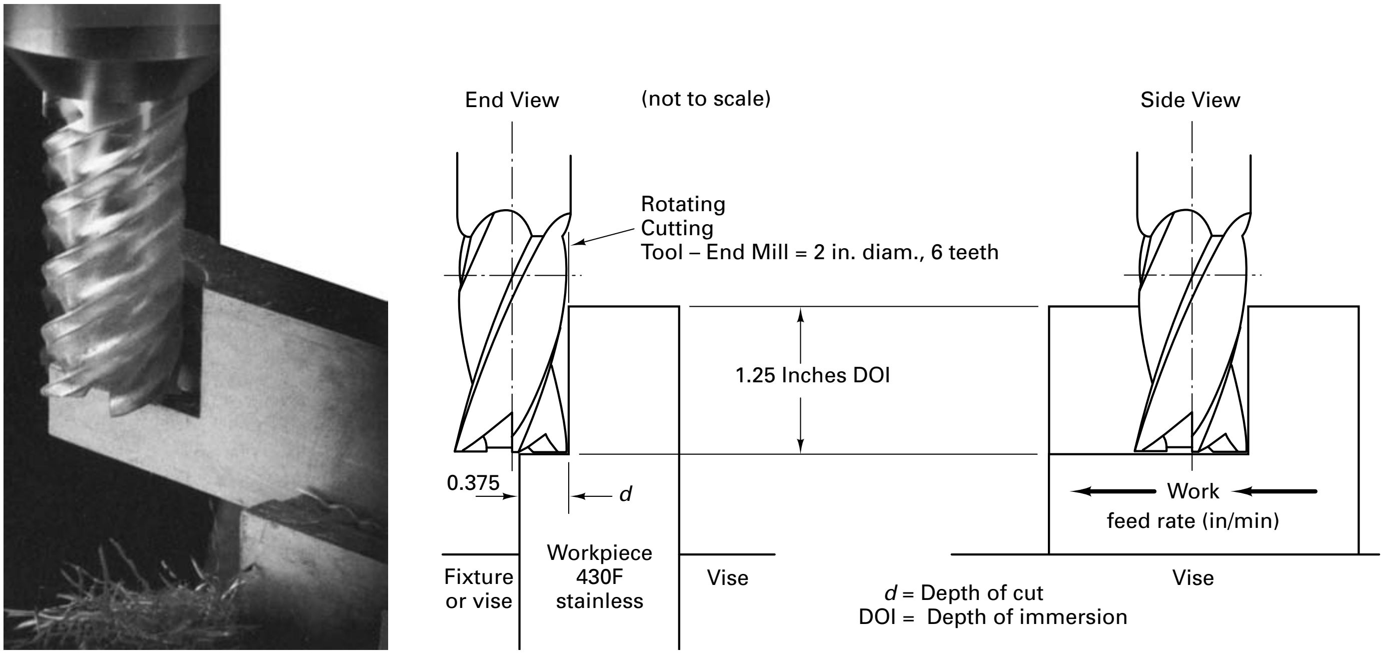

FIGURE 24-5 End milling a step feature in a block using a flat-bottomed, end mill cutter in a vertical spindle-milling machine. On left, photo. In middle, end view, table moving the block into the cutter. On right, side view, workpiece feeding right to left into tool.

430F stainless. The d (depth of cut) is 0.375 in., and the depth of immersion (DOI) is 1.25 in. The tool deflects due to the cutting forces, so the cut needs to be made at full immersion; but there may not be enough power for a full DOC. Can the step be cut in one pass or will multiple cuts be necessary? The vertical milling machine tool available has a 5-hp motor with an 80% efficiency. The specific horsepower for 430F stainless is 1.3 hp/in.^{3}/min.

The maximum amount of material that can be removed per pass is usually limited by the available power. Using the hp equation from Chapter 21,

$$\text{hp} = \text{HP}_s \times \text{MRR} = \text{HP}_s \times f_m W D = \text{HP}_s f_m \times \text{DOI} \times d \qquad (24\text{-}9)$$

Select $f_t = 0.005$ ipt and $V = 250$ fpm from Table 24-1. Calculate the spindle rpm:

$$N_s = \frac{12 \times 250}{3.14 \times 2} = 477 \text{ rpm of cutter}$$

Next, assuming the machine tool has this rpm available, calculate the table feed rate:

$$f_m = f_t \times n \times N_s = 0.005 \times 6 \times 477 = 14.31 \text{ in./min}$$

But the actual table feed rates for the selected machine are 11 in./min or 16 in./min, so, being conservative, select

$$f_m = \text{table feed rate} = 11.00 \text{ in./min}$$

Next, assuming 80% of the available power is used for cutting, calculate the depth of cut from equation 24-9:

$$d = \text{DOC} \cong \frac{5 \times 0.8}{1.3 \times 11.00 \times 1.25} \cong 0.225 \text{ in. maximum}$$

Therefore, two passes are needed because (0.375/0.225 = 1.6):

$$0.375 - 0.225 = 0.150 \text{ in. second pass DOC}$$

$$\begin{aligned} \text{2 passes: DOC} &= 0.225 \text{ rough cut} \\ \text{DOC} &= \underline{0.150} \text{ finish cut} \\ & 0.375 \text{ total DOC} \end{aligned}$$

Note that for $d = 0.150$, the feed per tooth would be only slightly increased to 0.0051 ipt:

$$f_t = \frac{0.5 \times 0.8}{1.3 \times 6 \times 477 \times 0.150 \times 1.25} = 0.0051 \text{ in./tooth}$$

You may want to change f_t to improve the surface finish. With a smaller f_t, a better surface finish is usually obtained. However, there are other factors to consider, like machining time.

In general (for face, slab, or end milling), if machine power is lacking the following actions may help.

1. Use a cutter with a positive rake as this can be more efficient than one with a negative rake.
2. Use a cutter with a coarser pitch (fewer teeth).
3. Use a smaller cutter and take several passes (reduce *d* or DOI).

UP VERSUS DOWN MILLING

For either slab or end or face milling, surfaces can be generated by two distinctly different methods (Figure 24-6). *Up milling* is the traditional way to mill and is called *conventional* milling. The cutter rotates against the direction of feed of the workpiece. In *climb* or *down milling*, the cutter rotation is in the same direction as the feed rate. The method of chip formation is completely different in the two cases.

In up milling, the chip is very thin at the beginning, where the tooth first contacts the work; then it increases in thickness, becoming a maximum where the tooth leaves the work. The cutter tends to push the work along and lift it upward from the table. This action tends to eliminate any effect of looseness in the feed screw and nut of the milling machine table and results in a smooth cut. However, the action tends to loosen the work from the fixture. Therefore, greater clamping forces must be employed, with the danger of deflecting the part. In addition, the smoothness of the generated surface depends greatly on the sharpness of the cutting edges. In up milling, chips can be carried into the newly machined surface, causing the surface finish to be poorer (rougher) than in down milling and causing damage to the insert.

In down milling, maximum chip thickness occurs close to the point at which the tooth contacts the work. Because the relative motion tends to pull the workpiece into the cutter, any possibility of looseness in the table feed screw must be eliminated if down

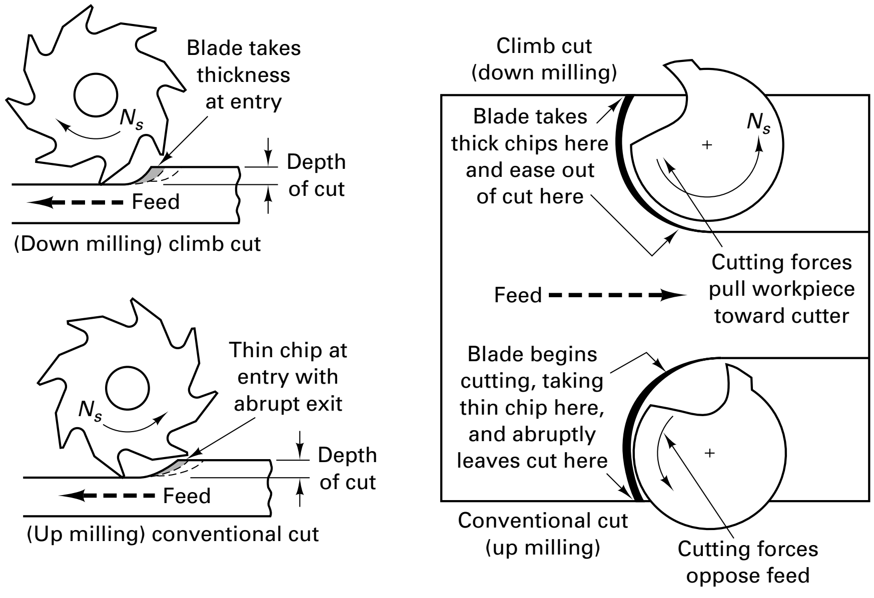

FIGURE 24-6 Climb cut or down milling versus conventional cut or up milling for slab or face or end milling.

Peripherial or slab milling

Face or end milling

milling is to be used. It should never be attempted on machines that are not designed for this type of milling. Virtually all modern milling machines are capable of down milling, and it is a most favorable application for carbide cutting edges. Because the material yields in approximately a tangential direction at the end of the tooth engagement, there is less tendency (than when up milling is used) for the machined surface to show toothmarks, and the cutting process is smoother, with less chatter. Another advantage of down milling is that the cutting force tends to hold the work against the machine table, permitting lower clamping forces. However, the fact that the cutter teeth strike against the surface of the work at the beginning of each chip can be a disadvantage if the workpiece has a hard surface, as castings sometimes do. This may cause the teeth to dull rapidly. Metals that readily workharden should be down milled, and many toolmakers recommend that down milling should always be the first choice.

MILLING SURFACE FINISH

The average surface finishes that can be expected on free-machining materials range from 60 to 150 μin. Conditions exist, however, that can produce wide variations on either side of these ranges. For example, some inserts are designed with wiper flats (short parallel surface behind the tool tip). If the feed per revolution [feed per tooth × number of teeth] of the cutter is smaller than the length of the wiper flat (the land on the tool), then the surface finish on the workpiece will be generated by the highest insert. In finishing cuts, keeping the depth of cut small will limit the axial cutting force, reducing vibrations and producing a superior finish. See Chapter 35 for discussions on measuring surface finish.

Milling is an interrupted cutting process wherein entering and leaving the cut subjects the tool to impact loading, cyclic heating, and cycle cutting forces. As shown in Figure 24-7, the cutting force, F_c, builds rapidly as the tool enters the work at A and progresses to B, peaks as the blade crosses the direction of feed at C, decreases to D, and then drops to zero abruptly upon exit. The diagram does not indicate the impulse loads caused by impacts. The interrupted-cut phenomenon explains in large part why milling cutter teeth are designed to have small positive or negative rakes, particularly when the tool material is carbide or ceramic. These brittle materials tend to be very strong in compression, and negative rake results in the cutting edges being placed in compression by the cutting forces rather than tension. Cutters made from high-speed steel (HSS) are made with positive rakes, in the main, but must be run at lower speeds. Positive rake tends to lift the workpiece, while negative rakes compress the workpiece and allow heavier cuts to be made. Table 24-2 summarizes some additional milling problems.

■ 24.3 MILLING TOOLS AND CUTTERS

Most milling work today is done with face mills and end mills. The face mills use indexable carbide insert tooling, while the end mills are either solid HSS or insert tooling (Figure 24-8). Basically, *mills* are shank-type cutters having teeth on the circumferential surface and one end. They thus can be used for facing, profiling, and end milling. The teeth

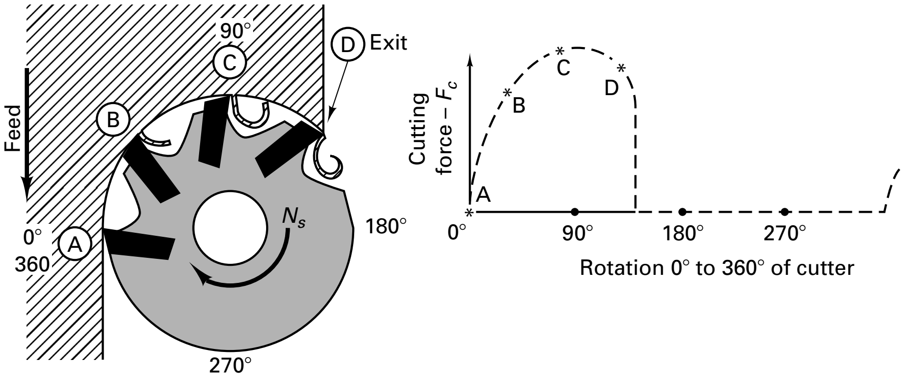

FIGURE 24-7 Conventional face milling (left) with cutting force diagram for F_c (right) showing the interrupted nature of the process. *(From* Metal Cutting Principles, *2nd ed., Ingersoll Cutting Tool Company.)*

TABLE 24-2 Probable Causes of Milling Problems

Problem	Probable Cause	Cures
Chatter (vibration)	1. Lack of rigidity in machine, fixtures, arbor, or workpiece	Use larger arbors. Change rpm (cutting speed).
	2. Cutting load too great	Decrease feed per tooth or number of teeth in contact with work.
	3. Dull cutter	Sharpen or replace inserts.
	4. Poor lubrication	Flood coolant.
	5. Straight-tooth cutter	Use helical cutter.
	6. Radial relief too great	
	7. Rubbing, insufficient clearance	Check tool angles.
Loss of accuracy (cannot hold size)	1. High cutting load causing deflection	Decrease number of teeth in contact with work or feed per tooth.
	2. Chip packing, between teeth	Adjust cutting fluid to wash chips out of teeth.
	3. Chips not cleaned away before mounting new piece of work	
Cutter rapidly dulls	1. Cutting load too great	Decrease feed per tooth or number of teeth in contact.
	2. Insufficient coolant	Add blending oil to coolant.
Poor surface finish	1. Feed too high	Check to see if all teeth are set at same height.
	2. Tool dull	
	3. Speed too low	
	4. Not enough cutter teeth	
Cutter digs in (hogs into work)	1. Radial relief too great	Check to see that workpiece is not deflecting and is securely clamped.
	2. Rake angle too large	
	3. Improper speed	
Work burnishing	1. Cut is too light	Enlarge feed per tooth.
	2. Tool edge worn	Sharpen cutter.
	3. Insufficient radial relief	
	4. Land too wide	
Cutter burns	1. Not enough lubricant	Add sulfur-based oil.
	2. Speed too high	Reduce cutting speed. Flood coolant.
Teeth breaking	1. Feed too high	Decrease feed per tooth.
	2. Depth of cut too large	Use cutter with more teeth. Reduce table feed rate.

Adapted from *Cutting Tool Engineering*, October 1990, p. 90, by Peter Liebhold, museum specialist, Division of Engineering and Industry, the Smithsonian Institute, Washington, DC.

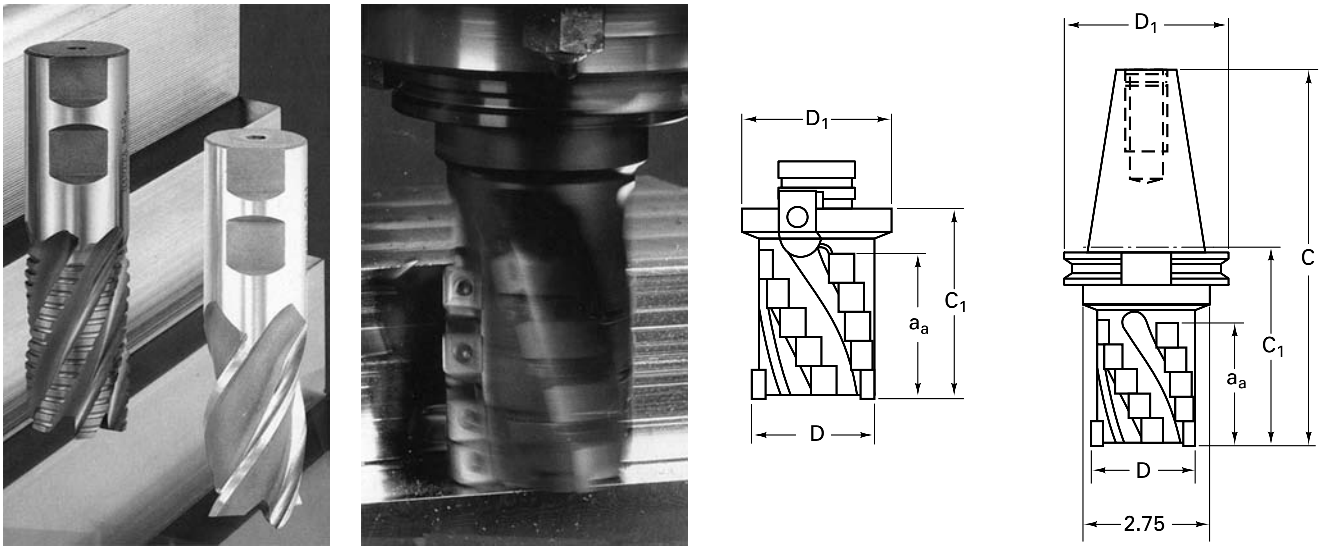

FIGURE 24-8 Solid end mills are often coated. Insert tooling end mills come in a variety of sizes and are mounted on taper shanks.

may be either straight or helical, but the latter is more common. Small end mills have straight shanks, whereas taper shanks are used on larger sizes (Figure 24-8).

Plain end mills have multiple teeth that extend only about halfway toward the center on the end. They are used in milling slots, profiling, and facing narrow surfaces. *Two-lip mills* have two straight or helical teeth that extend to the center. Thus they may be sunk into material, like a drill, and then fed lengthwise to form a groove, a slot, or a pocket.

Shell end mills are solid multiple-tooth cutters, similar to plain end mills but without a shank. The center of the face is recessed to receive a screw head or nut for mounting the cutter on a separate shank or a stub arbor. One shank can hold any of several cutters and thus provides great economy for larger-sized end mills.

Hollow end mills are tubular in cross section, with teeth only on the end but having internal clearance. They are used primarily on automatic screw machines for sizing cylindrical stock, producing a short cylindrical surface of accurate diameter.

Face mills have a center hole so that they can be arbor mounted. Face milling cutters are widely used in both horizontal- and vertical-spindle machine tools and come in a wide variety of sizes (diameters and heights) and geometries (round, square, triangular, etc.), as shown in Figure 24-9.

The insert can usually be indexed four times and must be well supported. Either the power or the rigidity of the machine tool will be the limiting factor, although sometimes setup can be the limiting factor.

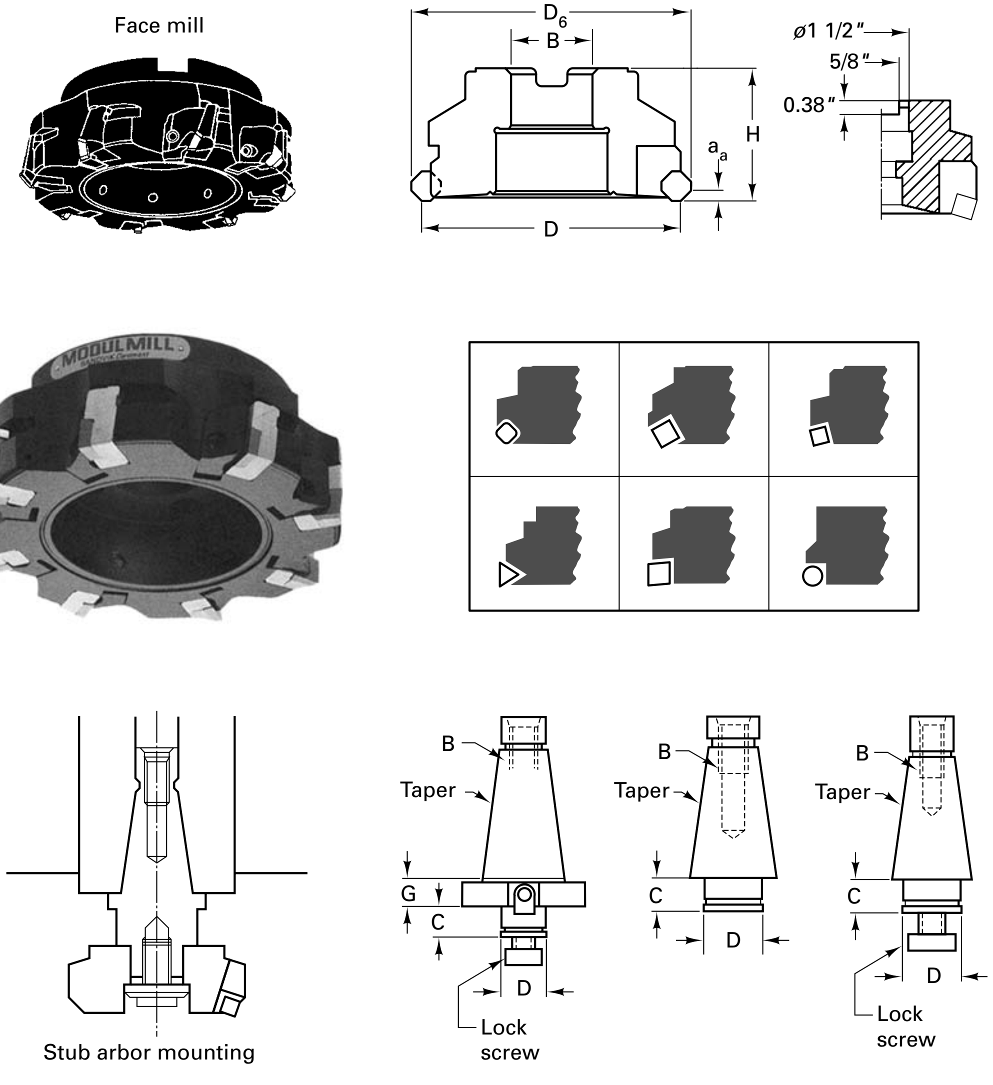

FIGURE 24-9 Face mills come in many different designs using many different insert geometries and different mounting arbors.

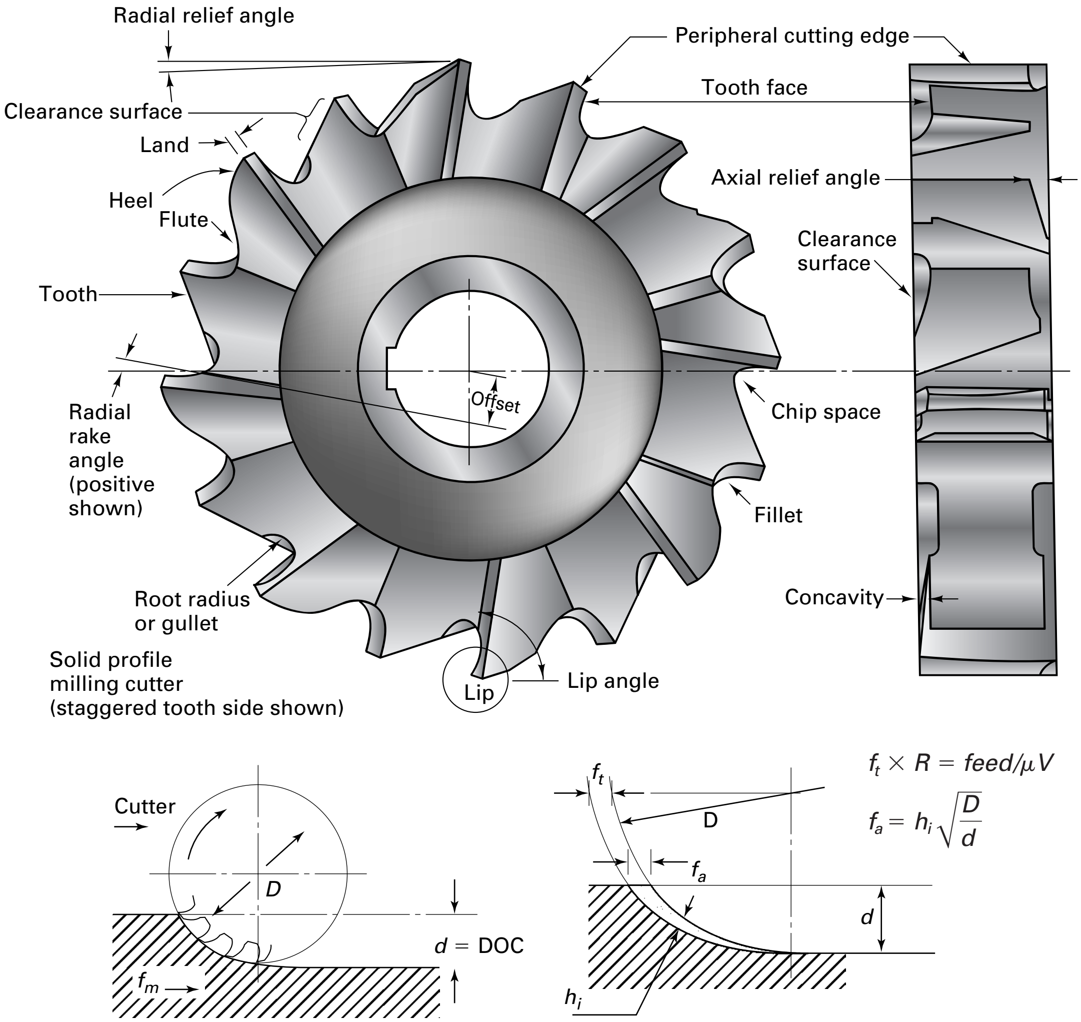

FIGURE 24-10 The side-milling cutter can cut on sides and ends of the teeth, so it makes slots or grooves. However, only a few teeth are engaged at any one point in time, causing heavy torsional vibrations. The average chip thickness, h_i, will be less than the feed per tooth, f_t. The actual feed per tooth f_a will be less than feed per tooth selected, F_t, according to $f_a = h_i\sqrt{\frac{D}{d}}$.

Another common type of arbor-mounted milling cutter is called a side mill because it cuts on the ends and sides of the cutters. Figure 24-10 shows the geometry of a staggered-tooth side milling cutter.

Staggered-tooth milling cutters are narrow cylindrical cutters having staggered teeth, and with alternate teeth having opposite helix angles. They are ground to cut only on the periphery, but each tooth also has chip clearance ground on the protruding side. These cutters have a free cutting action that makes them particularly effective in milling deep slots. *Staggered-tooth cutters* are really special *side-milling cutters*, which are similar to plain milling cutters except that the teeth extend radially part way across one or both ends of the cylinder toward the center. The teeth may be either straight or helical. Frequently, these cutters are relatively narrow, being disklike in shape. Two or more side milling cutters often are spaced on an arbor to straddle the workpiece (called *straddle milling*), and two or more parallel surfaces are machined at once.

In Figure 24-11 insert-tooth side mills are arranged in a gang-milling setup to cut three slots in the workpiece simultaneously. Thus the desired part geometry is repeatedly produced by the setup as the position of the cutters is fixed. However, in side- and face-milling operations only a few teeth are engaged at any point in time, resulting in heavy torsional vibrations detrimental to the resulting machined product. A flywheel can solve this problem and in many cases be the key to improved productivity.

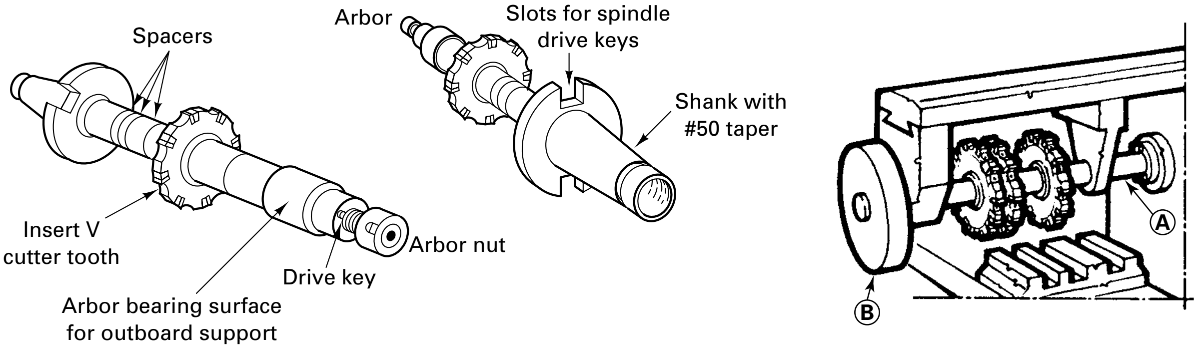

FIGURE 24-11 Arbor (two views) used on a horizontal-spindle milling machine on left. On right, a gang-milling setup showing three side-milling cutters mounted on an arbor (A) with an outboard flywheel (B).

For the gang milling as shown in Figure 24-11 the diameter of the flywheel should be as large as possible. (The moment of inertia increases with the square of the radius.) The best position of the flywheel is inboard on the arbor at A, but depending on the setup, this may not be possible, so then position B should be chosen. It is important that the distance between the cutters and flywheel be as small as possible.

A flywheel can be built up from a number of carbon steel disks, each having a center hole and keyway to fit the arbor, so the weight can be easily varied.

Interlocking slotting cutters consist of two cutters similar to side mills but made to operate as a unit for milling slots. The two cutters are adjusted to the desired width by inserting shims between them.

Slitting saws are thin, plain milling cutters, usually from $^1/_{32}$ to $^3/_{16}$ in. thick, which have their sides slightly "dished" to provide clearance and prevent binding. They usually have more teeth per unit of diameter than ordinary plain milling cutters and are used for milling deep narrow slots and cutting-off operations.

In milling, the average chip thickness (h_i) is not the same as the feed per tooth. For example, a thickness (h_i) of 0.004 in. corresponds to 0.012 in. feed per tooth in most side and face milling operations.

If the radial depth of cut, d, is very small compared to the cutter diameter, D, use this formula:

$$\text{feed per tooth} = f_t = 0.004\sqrt{\frac{D}{d}}\ (\text{ipt})$$

(*Note:* For calculating the table feed, use half the number of inserts in a full side and face mill to arrive at the effective number of teeth.)

$$\text{table feed rate (ipm)} = \text{rpm} \times \text{number of effective teeth} \times \text{feed per tooth}$$

Another method of classification for face and end mill cutters relates to the direction of rotation. A *right-hand cutter* must rotate counterclockwise when viewed from the front end of the machine spindle. Similarly, a *left-hand cutter* must rotate clockwise. All other cutters can be reversed on the arbor to change them from one hand to the other. Positive rake angles are used on general-purpose HSS milling cutters. Negative rake angles are commonly used on carbide- and ceramic-tipped cutters employed in mass-production milling in order to obtain the greater strength and cooling capacity. TiN coating of these tools is quite common, resulting in significant increases in tool life.

Plain milling cutters used for plain or slab milling have straight or helical teeth on the periphery and are used for milling flat surfaces. *Helical mills* (Figure 24-12) engage the work gradually, and usually more than one tooth cuts at a given time. This reduces shock and chattering tendencies and promotes a smoother surface. Consequently, this type of cutter usually is preferred over one with straight teeth.

Angle milling cutters are made in two types: single angle and double angle. Angle cutters are used for milling slots of various angles or for milling the edges of workpieces to a desired angle. *Single-angle cutters* have teeth on the conical surface, usually at an

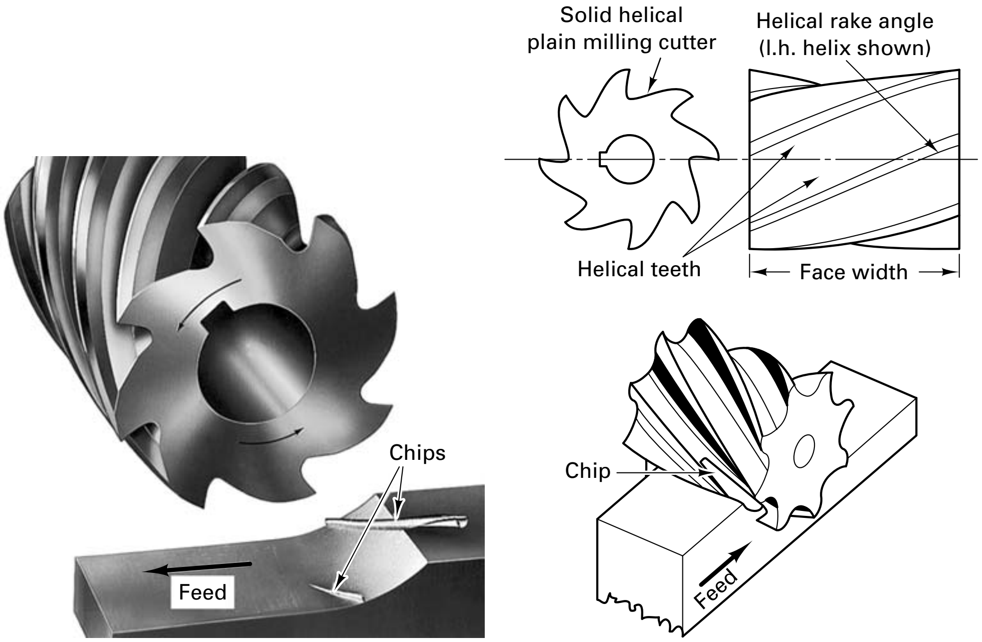

FIGURE 24-12 The chips are formed progressively by the teeth of a plain helical-tooth milling cutter during up milling.

angle of 45° to 60° to the plane face. *Double-angle cutters* have V-shaped teeth, with both conical surfaces at an angle to the end faces but not necessarily at the same angle. The V-angle usually is 45°, 60°, or 90°.

Form milling cutters have the teeth ground to a special shape—usually an irregular contour—to produce a surface having a desired transverse contour. They must be sharpened by grinding only the tooth face, thereby retaining the original contour as long as the plane of the face remains unchanged with respect to the axis of rotation. Convex, concave, corner-rounding, and gear-tooth cutters are common examples (Figure 24-13). Solid HSS cutters of simple shape and reasonably small size are usually more economical in initial cost than inserted-blade cutters. However, inserted-blade cutters may be lowest in overall cost on large production jobs.

Form-relieved cutters can be cost effective where intricately shaped cuts are needed. Solid or carbide insert tool cutters may need large volumes to be cost-justified by high-production requirements.

Most larger-sized milling cutters are of the *inserted-tooth type*. The cutter body is made of steel, with the teeth made of high-speed steel, carbides, or TiN carbides, fastened to the body by various methods. An insert tooth cutter uses indexable carbide or ceramic inserts, as shown in Figure 24-9. This type of construction reduces the amount of costly material that is required and can be used for any type of cutter, but it is most often used with face mills.

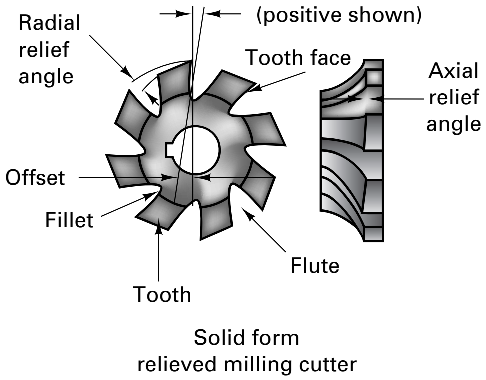

FIGURE 24-13 Solid form relieved milling cutter, would be mounted on an arbor in a horizontal milling machine.

T-slot cutters are integral-shank cutters with teeth on the periphery and *both* sides. They are used for milling the wide groove of a T-slot. To use them, the vertical groove must first be made with a slotting mill or an end mill to provide clearance for the shank. Because the T-slot cutter cuts on five surfaces simultaneously, it must be fed with care.

Woodruff keyseat cutters are made for the single purpose of milling the semicylindrical seats required in shafts for Woodruff keys. They come in standard sizes corresponding to Woodruff key sizes. Those below 2 in. in diameter have integral shanks; the larger sizes may be arbor mounted.

Occasionally, *fly cutters* may be used for face milling or boring. Both operations may be done with a single tool at one setup. A single-point cutting tool is attached to a special shank, usually with provision for adjusting the effective radius of the cutting tool with respect to the axis of rotation. The cutting edge can be made in any desired shape and, because it is a single-point tool, is very easy to grind.

24.4 MACHINES FOR MILLING

The four most common types of manually controlled milling machines are listed below in order of increasing power (and therefore metal removal capability):

1. Ram-type milling machines
2. Column-and-knee-type milling machines
   a. Horizontal spindle
   b. Vertical spindle
3. Fixed-bed-type milling machines
4. Planer-type milling machines

Milling machines whose motions are electronically controlled are listed in order of increasing production capacity and decreasing flexibility:

1. Manual data input milling machines
2. Programmable CNC milling machines
3. Machining centers (tool changer and pallet exchange capability)
4. Flexible Manufacturing Cell and Flexible Manufacturing System
5. Transfer lines

BASIC MILLING MACHINE CONSTRUCTION

Most basic milling machines are of *column-and-knee* construction, employing the components and motions shown in Figure 24-14. The column, mounted on the base, is the main supporting frame for all the other parts and contains the spindle with its driving mechanism. This construction provides controlled motion of the worktable in three mutually perpendicular directions: (1) through the *knee*, moving vertically on ways on the front of the column; (2) through the *saddle*, moving transversely on ways on the knee; and (3) through the *table*, moving longitudinally on ways on the saddle. All these motions can be imparted by either manual or powered means. In most cases, a powered rapid traverse is provided in addition to the regular feed rates for use in setting up work and in returning the table at the end of a cut.

The ram-type milling machine is one of the most versatile and popular milling machines, using the knee and column design. Ram-type machines have a head equipped with a motor-stopped pulley and belt drive as well as a spindle. The ram, mounted on horizontal ways at the top of the column, supports the head and permits positioning of the spindle with respect to the table. Ram-type milling machines are normally 10 hp or less and suitable for light-duty milling, drilling, reaming, and so on (Figure 24-15).

Milling machines having only the three mutually perpendicular table motions are called *plain column-and-knee type*. These are available with both horizontal and vertical spindles (Figure 24-14). On the older horizontal-spindle-type machines, an adjustable overarm provides an outboard bearing support for the end of the cutter arbor, which is shown in Figure 24-11. These machines are well suited for slab, side, or straddle milling.

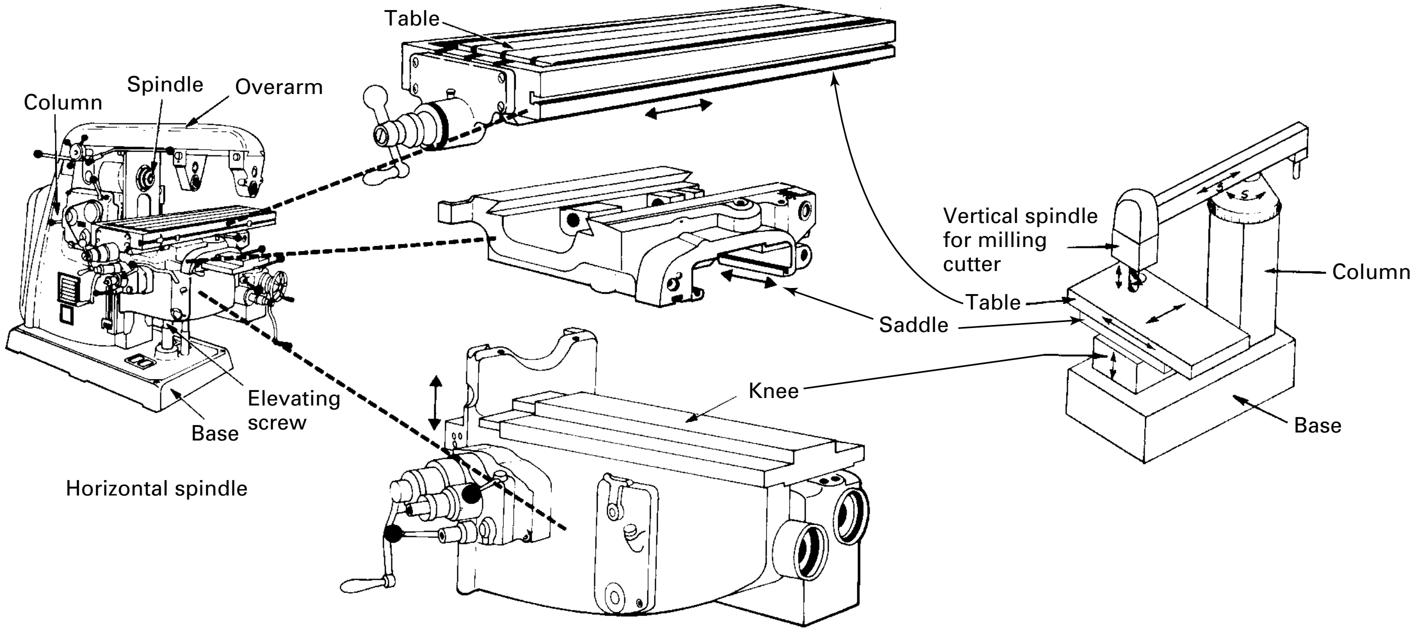

FIGURE 24-14 Major components of a plain column-and-knee-type milling machine, which can have horizontal spindle shown on the left, or a turret type machine with a vertical spindle, shown on the right. The workpiece and workholder on the table can be translated in *X, Y,* and *Z* directions with respect to the tool.

In some vertical-spindle machines the spindle can be fed up and down, either by power or by hand. Vertical-spindle machines are especially well suited for face and end milling operations. They also are very useful for drilling and boring, particularly where holes must be spaced accurately in a horizontal plane, because of the controlled table motion.

Turret-type column-and-knee milling machines have dual heads that can be swiveled about a horizontal axis on the end of a horizontally adjustable ram. This permits milling to be done horizontally, vertically, or at any angle. This added flexibility is advantageous when a variety of work has to be done, as in tool and die or experimental shops. They are available with either plain or universal tables.

Universal column-and-knee milling machines differ from plain column-and-knee machines in that the table is mounted on a housing that can be swiveled in a horizontal plane, thereby increasing its flexibility. Helices, as found in twist drills, milling cutters, and helical gear teeth, can be milled on universal machines.

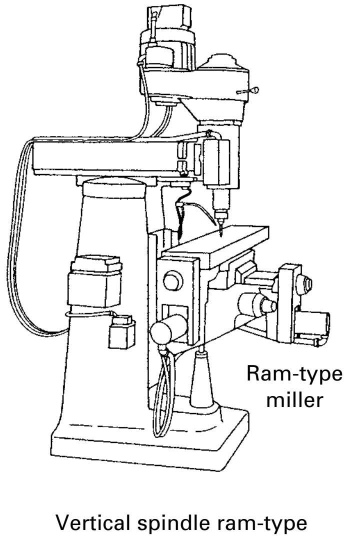

FIGURE 24-15 The ram-type knee-and-column milling machine is one of the most versatile and popular milling machine tools ever designed.

BED-TYPE MILLING MACHINES

In production manufacturing operations, ruggedness and the capability of making heavy cuts are of more importance than versatility. *Bed-type milling machines* (Figure 24-16) are made for these conditions. The table is mounted directly on the bed and has only longitudinal motion. The spindle head can be moved vertically in order to set up the machine for a given operation. Normally, once the setup is completed, the spindle head is clamped in position and no further motion of it occurs during machining. However, on some machines vertical motion of the spindle occurs during each cycle.

After such milling machines are set up, little skill is required to operate them, permitting faster learning time for the operators. Some machines of this type are equipped with automatic controls so that all the operator has to do is load and unload workpieces into the fixture and set the machine into operation. For stand-alone machines, a fixture can be located at each end of the table so that one workpiece can be loaded while another is being machined.

Bed-type milling machines with single spindles are sometimes called *simplex milling machines*; they are made with both horizontal and vertical spindles. Bed-type machines also are made in *duplex* and *triplex* types, having two or three spindles respectively, permitting the simultaneous milling of two or three surfaces at a single pass.

PLANER-TYPE MILLING MACHINES

Planer-type milling machines (Figure 24-17) utilize several milling heads, which can remove large amounts of metal while permitting the table and workpiece to feed quite slowly. Often only a single pass of the workpiece past the cutters is required. Through the use of different types of milling heads and cutters, a wide variety of surfaces can be machined with a single setup of the workpiece. This is an advantage when heavy workpieces are involved.

ROTARY-TABLE MILLING MACHINES

Some types of face milling in mass-production manufacturing are often done on *rotary-table milling machines*. Roughing and finishing cuts can be made in succession as the workpieces are moved past the several milling cutters while held in fixtures on the rotating table. The operator can load and unload the work without stopping the machine.

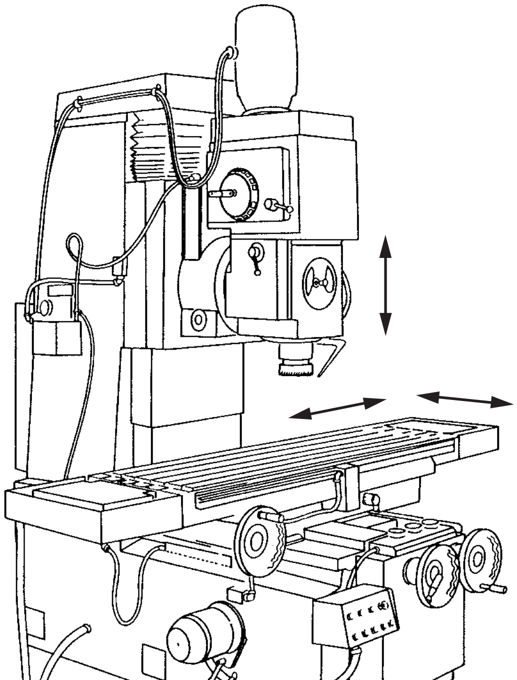

FIGURE 24-16 Bed-type vertical-spindle heavy-duty production machine tools for milling usually have three axes of motion.

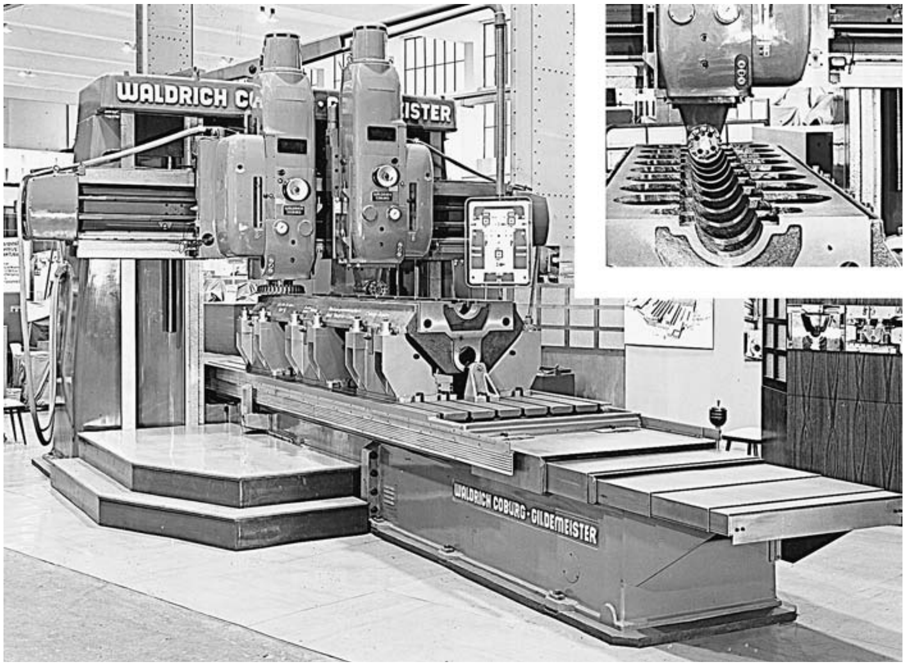

FIGURE 24-17 Large planer-type milling machine. Inset shows 90° head being used. *(Courtesy of Cosa Corporation.)*

PROFILERS AND DUPLICATORS

Milling machines that can duplicate external or internal geometries in two dimensions are called *profilers* or tracer-controlled machines. A tracing probe follows a two-dimensional pattern or template and, through electronic or hydraulic air-actuated mechanisms, controls the cutting spindles in two mutually perpendicular directions.

All hydraulic tracers work basically the same way, in that they utilize a stylus connected to a precision servomechanism for each axis of control. The servos are connected to hydraulic actuators on the machine slides. As the stylus traces a template, the servos control the motion of the slides so that the milling cutter duplicates the template shape onto the workpiece.

Duplicators produce forms in three dimensions and are widely used to machine molds and dies. Sometimes these machines are called *die-sinking machines*. They are used extensively in the aerospace industry to machine parts from wrought plate or bar stock as substitutes for forgings when the small number of parts required would make the cost of forging dies uneconomical. Many of these kinds of jobs are now done on NC- and CNC-type machines; their applications are discussed in Chapters 26.

MILLING MACHINE SELECTION

When purchasing or using a milling machine, consider the following issues:

1. Spindle orientation and rpm
2. Machine capability (accuracy and precision)
3. Machine capacity (size of workpieces)
4. Horsepower available at spindle (usually 70% of machine horsepower)
5. Automatic tool changing

The choice of spindle orientation, horizontal or vertical, depends on the parts to be machined. Relatively flat parts are usually done on vertical machines. Cubic parts are usually done on a horizontal machine, where chips tend to fall free of the part. Operations like slotting and side milling are best done on horizontal machines with outboard supports for the arbor. Use the largest-diameter arbor possible to reduce twist and deflection due to cutting forces.

Machine capability refers to the tolerances, while *capacity* refers to the size of parts and the power available.

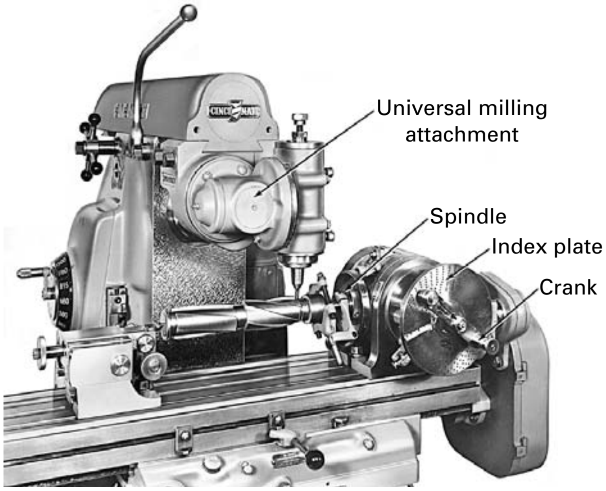

FIGURE 24-18 End milling a helical groove on a horizontal-spindle milling machine using a universal dividing head and a universal milling attachment. *(Courtesy of Cincinnati Milacron, Inc.)*

As with all tooling applications, the tolerances that can be maintained in milling are dependent upon the rigidity of the workpiece, the accuracy and rigidity of the machine spindle, the precision and accuracy of the workholding device, and the quality of the cutting tool itself. Milling produces forces that contribute to chatter and vibration because of the intermittent cutting action. Soft materials tend to adhere to the cutter teeth and make it more difficult to hold tolerances. Materials such as cast iron and aluminum are easy to mill.

Within these criteria, properly maintained cutters used in rigid spindles on properly fixtured workpieces can expect to machine within tolerances with surface flatness tolerances of 0.001 in./ft. Such tolerances are also possible on "slotting" operations with milling cutters, but $+0.001$ in. to $+0.002$ in. is more probable. Flatness specifications are more difficult to maintain in steel and easier to maintain in some types of aluminum, cast iron, and other nonferrous material.

Part size is the primary factor in selecting the machine size, but the length of the tooling as mounted in the spindle must be considered. Horsepower required at the spindle depends on the MRR and the materials (unit horsepower, hp_s). Remember, coated inserts allow the MRR (the cutting speed) to be increased and available power may be exceeded.

Finally, the capacity of the tool changers on machining centers is limited by the number, size, and weight of the tools, especially if large-diameter tools are being employed. These often have to be stored in every other space in the storage mechanism.

ACCESSORIES FOR MILLING MACHINES

The usefulness of ordinary milling machines can be greatly extended by employing various accessories or attachments. Here are some examples.

A horizontal milling machine can be equipped with a vertical milling attachment to permit vertical milling to be done. Ordinarily, heavy cuts cannot be made with such an attachment.

The *universal milling attachment* (Figure 24-18) is similar to the vertical attachment but can be swiveled about both the axis of the milling machine spindle and a second, perpendicular axis to permit milling to be done at any angle.

The *universal dividing head* is by far the most widely used milling machine accessory, providing a means for holding and indexing work through any desired arc of rotation. The work may be mounted between centers (Figure 24-18) or held in a chuck that is mounted in the spindle hole of the dividing head. The spindle can be tiled from about 5° below horizontal to beyond the vertical position.

Basically, a dividing head is a rugged, accurate, 40:1 worm-gear reduction unit. The spindle of the dividing head is rotated one revolution by turning the input crank 40 turns. An index plate mounted beneath the crank contains a number of holes, arranged in concentric circles and equally spaced, with each circle having a different number of holes. A plunger pin on the crank handle can be adjusted to engage the holes of any circle. This permits the crank to be turned an accurate, fractional part of a complete circle as represented by the increment between any two holes of a given circle on the index plate. Utilizing the 40:1 gear ratio and the proper hole circle on the index plate, the spindle can be rotated a precise amount by the application of either of the following rules:

$$\text{number of turns of crank} = \frac{40}{\text{cuts per revolution of work}}$$

$$\text{holes to be indexed} = \frac{40 \times \text{holes index circle}}{\text{cuts per revolution of work}}$$

If the first rule is used, an index circle must be selected that has the proper number of holes to be divisible by the denominator of any resulting fractional portion of a turn of the crank. In using the second rule, the number of holes in the index circle must be such that the numerator of the fraction is an even multiple of the denominator. For example, if 24 cuts are to be taken about the circumference of a workpiece, the number of turns of the crank required would be $1^{2}/_{3}$. An index circle having 12 holes could be used with one full turn plus eight additional holes. The second rule would give the same result. Adjustable *sector arms* are provided on the index plate that can be set to a desired number of holes, less than a full turn, so that fractional turns can be made readily without the necessity for counting holes each time. Dividing heads are made having ratios other than 40:1. The ratio should be checked before using.

Because each full turn of the crank on a standard dividing head represents 360/40, or 9° of rotation of the spindle, indexing to a fraction of a degree can be obtained. Indexing can be done in three ways. *Plain indexing* is done solely by the use of the 40:1 ratio in the dividing head. In *compound indexing*, the index plate is moved forward or backward a number of hole spaces each time the crank handle is advanced. For *differential indexing* the spindle and the index plate are connected by suitable gearing so that as the spindle is turned by means of the crank, the index plate is rotated a proportional amount.

The dividing head can also be connected to the feed screw of the milling machine table by means of gearing. This procedure is used to provide a definite rotation of the workpiece with respect to the longitudinal movement of the table, as in cutting helical gears. This procedure is illustrated in Chapter 29.

■ Key Words

■ Review Questions

1. Suppose you wanted to machine a cast iron with BHN of 275. The process to be used is face milling and an HSS cutter is going to be used. What feed and speed values would you select?
2. Explain how table feed (ipm) and spindle rpm are specified or computed for a milling machine after speed and feed per tooth are selected.
3. Why must the number of teeth on the cutter be known when calculating milling machine table feed, in in./min?
4. Why is the question of up or down milling more critical in horizontal slab milling than in vertical-spindle (end or face) milling?
5. For producing flat surfaces in mass production machining, how does face milling differ basically from peripheral milling?
6. Milling has a higher metal removal rate than planing. Why?
7. Which type of milling (up or down) is being done in Figures 24-1, Figure 24-2, and 24-7?
8. Why does down milling dull the cutter more rapidly than up milling when machining sand castings?
9. What parameters do you need to specify in order to calculate MRR in milling?
10. In Figure 24-2b the tool material is carbide. What would you change in the process?

11. What is the advantage of a helical-tooth cutter over a straight-tooth cutter for slab milling?
12. What would the cutting force diagram for F_c look like if the cutter were performing climb milling?
13. Could the stub arbor–mounted face mill shown in Figure 24-9 be used to machine a T-slot? Why or why not?
14. In a typical solid arbor milling cutter shown in Figure 24-10, why are the teeth staggered? (Check in Chapter 19 for discussion of dynamics.)
15. Make some sketches to show how would you set up a plain column-and-knee milling machine to make it suitable for milling the top and sides of a large block.
16. Make some sketches to show how you would set up a horizontal milling machine to cut both sides of a block of metal simultaneously.
17. Explain how controlled movements of the work in three mutually perpendicular directions are obtained in column-and-knee-type milling machines.
18. What is the basic principle of a universal dividing head?
19. What is the purpose of the hole-circle plate on a universal dividing head?

Problems

1. You have selected a feed per tooth and a cutting speed for a face milling process. Reasonable values for feed and speed are 0.010 in. per tooth and 200 sfpm. The cutter is 8 in. in diameter, as shown in Figure 24-9. Compute the input values for the machine tool.
2. How much time will be required to face mill an AISI 1020 steel surface Bhn, 150, that is 12 in. long and 5 in. wide, using a 6-in-diameter, eight-tooth tungsten carbide inserted-tooth face mill cutter? Select values of feed per tooth and cutting speed from Table 24-1.
3. If the depth of cut is 0.35 in., what is the metal removal rate in Problem 2?
4. Estimate the power required for the operation of Problem 3. Do not forget to consider Figure 24-7.
5. Examine the part shown in Figure 1-6. The slot on the left end must be produced by machining. Provide a process plan (a description [sketch] of how the part would set up in the machine for machining the slot and the details regarding cutting tools, such as material, sizes, and so on). Specify (select) the type of milling machine, the cutting parameters, and any other information needed to make this component.
6. A gray cast iron surface 6 in. wide and 18 in. long may be machined on either a vertical milling machine, using an 8-in.-diameter face mill having eight inserted HSS teeth, or on a horizontal milling machine using an HSS slab mill with eight teeth on a 4-in. diameter. Which machine has the faster cutting time?
7. An operation is to be performed to machine three grooves on a number of parts shown in Figure 24-11. Setup time is 20 minutes on a shaper (not shown) and 30 minutes on the horizontal milling machine. The direct time to machine each piece on the shaper is 14 min and on the miller is 6 min. Labor costs $10/hr. The charge for the use of the shaper is $10/hr and for the milling machine $20/hr. What is the breakeven quantity, below which the shaper is more economical than the mill.
8. In Figure 24-12, the feed is 0.006 in. per tooth. The cutter is rotating at an rpm that will produce the desired surface cutting speed of 125 sfpm. The cutter diameter is 5 in. The depth of cut is 0.5 in. The block is 2 in. wide.
   a. What is the feed, in inches per minute, of the milling machine table?
   b. What is the MRR for this situation?
   c. What is horsepower (HP) consumed by this process, assuming an 80% efficiency and a HP_s value for this material of 1.8?
9. Suppose you want to do the job described in Problem 6 by slab milling. You have selected a 6-in.-diameter cutter with eight TiN-coated carbide teeth. The cutting speed will be 500 sfpm and the feed per tooth will be 0.010 in. per tooth. Determine the input parameters for the machine (rpm of arbor and table feed), then calculate the T_m and MRR. Compare these answers with what you got for face milling the block with HSS teeth.
10. The Bridgeport vertical-spindle milling machine is perhaps the single most popular machine tool. Virtually every factory (or shop) that does machining has one or more of these type machines. Go to your nearest machine shop and find a Bridgeport, make a sketch to show how it works, and explain what makes it so popular.

Chapter 24 CASE STUDY

HSS versus Tungsten Carbide Milling

The K & C Machine works, which does job shop machining, has received an order to make 40 duplicate pieces, made of AISI 4140 steel, which will require 1 hour per piece of actual cutting time if a high-speed-steel (MI) milling cutter is used. Abigail Langley, a new machinist, says the cutting time could be reduced significantly if the company would purchase a suitable tungsten carbide milling cutter. Hugh Fellows, the foreman for the milling area, says he does not believe that Abigail's estimate is realistic, and he is not going to spend $450 (the current price from the vendor) of the company's money on a carbide cutter that probably would not be used again. The machine hour rate, including labor for your shop is $40 per hour. Abigail and Hugh have come to you, the supervisor of the shop, for a decision on whether or not to buy the cutter, which is readily available from a local supplier.

What factors should you consider in this situation? How much faster could the carbide cutter cut compared to the HSS cutter? See reference table. Based on your best guess as to the savings in actual cutting time per piece, who do you think is correct, Abigail or Hugh?

Representative Cutting Data

Material						**Forces**

CHAPTER 25

WORKHOLDING DEVICES FOR MACHINE TOOLS

25.1 INTRODUCTION

In the chapters on machining processes, the manner in which workpieces are mounted and held in the various machine tools was discussed. Workholding devices, often called jigs and fixtures, are critical components in the manufacturing of interchangeable parts. *Workholders* hold and locate the work in the machine tool with respect to the cutting tool. For example, Figure 25-1 shows an engine lathe and a CNC turning center with two spindles, each holding a chuck that holds the workpiece in the correct location with respect to the cutting tools. For many machine tools, fixtures hold the workpieces while providing location with respect to the cutting tools. With workholders, process accuracy and precision (repeatability) can be achieved that otherwise would be impossible with a given combination of cutting tools and machine tools. In this chapter, workholding devices (jigs and fixtures) will be considered as important production tools or adjuncts, with primary attention being directed toward their functional characteristics, their relationship to the machine tools, and the manufacturing processes.

In recent years, workholding devices have become more flexible; that is, (1) able to hold more than one part and (2) able to be quickly exchanged. Flexible workholders are critical elements in lean manufacturing cells, where components are made in families of parts (groups of parts of similar design). Further, being able to change from one device to another quickly to accommodate different parts means smaller lot sizes can be run, which reduces inventory levels in plants. These flexibility requirements add significantly to the complexity of conventional jig and fixture design. Let's begin with a discussion of the basics of jig and fixture design.

25.2 CONVENTIONAL FIXTURE DESIGN

In the conventional method of fixture design, tool designers rely on their experience and intuition to design simple, single-purpose fixtures for specific machining operations, often using a trial-and-error method until the workholders perform satisfactorily. Of course, these designers should calculate the clamping forces or stress distributions in the fixturing elements to make sure that the loads will not deform the fixtures or the workpieces elastically or plastically. In the design of the workholding devices, two primary functions must be considered: *locating and clamping*. *Locating* refers to orienting and positioning the part in the machine tool with respect to the cutting tools to achieve

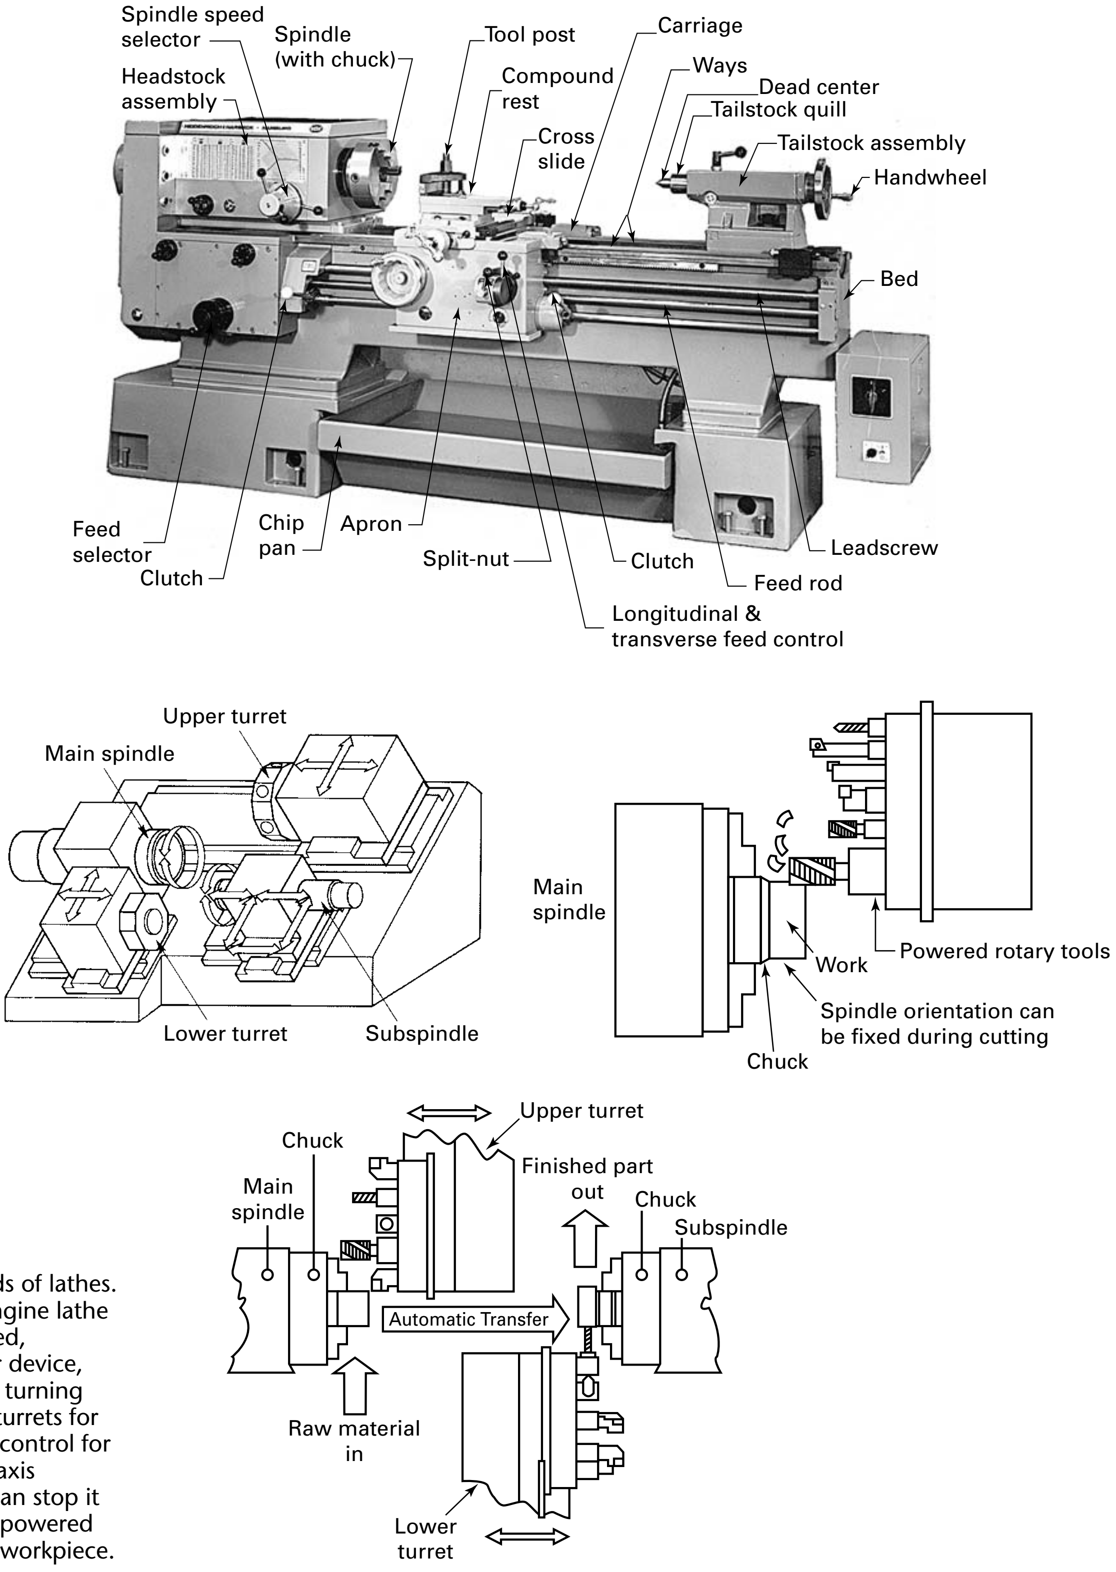

FIGURE 25-1 Two kinds of lathes. Above, a conventional engine lathe with principal parts named, including the workholder device, the chuck. Below, a CNC turning center with two chucks, turrets for cutting tools, and C-axis control for the main spindle. The C-axis control, on the spindle, can stop it in any orientation so the powered tools can operate on the workpiece.

the required specifications. *Clamping* refers to holding or maintaining the part in that location during the cutting operations (resisting the cutting forces).

Jigs and *fixtures* are specially designed and built workholding devices that hold the work during machining or assembly operations. In addition, a jig determines a location dimension that is produced by machining or fastening. For example, location dimensions determine the position of a hole on a plate (Figure 25-2). Consider the subject of dimensioning as used in drafting practice. Dimensions are of two types: *size* and

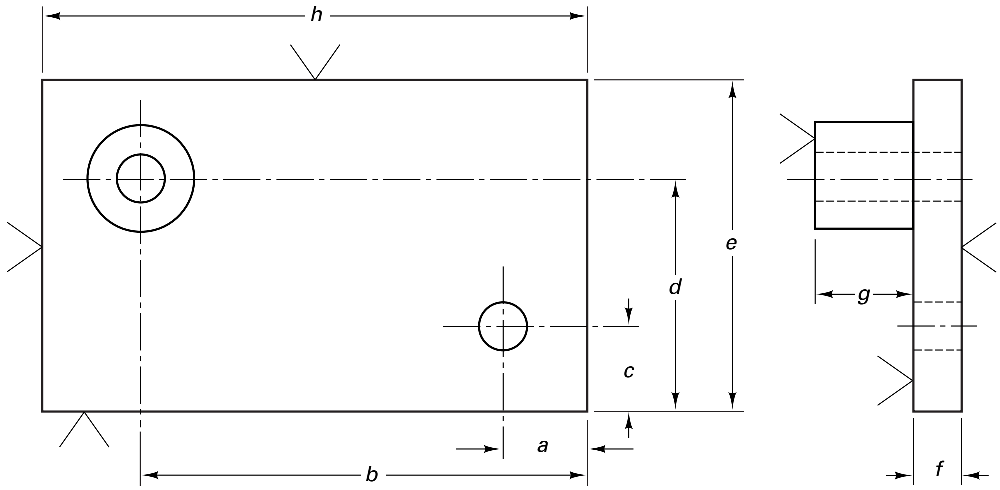

FIGURE 25-2 Drawing of a plate showing locating dimensions *(a, b, c, d)* versus sizing dimensions *(e, f, g, h)*.

location. *Size* dimensions denote the size of geometrical shapes—holes, cubes, parallelepipeds, and so on—of which objects are composed. *Location* dimensions, on the other hand, determine the position or location of these geometrical shapes *with respect to each other*. Thus *a* and *c* in Figure 25-2 are location dimensions, whereas *e* and *g* are size dimensions. With location dimensions in mind, one can precisely define a jig as follows: *A jig is a special workholding device that, through built-in features, determines location dimensions that are produced by machining or fastening operations*. The key requirement of a jig is that it determine a location dimension. Thus, jigs accomplish layout by means of their design.

In order to establish location dimensions, jigs may do a number of other things. They frequently guide tools, as in drill jigs, and thus determine the location of a component geometrical shape. However, they do not always guide tools. In the case of welding jigs, component parts are held (located) in a desired relationship with respect to each other while an unguided tool accomplishes the fastening. The guiding of a tool is not a necessary requirement of a jig.

Similarly, jigs usually hold the work that is to be machined, fastened, or assembled. However, in certain cases, the work actually supports the jig. Thus, although a jig *may* incidentally perform other functions, the basic requirement is that, through qualities that are built into it, certain critical dimensions of the workpiece are determined.

A *fixture* is *a special workholding device that holds work during machining or assembly operations and establishes size dimensions*. The key characteristic is that it is a *special* workholding device, designed and constructed for a particular part or shape. A general-purpose device, such as a chuck in a lathe or a clamp on a milling machine table, is usually not considered to be a fixture. Thus a fixture has as its specific objective the facilitating of *setup*, or making the part holding easier. Because many jigs hold the work while determining critical location dimensions, they usually meet all the requirements of a fixture. Alternatively, many fixtures are used in NC machines holding parts where holes are located and drilled according to a program. So the strict definition of jigs and fixtures has been blurred by the changes in technology.

In designing workholders, the designer must consider whether the part is a casting, forging, or bar stock. With castings and forgings, variations in shape and size must be accommodated in the design, and usually a machining operation is required to establish a reference surface (called the datum surface) to aid initial fixturing.

In parts cut from bar stock, allowances must be made for inaccuracies and irregularities produced by the cutoff operations. Table 25-1 provides a summary of design criteria for workholders for you to review. Obviously, it is impossible to meet all these design criteria for workholders. Compromise is inevitable. Still, it is useful to know the optimal design objectives to illustrate the positioning, holding, and supporting functions that fixtures must fulfill.

TABLE 25-1 Design Criteria for Workholders

Positive location	A fixture must, above all else, hold the workpiece precisely in space to prevent each of 12 kinds of degrees of freedom—linear movement in either direction along the X-, Y-, and Z-axes and rotational movement in either direction about each axis.
Repeatability	Identical workpieces should be located by the workholder in precisely the same space on repeated loading and unloading cycles. It should be impossible to load the workpiece incorrectly. This is called "foolproofing" the jig or fixture.
Adequate clamping forces	The workholder must hold the workpiece immobile against the forces of gravity, centrifugal forces, inertial forces, and cutting forces but not distort the part. Milling and broaching operations, in particular, tend to pull the workpiece out of the fixture, and the designer must calculate these machining forces against the fixture's holding capacity. The device must be rigid.
Reliability	The clamping forces must be maintained during machine operation every time the device is used. The mechanism must be easy to maintain and lubricate.
Ruggedness	Workholders usually receive more punishment during the loading and unloading cycle than during the machining operation. The device must endure impact and abrasion for at least the life of the job. Elements of a device that are subject to damage and wear should be easily replaceable.
Design and construction ease	Workholders should use standard elements as much as possible to allow the engineer to concentrate on function rather than on construction details. Modular fixtures epitomize this design rule as the entire workholder is made from standard elements, permitting a bolt-together approach for substantial time and cost savings over custom workholders.
Low profile	Workholder elements must be clear of the cutting-tool path. Designing lugs on the part for clamping can simplify the fixture and allow proper tool clearance.
Workpiece accommodation	Surface contours of castings or forgings vary from one part to the next. The device should tolerate these variations without sacrificing positive location or other design objectives.
Ergonomics and safety	Clamps should be selected and positioned to eliminate pinch points and facilitate ease of operation. The workholder elements should not obstruct the loading or unloading of workpieces. In manual operations, the operator should not have to reach past the tool to load or unload parts. A rule sometimes used is that the operator can repeatedly exert a force of 30 to 40 lb to open or close a clamp but greater forces than this can cause ergonomic problems.
Freedom from part distortion	Parts being machined can be distorted by gravity, the machining forces, or the clamping forces. Once clamped into the device, the part must be unstressed or, at least, undistorted. Otherwise, the newly machined surfaces take on any distortions caused by the clamping forces.
Flexibility	The workholding device can locate and restrain more than one type (design) of part. Many different schemes are being proposed to provide workholder flexibility. Modular vise fixturing, programmable clamps using air-activated plungers, part encapsulation with a low-melting-point alloy, and NC-controlled clamping machines are some of the more recently developed systems. Despite their flexibilities, these clamping systems have some significant drawbacks. They are expensive, and the individual systems may not integrate well into individual machine tools. (See the discussions of intermediate jig concept and group jigs for additional thoughts on flexibility.)

25.3 DESIGN STEPS

The classical design of a workholder (e.g., a drill jig) involves the following steps:

1. Analyze the drawing of the workpiece and determine (visualize) the machining operations required to machine it. Note the critical (size and location) dimensions and tolerances.
2. Determine the orientations of the workpiece in relation to the cutting tools and the movements of the tools and tables.
3. Perform an analysis to estimate the magnitude and direction of the cutting forces (see Chapter 21).
4. Study the standard devices available for workholders and for the clamping functions. Can an off-the-shelf device be modified? What standard elements can be used?
5. Form a mental picture of the workpiece in position in the workholder in the machine tool with the cutting tools performing the required operation(s). See the figures in chapters on machining for examples.
6. Make a three-dimensional sketch of the workpiece in the workholder in its required position to determine the location of all the elements: clamps, locator buttons, bushings, and so on.
7. Make a sketch of the workholder and workpiece in the machine tool to show the orientation of these elements with respect to the cutting tool in the machine tool.

3-2-1 LOCATION PRINCIPLE

After determining the orientation of the workpiece in the workholder, the next step is to locate it in that position. This location is also used for all similar workpieces. The designer must select or design locating devices (supports) *that ensure that every workpiece placed*

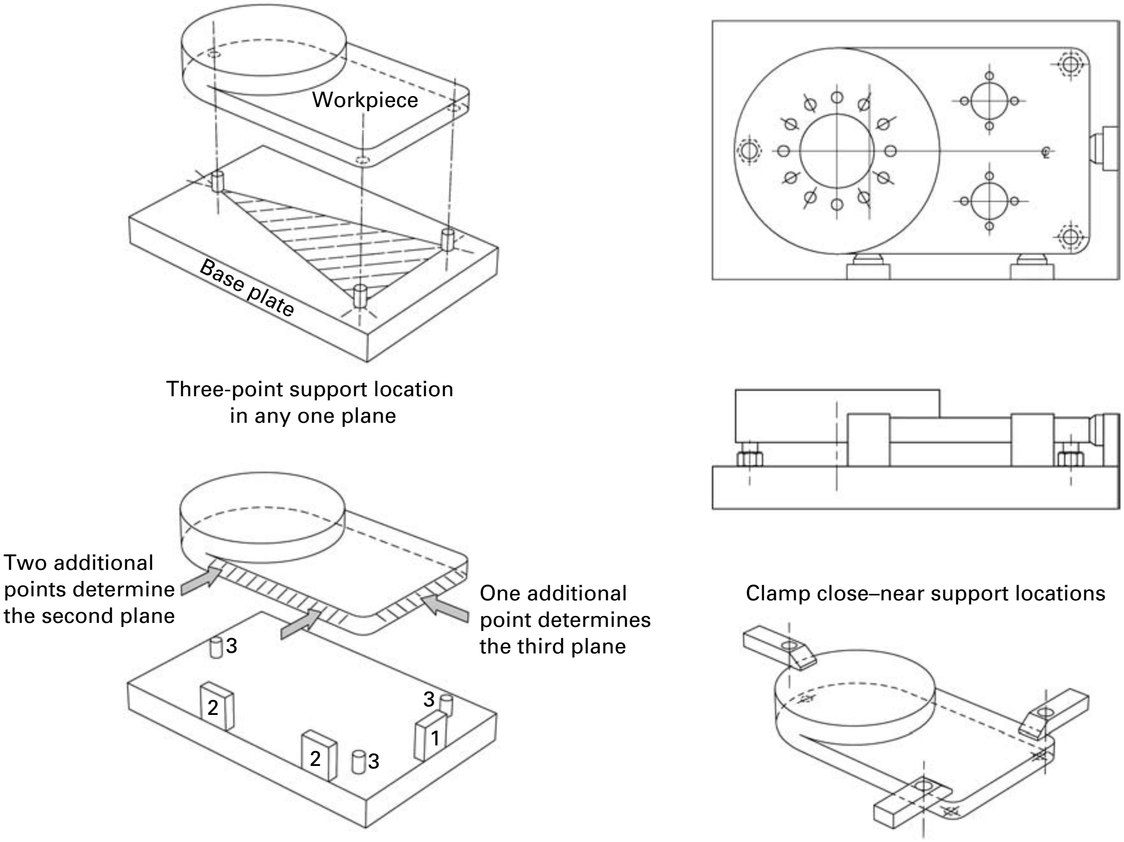

FIGURE 25-3 Workpiece location is based on the 3-2-1 principle. Three points will define a base surface, two points in a vertical plane will establish an end reference, and one point in a third plane will positively locate most parts.

in the device occupies the same position with respect to the cutting tools. Thus, when the machining operation is performed, the workpieces are processed identically. This is, of course, the key to making interchangeable parts. In locating the workpiece, the basic *3-2-1 principle* of location is used (Figure 25-3). For positive location, the fixture must position the workpiece in each of three perpendicular planes. Positioning processes can vary greatly, but workholder design always begins by defining the first plane of reference with three points. Once the object is defined in a single plane, supported at three points (like a three-legged stool on a floor), a second plane can be assigned that is perpendicular to the first. To do this, the object is brought up against any two points in the second plane. To continue the example, the stool is slid along the floor until two legs touch a wall.

A third plane, perpendicular to each of the other two, is then defined by designating one point on it. As long as an object is in contact with three points on the first plane, two points on the second, and a single point on the third, it is positively located in space. The location points within each plane should be selected as far apart as possible for maximum stability.

In practice, it is often necessary to support a workpiece on more points than this 3-2-1 formula dictates. The machining of a large rectangular plate, for example, typically requires support at four or more points. However, any extra points must be established carefully to support the workpiece in a plane defined by three—and only three—points.

Appropriate clamping devices are selected so that the clamping forces hold the workpiece in the proper location and resist the effects of the cutting forces, centrifugal forces, and vibrations. If possible, the machining forces should act into the location points, not into the clamps, so that smaller clamps can be used. In reality, the worker often determines clamping force when loading the part into the workholder. Fixtures are usually fastened to the table of the machine tool. Although used primarily on milling and

TABLE 25-2 Twenty Principles for Workholder Design

1. Determine the critical surfaces or points for the part.
2. Decide on locating points and clamping arrangements.
3. For mating parts, use corresponding locating points or surfaces to ensure proper alignment when assembled.
4. Try to use 3-2-1 location, with 3 assigned to largest surface. Additional points should be adjustable.
5. Locating points should be visible so that the operator can see if they are clean. Can they be replaced if worn?
6. Provide clamps that are as quick acting and easy to use as is economically justifiable for rapid loading and unloading.
7. Clamps should not require undue effort by the operator to close or to open, nor should they harm hands and fingers during use.
8. Clamps should be integral parts of device. Avoid loose parts that can get lost.
9. Avoid complicated clamping arrangements or combinations that can wear out or malfunction. Keep it simple.
10. Locate clamps opposite locaters (if possible) to avoid deflection/distortion during machining and spring-back afterward.
11. Take the thrust of the cutting forces on the locaters (if possible), not on the clamps.
12. Arrange the workholder so that the workpiece can easily be loaded and unloaded from the device and so that it can be loaded only in the correct manner (mistake-proof) and in such a way that the location can be found quickly (visually).
13. Consistent with strength and rigidity, make the workholder as light as possible.
14. Provide ample room for chip clearance and removal.
15. Provide accessibility for cleaning.
16. Provide for entrance and exit of cutting fluid (which may carry off chips) if one is to be used.
17. Provide four feet on all movable workholders.
18. Provide hold-down lugs on all fixed workholders.
19. Provide keys to align fixtures on machine tables so fixtures can be replaced in exactly the same position.
20. Do not sacrifice safety for production.

broaching machines, fixtures are also designed and used to hold workpieces for various operations on most of the standard machine tools and machining centers. Some additional design rules for fixture design are given in Table 25-2.

25.4 CLAMPING CONSIDERATIONS

Clamping of the work is closely related to support of the work. Any clamping, of course, induces some stresses into the part that can cause some distortion of the workpiece, usually elastic. If this distortion is measurable, it will cause some inaccuracy in final dimensions, as illustrated in an exaggerated manner in Figure 25-4. The obvious solution is to spread the clamping forces over a sufficient area to reduce the stresses to a level that will not produce appreciable distortion. The clamping forces should direct the work against the points of location and work support. Clamped surfaces often have some irregularities that may produce force components in an undesired direction. Consequently, clamping forces should be applied in directions that will assure that the work will remain in the desired position.

Whenever possible, jigs and fixtures should be designed so that the forces induced by the cutting process act to hold the workpiece in position against the supports. These

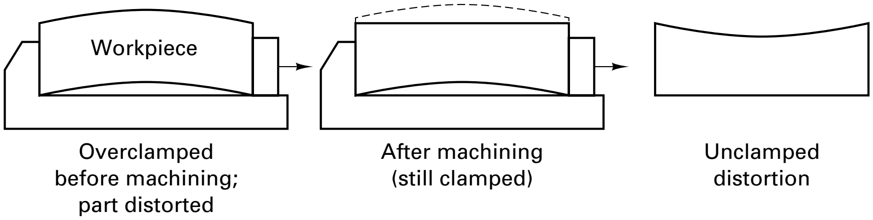

FIGURE 25-4 Exaggerated illustration of the manner in which excessive clamping forces can affect the final dimensions of a workpiece.

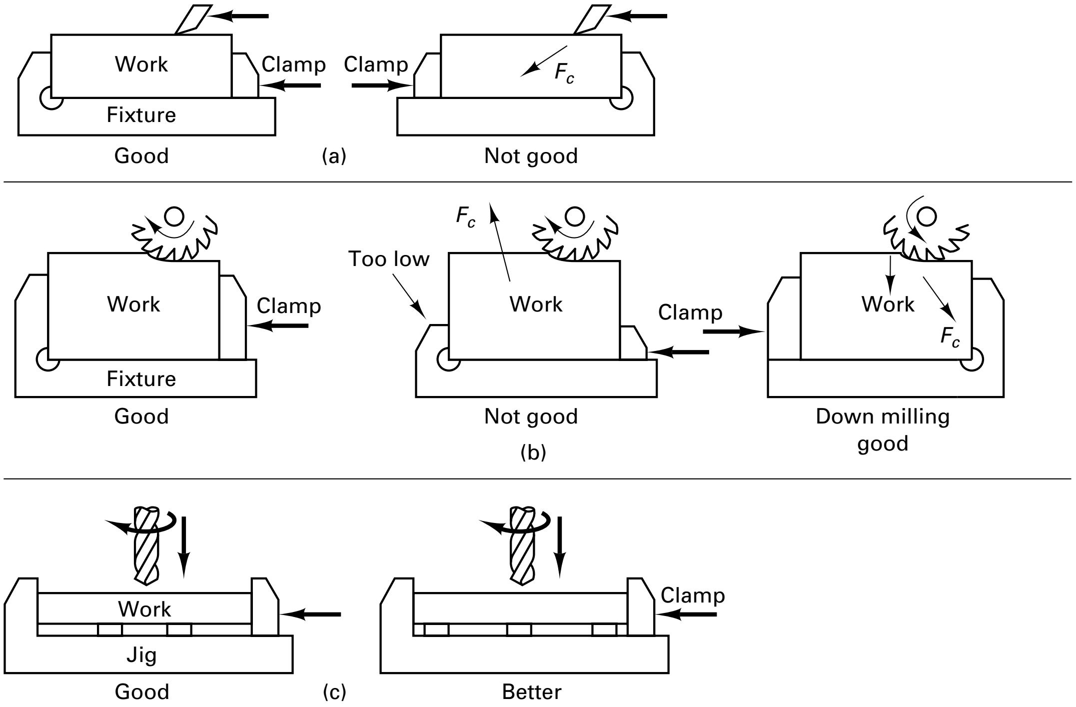

FIGURE 25-5 In (a) and (b), proper work support to resist the forces imposed by cutting tools is demonstrated. In (c), three buttons form a triangle for the work to rest on.

forces are predictable, and proper utilization of them can materially aid in reducing the magnitude of the clamping stresses required. In addition to locating the work properly, the stops or work-supporting areas must be arranged so as to provide adequate support against the cutting forces. As shown in Figure 25-5a, having the cutting force act against a fixed portion of the jig or fixture and not against a movable section permits lower clamping forces to be used. Figure 25-5b illustrates the principle of keeping the points of clamping as nearly as possible in line with the action forces of the cutting tool so as to reduce their tendency to pull the work from the clamping jaws. Compliance with this principle results both in lower clamping stresses and less massive clamping devices. Don't forget that down milling produces different forces than up milling. The location points should be as far apart as possible but positioned so as not to allow the cutting force to distort the work, as shown in Figure 25-5c. The cutting forces may distort the work, with resulting inaccuracy or broken tools. These design suggestions materially reduce vibration and chatter during the cutting process.

As many operations as are possible and practical should be performed with each clamping of the workpiece. This principle has both physical and economic aspects. Because some stresses result from each clamping, with the possibility of accompanying distortion, greater accuracy is achieved if multiple operations are performed with each clamping. From the economic viewpoint, if the number of jigs or fixtures is reduced, less capital will be required and less time will be spent handling the workpiece loading and unloading.

■ 25.5 CHIP DISPOSAL

When jigs or fixtures are used in connection with chip-making operations, adequate provision must be made for the easy removal of the chips. This is essential for several reasons. First, if chips become packed around the tool, heat will not be carried away and tool life can be decreased. Figure 25-6 illustrates how insufficient clearance between the end of a drill bushing and the workpiece can prevent the chips from escaping, whereas too much clearance may not provide accurate drill guidance and can result in broken drills.

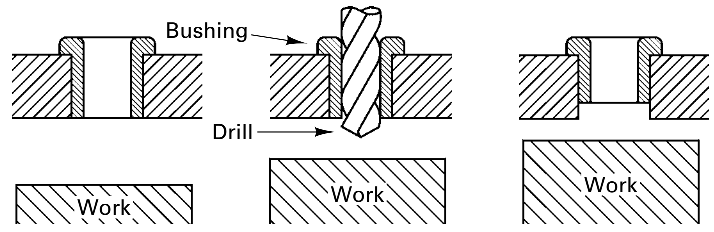

FIGURE 25-6 Proper clearance between drill bushing and tool of workpiece is important.

Too much clearance permits tool drift

Correct

Drill fills with chips; too little clearance

A second reason chips must be removed is so that they do not interfere with the proper seating of the work in the jig or fixture (Figure 25-7). Even though chips and dirt always have to be cleaned from the locating and supporting surfaces by a worker or by automatic means, such as an air blast, the design details should be such that chips and other debris will not readily adhere to, or be caught in or on, the locating surfaces, corners, or overhanging elements and thereby prevent the work from seating properly. Such a condition results in distortion, high clamping stresses, and incorrect workpiece dimensions.

25.6 UNLOADING AND LOADING TIME

The cost of the workholders must be justified by the quantities of production involved, and their primary purpose is to increase productivity and quality. While work is being put into or being taken out of jigs and fixtures, the machines with which they are used are not making chips. The loading and unloading time plus the machining time (also called the run time) plus any delay times equals the cycle time for a part. The loading and unloading time is greatly influenced by the choice of clamps.

There are many ways in which jigs and fixtures can be made easier to load and unload. Some clamping methods can be operated more readily than others. For example, in the drill jig shown in Figure 25-8, a *knurled clamping screw* is used to hold the block against the buttons at the end of the jig. To clamp or unclamp the block in this direction requires several motions. On the other hand, a *cam latch* is used to close the jig and hold the workpiece against the rear locating buttons. This type of latch can be operated with a single motion.

Certainly, the device should be designed so that the part cannot be loaded incorrectly. Defect prevention is often accomplished by the clamping device so that a part loaded improperly cannot be clamped. Ease of operation of workholders not only directly increases the productivity of such equipment but also results indirectly in better quality and fewer lost-time accidents.

The workholder is as critical as the machine tool and the cutting tool to the final quality of the part. The use of the workholder eliminates manual layout of the desired features of the part on the raw material. Manual layout requires a highly skilled worker and is very time consuming. The workholder permits a less skilled person to achieve quality and repeatable production with far greater efficiency.

25.7 EXAMPLE OF JIG DESIGN

Several principles of work location and tool guidance are illustrated in Figure 25-8. The two mounting holes in the base of the bearing block are to be located and drilled. The dimensions A, B, and C are determined by the jig. While it is not specified on the drawing,

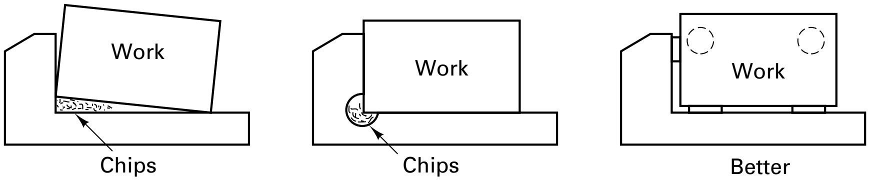

FIGURE 25-7 Methods of providing chip clearance to ensure proper seating of the work.

Not good

Good

Better

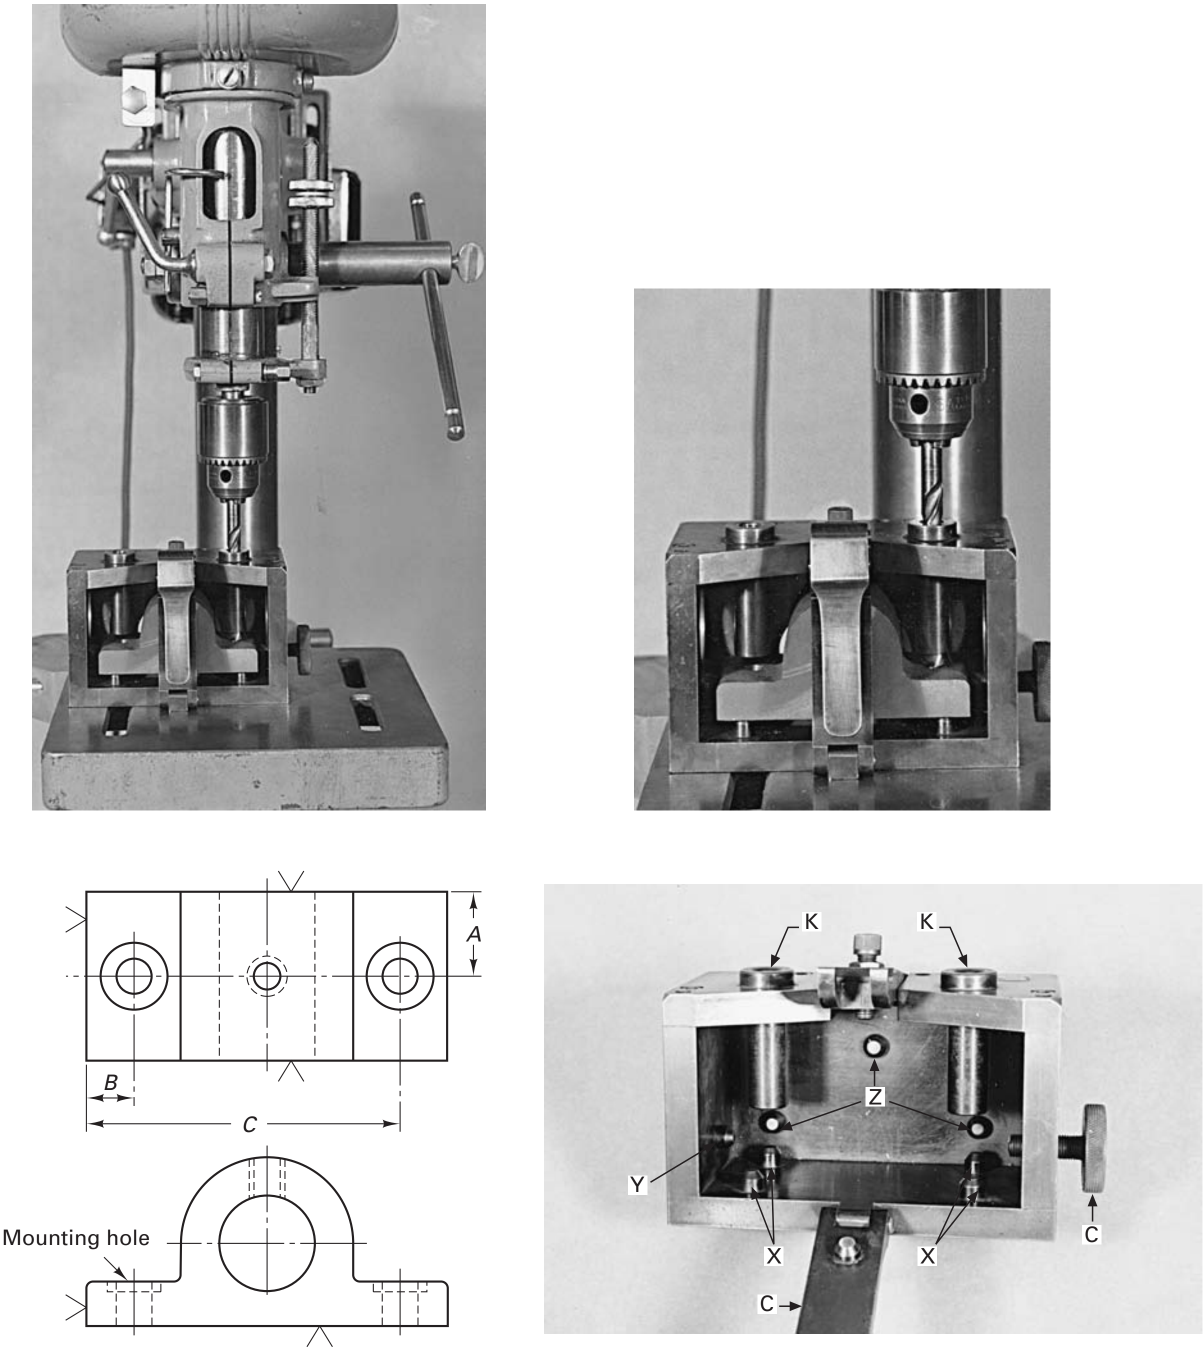

FIGURE 25-8 (Lower left) Part to be drilled; (lower right) box drill jig for drilling two holes; (upper left) jig in drill press; (upper right) drill being guided by drill bushing.

there is one other location dimension that must be controlled. The axes of the mounting holes must be at right angles to the bottom surface of the block, so the bottom must be machined (milled) prior to this drilling step.

The way in which the part dimensions are obtained in the finished workpiece is as follows. The surfaces marked with a large carats ∨ are reference (or location) surfaces and are finished (machined) prior to insertion of the part into the drill jig. The part rests in the jig on four buttons marked X in Figure 25-8. These buttons, made of hardened steel, are set into the bottom plate of the jig and are accurately ground so that their surfaces are in a single plane. The left-hand end of the part is held against another button Y. This locating button is built into the jig so that its surface is at right angles to the plane of the

X buttons. When the block is placed in the jig, its rear surface rests against three more buttons marked Z. These buttons are located and ground so that their surfaces lie in a plane that is at right angles to the planes of both the X and Y buttons. The part is held in its located position by the two clamps marked C.

The use of four buttons on the bottom of this jig (X buttons) appears not to adhere to the 3-2-1 principle stated previously. However, although only two X buttons would have been required for complete location, the use of only two buttons would not have provided adequate support during drilling. The thrust from the drills would have dislodged the part from the locators. Thus the 3-2-1 principle is a *minimum* concept and often must be exceeded.

To ensure that the mounting holes are drilled in their proper locations, the drill must be located and then guided during the drilling process. This is accomplished by the two drill bushings marked K. Such drill bushings are accurately made of hardened steel, with their inner and outer cylindrical surfaces concentric. The inner diameter is made slightly larger than the drill—usually 0.0005 to 0.002 in.—so that the drill can turn freely but not shift appreciably. The bushings are accurately mounted in the upper plate of the jig and positioned so that their axes are exactly perpendicular to the plane of the X buttons, at a distance A from the Z buttons and at distances B and C, respectively, from the plane of the Y button. Note that the bushings are sufficiently long that the drill is guided close to the surface where it will start drilling. Consequently, when the workpiece is properly placed and clamped in the jig, the drill will be located and guided by the bushings so that the critical dimensions on the workpiece will be correct. The right hole will be drilled in a vertical-spindle drill press (not running), and then the jig will be shifted (manually by the operator) to the right, and the left hole will be drilled. The box construction is rigid but open for chip removal.

25.8 TYPES OF JIGS

Jigs are made in several basic forms and carry names that are descriptive of their general configurations or predominant features. Several of these are illustrated in Figure 25-9.

A *plate jig* is one of the simplest types, consisting only of a plate that contains the drill bushings and a simple means of clamping the work in the jig or the jig to the work. In the latter case, wherein the jig is clamped to the work, the device is sometimes called a *clamp-on jig*. Such jigs are frequently used on large parts, where it is necessary to drill one or more holes that must be spaced accurately with respect to each other, or to a corner of the part, but that need not have an exact relationship with other portions of the work.

Channel jigs also are simple and derive their name from the cross-sectional shape of the main member. They can be used only with parts having fairly simple shapes.

Ring jigs are used only for drilling round parts, such as pipe flanges. The clamping force must be sufficient to prevent the part from rotating in the jig. *Diameter jigs* provide a means of locating a drilled hole exactly on a diameter of a cylindrical or spherical piece.

Leaf jigs derive their name from the hinged leaf or cover that can be swung open to permit the workpiece to be inserted and then closed to clamp the work in position. Drill bushings may be located in the leaf as well as in the body of the jig to permit locating and drilling holes on more than one side of the workpiece. Such jigs are called *rollover jigs* or *tumble jigs* when they require turning to permit drilling from more than one side.

Box jigs are very common, deriving their name from their boxlike construction. They have five fixed sides and a hinged cover or leaf, which opens to permit loading the workpiece, and a cam that locks the workpiece in place. Usually, the drill bushings are located in the fixed sides to ensure retention of their accuracy. The fixed sides of the box are usually fastened by means of dowel pins and screws so that they can be taken apart and reassembled without loss of accuracy. Because of their more complex construction, box jigs are costly, but their inherent accuracy and strength can be justified when there is sufficient volume of production. They have two obvious disadvantages: (1) it is usually more difficult to put work into them than into simpler types, and (2) there is a greater tendency for chips to accumulate within them. Figure 25-8 shows a box-type jig.

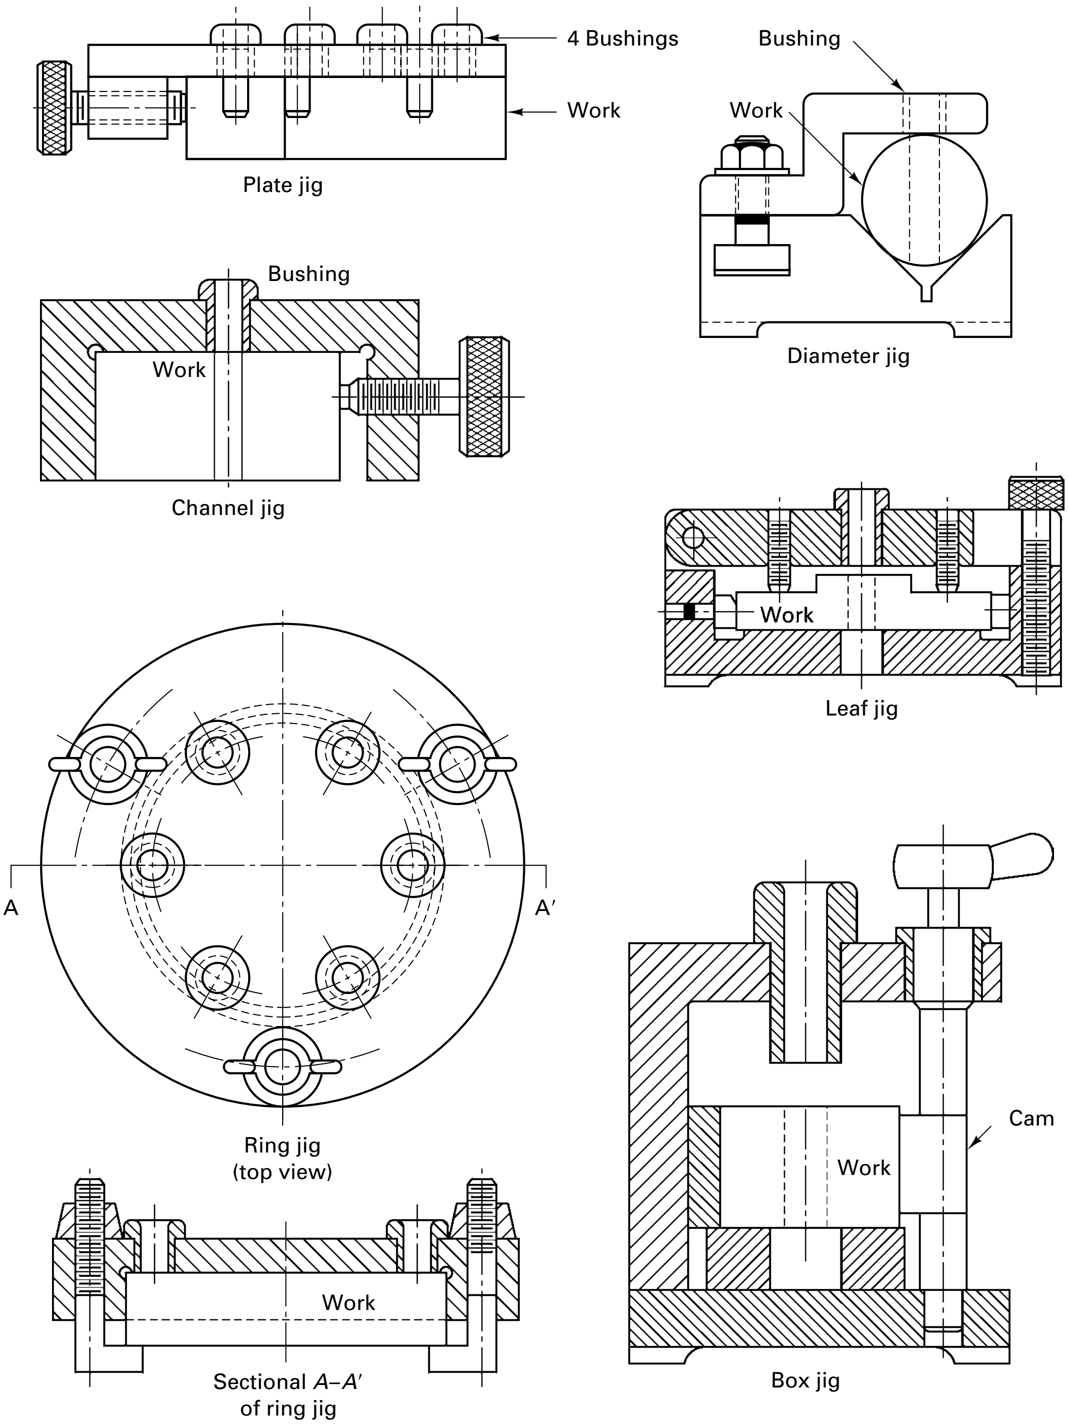

FIGURE 25-9 Examples of some common types of workholders—jigs.

Because jigs must be constructed very accurately and be made sufficiently rugged so as to maintain their accuracy despite the use (and abuse) to which they inevitably are subjected, they are expensive. Consequently, several methods have been devised to aid in lowering the cost of manufacturing jigs. One way to reduce this cost is to use simple, standardized plate and clamping mechanisms called *universal jigs* (Figure 25-10).

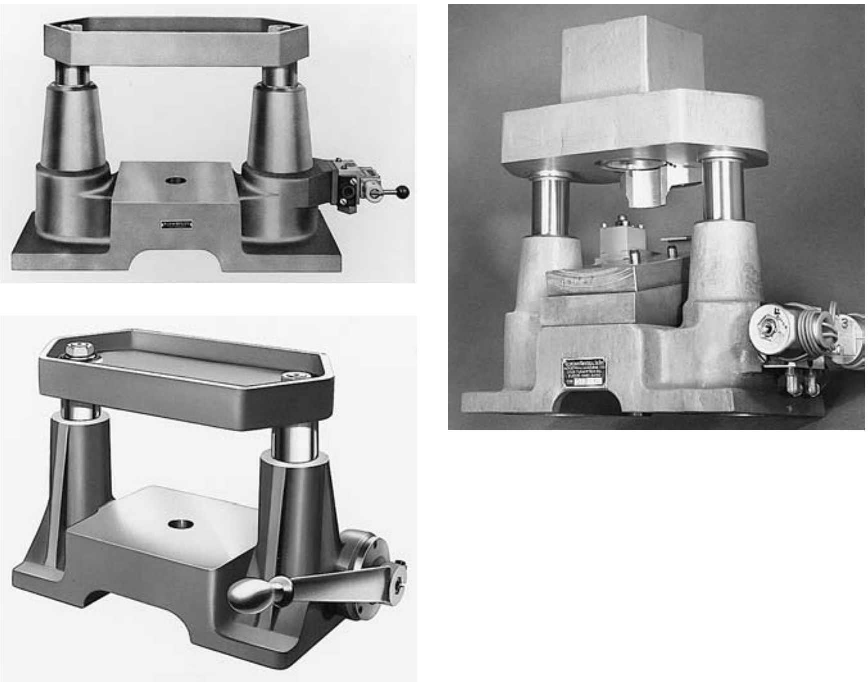

FIGURE 25-10 Two types of universal jigs are manual (bottom) and power-actuated (center). A completed jig (on the top) made from unit right below. *(Courtesy of Cleveland Universal Jig Division, The Industrial Machine Company.)*

These can easily be equipped with suitable locating buttons and drill bushings to construct a jig for a particular job. Such universal jigs are available in a variety of configurations and sizes, and because they can be produced in quantities, their cost is relatively low. However, the variety of work that can be accommodated by such jigs obviously is limited. While the drill bushing should be spaced far enough from the work to allow chips to escape without entering the bushing, when drilling into an angled surface, the bushing should be very close. Once the drill has penetrated to at least one-half of the drill diameter, the bushing should be retracted to provide chip clearance. Design of the drill jig must not obstruct coolant flow to where it is needed. Bushing length should be 1.75 to 2.5 times the drill diameter.

■ 25.9 CONVENTIONAL FIXTURES

Many examples of conventional fixtures have appeared in the text. Production milling, broaching, and boring processes as performed on NC machines, conventional equipment, or machining centers routinely use fixtures to locate and hold the part properly with respect to the cutting tools on the machine tool. Like cutting tools, tooling for workholding is sold separately and is not usually supplied by the machine tool builder. Traditionally, beginning with Eli Whitney, manufacturers have designed and built custom-made, dedicated fixtures. Because of the pressure of shorter production runs and smaller lot sizes, many companies are turning to modified fixturing approaches. The greatest advantage of these systems is that the fixture can be constructed quickly.

Perhaps the most common fixture uses the *vise* as its base element. Figure 25-11 shows a schematic and photo of a typical commercially available vise that can be adapted for use as a fixture. As shown, the vise jaws are readily modified to conform to the 3-2-1 location principle and provide adequate clamping forces for almost every machining operation. Four vises (also shown in Figure 25-11) can be mounted on a subplate for rapid insertion and location in the machine, or four vices can be mounted on a tombstone for milling parts in a CNC machine.

		Smooth jaws for parts with sensitive clamping surfaces.
		Grooved jaws (standard jaws) with smaller surface for increasing the specific surface pressure.
		Soft basic jaws for manufacturing your own special jaws. Mat: 21 Mn Cr 5 G.
		Spring leaf pull-down jaws for parts with rough clamping surfaces. Spring leaves press the workpiece against the supporting surfaces.
		Roller pull-down jaws for parts with sensitive clamping surfaces. Jaw components adjacent to the workpiece "put" the workpiece to the supporting surface.
		Prismatic jaws for the horizontal and vertical clamping of round and flat workpieces.
		Hold-down jaws for horizontal clamping of round workpieces.
		Swivel jaws for nonparallel clamping surface, compensation of conicity up to approx. 7.5 in.
		Compensation jaws I for multiple clamping of workpieces. Compensates differences in dimensions up to +3 mm.
		Compensation jaws II for workpieces with greatly varying surfaces. Compensated differences in dimensions up to +3 mm.
		Pull-down jaws for horizontal clamping of round workpieces. Roller jaw "pulls" workpiece to the supporting surface.

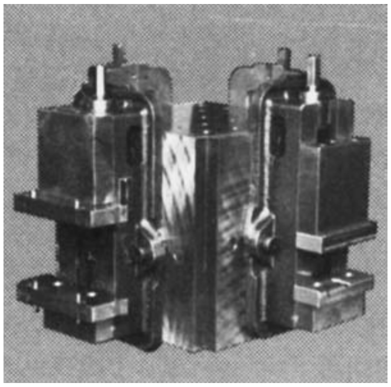

FIGURE 25-11 The conventional or standard vise (top left and right) can be modified with removable jaw plates to adapt to different part geometries. These vices can be integrated into milling fixtures (right middle and bottom).

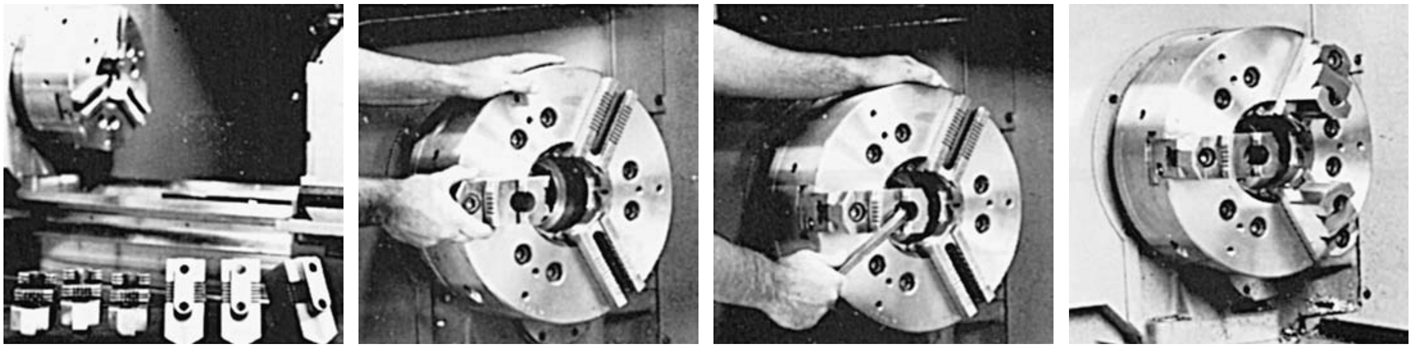
The chucks used in lathes are really general-purpose fixtures for rotational parts. Newer chuck designs have greatly improved their flexibility (the range of diameters the chuck can accommodate in a given setup and speed of setup). Figure 25-12 shows a complete change of top jaws for a three-jaw chuck being done in less than 5 minutes. The normal time for this part of the setup might exceed 15 minutes. New quick-change insert top jaws may even snap in by hand with no jaw nuts, keys, screws, or tools. Jaws that can be exchanged by robots can also be designed.



1. Pre-assembled Mini-System and top jaws.
2. Assembly being inserted into the Master Jaw.
3. Quickly retighten cap screw.
4. All 3 jaws changed in 5 minutes or less.

FIGURE 25-12 Quick-changing of the top jaws on a three-jaw chuck. *(Courtesy of Huron Machine Products.)*

Most producers of chucks use some variation of equation 25-1 to compute the maximum rpm rate at which the chuck can run:

$$S_m^2 = \frac{F_m}{3 \times (2.84 \times 10^{-5}) \times W \times D} \tag{25-1}$$

where

S_m = maximum rpm value at which gripping force equals $^1/_3\, F_m$

F_m = maximum rate gripping force, at rest (lb)

W = combined weight of jaws (lb)

D = distance from spindle centerline to center of jaw mass (in.)

Thus, with this equation, a 10-in. power chuck with a published rating F_m of 13,200 lb would retain one-third of its initial gripping force at 2507 rpm. (Check this calculation using $W = 8$ lb, $D = 3.1$ in.) The higher the rpm value, the greater the centrifugal force factor. This is an important factor in high-speed machining operations in which the part is rotating.

■ 25.10 MODULAR FIXTURING

Modular fixtures have all the same design criteria as those of conventional fixtures, plus one more—*versatility*. Modular fixture elements must be useful for a variety of machining applications and easily adaptable to different workpiece geometries. Individual fixture designs can be photographed or entered into a computer-aided design (CAD) library for future reference. After the job is done, the fixture itself can be dismantled and the elements returned to the toolroom. The erector-set approach uses either T-slot or dowel-pin designs. Figures 25-13 and 25-14 show two examples of modular fixturing. The designs begin with base plates. Elements for locating and clamping are added to the subplate. Rectangular, square, and round are the typical patterns for the subplates. Also shown are the typical components for modular fixturing systems used for mounting points, locators, attachments, and so on. The standard elements needed to construct the fixture include riser blocks, vee blocks, angle plates, cubes, box parallels, and the like. Smaller elements such as locator pins, supports, pads, and clamps are added to the subplate on the larger structural elements. Mechanical clamping devices are shown, but power-assisted clamps are available. The base and fixturing elements are made to tolerances of ±0.0002 to 0.0004 in. in flatness, parallelism, and size. Figure 25-14 shows a part in a dedicated fixture compared to a modular fixture. The dedicated fixture represents a capital investment that must be absorbed by the job and must be maintained after the job is complete. The modular fixture is disassembled and the elements reused later in fixtures for other parts. Modular fixtures are commonly used for prototype tooling and small-batch production runs. They are being incorporated more frequently into regular production as users gain confidence in this approach.

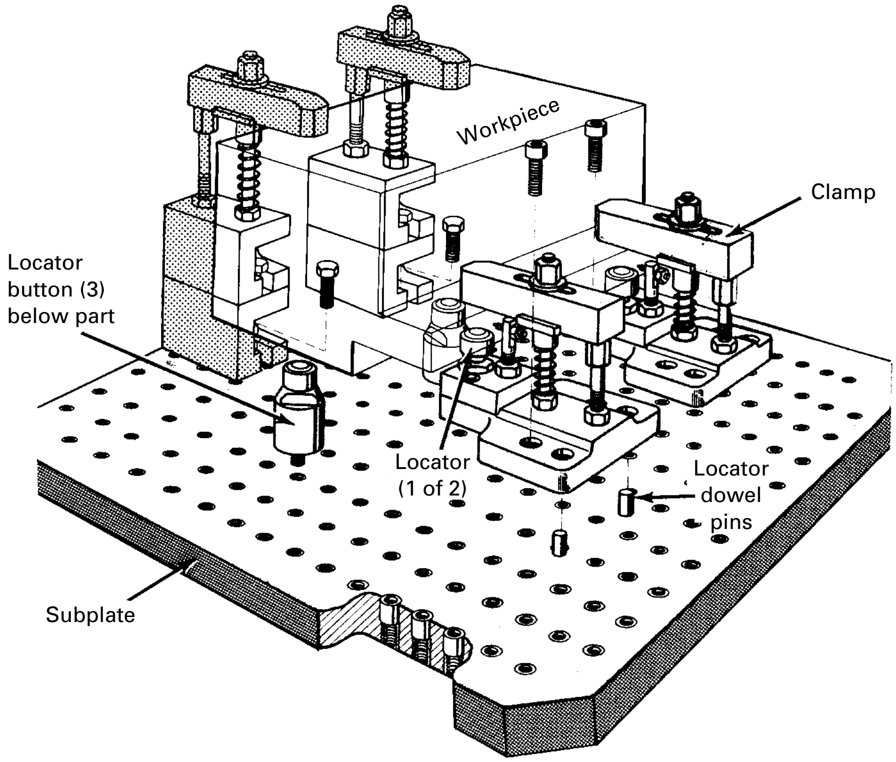


FIGURE 25-13 Modular fixturing begins with a subplate (grid base) and adds locators and clamps.

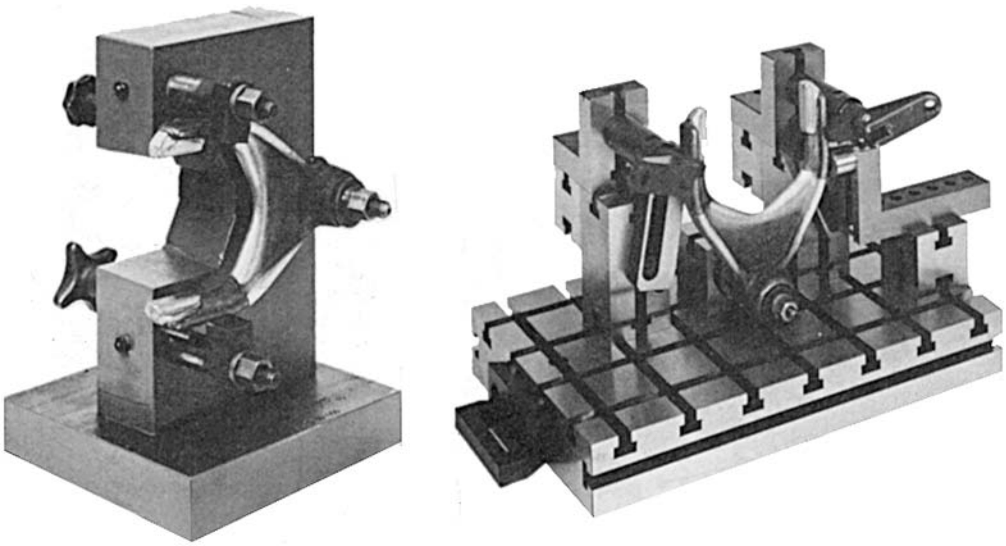

FIGURE 25-14 Dedicated fixture on the left versus modular fixture on the right. *(From* Manufacturing Engineering, *January, 1984.)*

■ 25.11 SETUP AND CHANGEOVER

Every part coming out of the workholder should be the same, resulting in interchangeable parts. But what about the first part? Does it meet specifications? What about the initial setup of the workholder into the machine tool? In many cases, the setup operation takes hours and the machine is not producing anything during this time. Rapid exchanges of workholding devices is a key technique in modern manufacturing systems. (See Shingo, 1985 for more discussion of the elimination of setup and SMED.) Reducing setup times permits shorter production runs (smaller lot sizes). Do not confuse initial setup (of workholders) with part loading and unloading or tool changing. The trick with initial setup is to do it quickly and to get the first part out of the process as a good part, with no adjustment of the machine, the tooling, or the workholder. Quick tool and die exchange is a critical component in the strategy for the factory with a future.

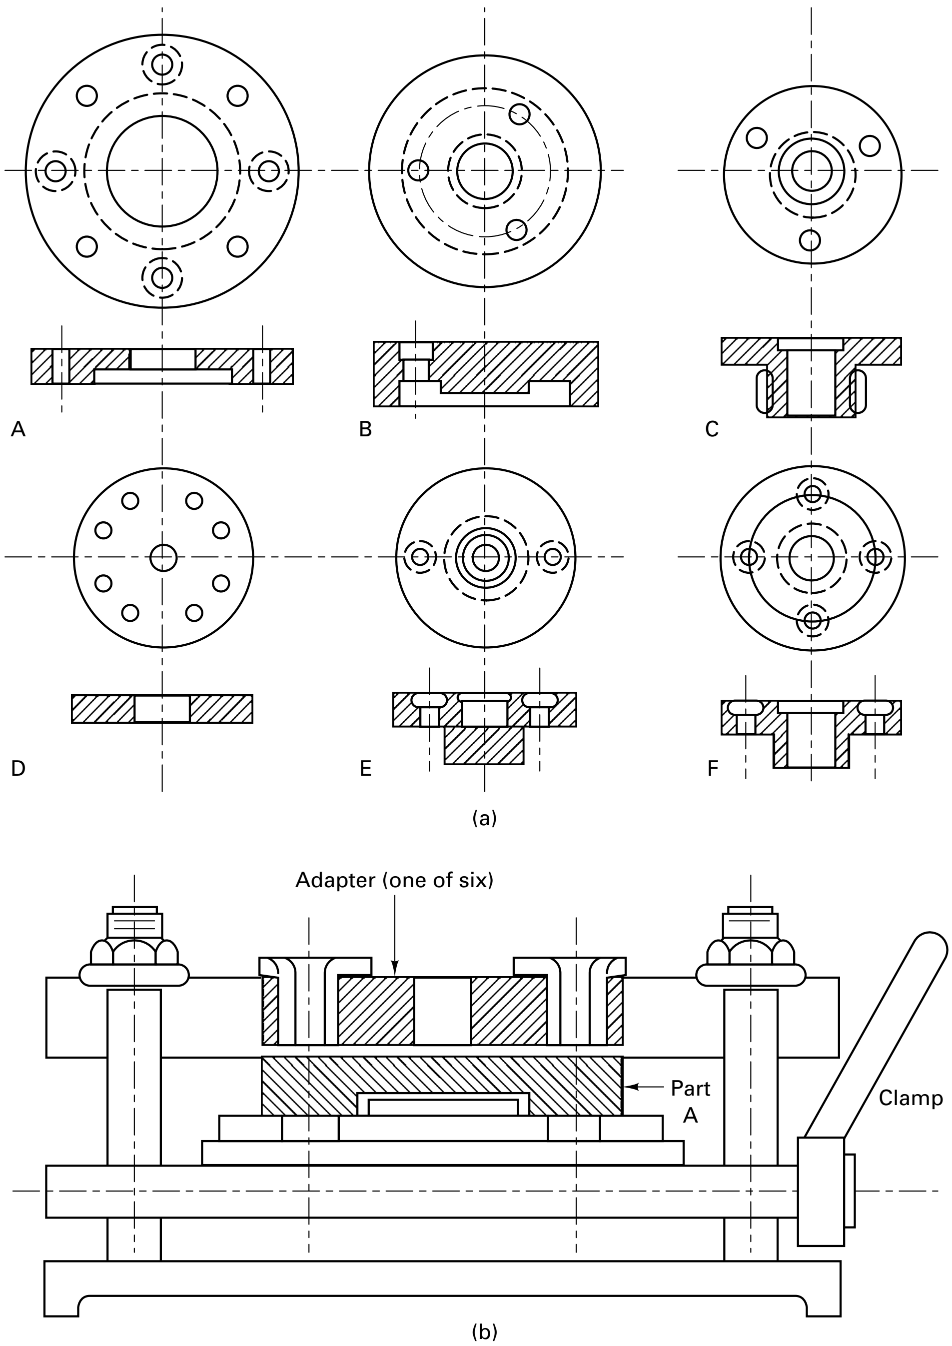

FIGURE 25-15 Master jig designed for a family of similar components. (a) Part family of rounds plates (six parts, A–F); (b) group jig for drilling, showing adapter and part A.

Another approach to rapid setup is shown in Figure 25-15, where instead of six different jigs, a master jig is made (also called a group jig) for a family of similar components and then a set of adapters is made that customizes the jig for each part in the part family. This concept of group jigs and fixtures originated from the group technology (GT) concept for master jigs as a method to form cellular manufacturing systems by determining a family of parts where an imaginary part, called the composite part, is designed that has all the key features of all the parts in the family. In other words, the composite part is an envelope, the shape of which encompasses the shapes of all the parts in the family. The theory is that if the tooling is designed for the composite part, any part that fits within the envelope could be machined without any tooling changes. This part is used for designing the workholder. The workholding devices should be able to accommodate all the parts within the parts family. For manufacturing cells, the workholders will also have to compensate for variation in cutting forces, centrifugal forces, and so on. Group workholders are designed to accept every part-family member, with or without adapters, that accommodate minor part variations.

INTERMEDIATE JIG CONCEPT

One way to achieve rapid fixture exchange is to employ the intermediate jig concept. This means that the workholding devices are designed so that they all appear the same to the machine tool but different to the parts. This usually requires one to construct intermediate jig or fixture plates to which the jig or fixture is attached. The jigs or fixtures are all different, but the plates are all identical.

The cassette tape for your VCR is an example of an intermediate workholder. To the VCR, every cassette appears to be the same and can be quickly loaded and unloaded with one handling—that is, one touch. From the outside, every tape appears to be the same, but on the inside, every tape is different. If you think about the workholding devices in terms of the intermediate jig concept, you can quickly achieve one-touch setups.

Figure 25-16 shows an example of the *intermediate jig concept*, applied to lathes and chucks. An adapter or intermediate fixture is bolted to the lathe's spindle and is a permanent part of the machine tool. The intermediate fixture will accept mating chucks that have been preset for the workpiece prior to insertion. Different chuck designs mount interchangeably on the common actuator. This method greatly reduces setup time and permits the operator to perform chuck maintenance and retooling (setup) while the machine is running. The chucks can be exchanged automatically.

Quick-change fixtures for CNC milling machines and machining centers (using the intermediate jig concept) are now available commercially.

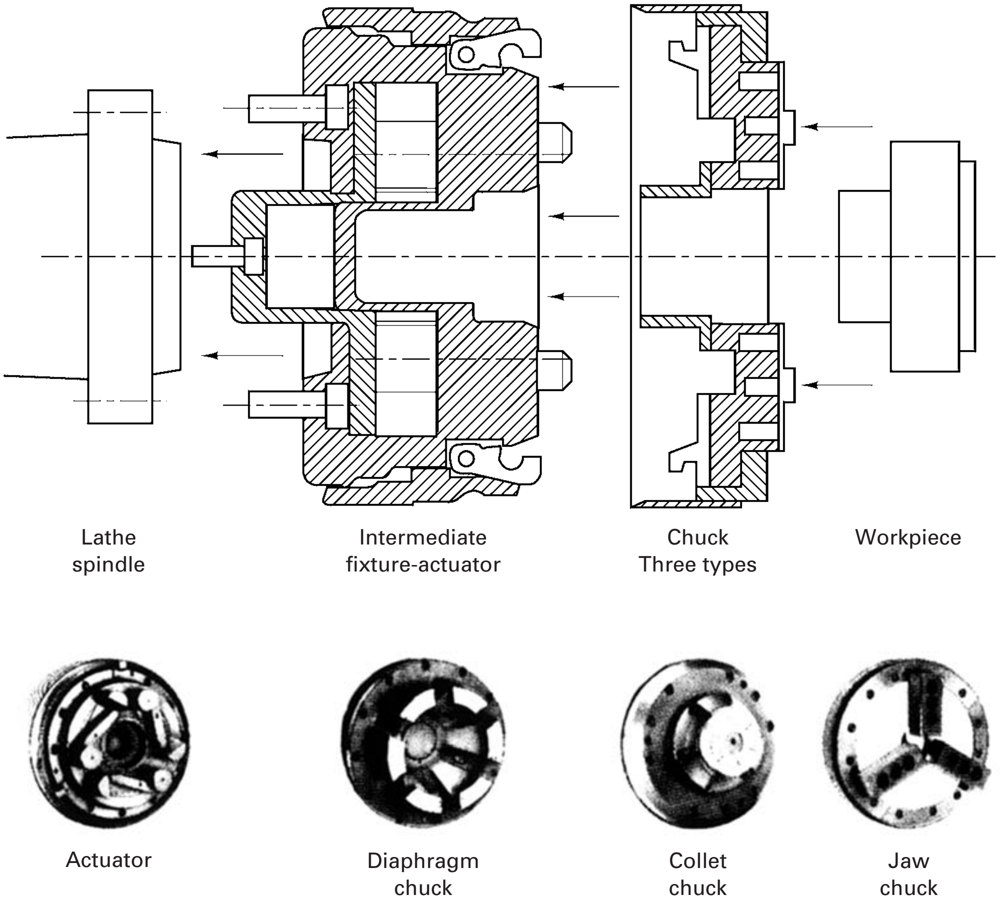

FIGURE 25-16 Example of the intermediate jig concept applied to lathe chucks. The actuator is mounted on the lathe and can quickly adapt to three different chuck types. *(Courtesy of Sheffer Collet Company.)*

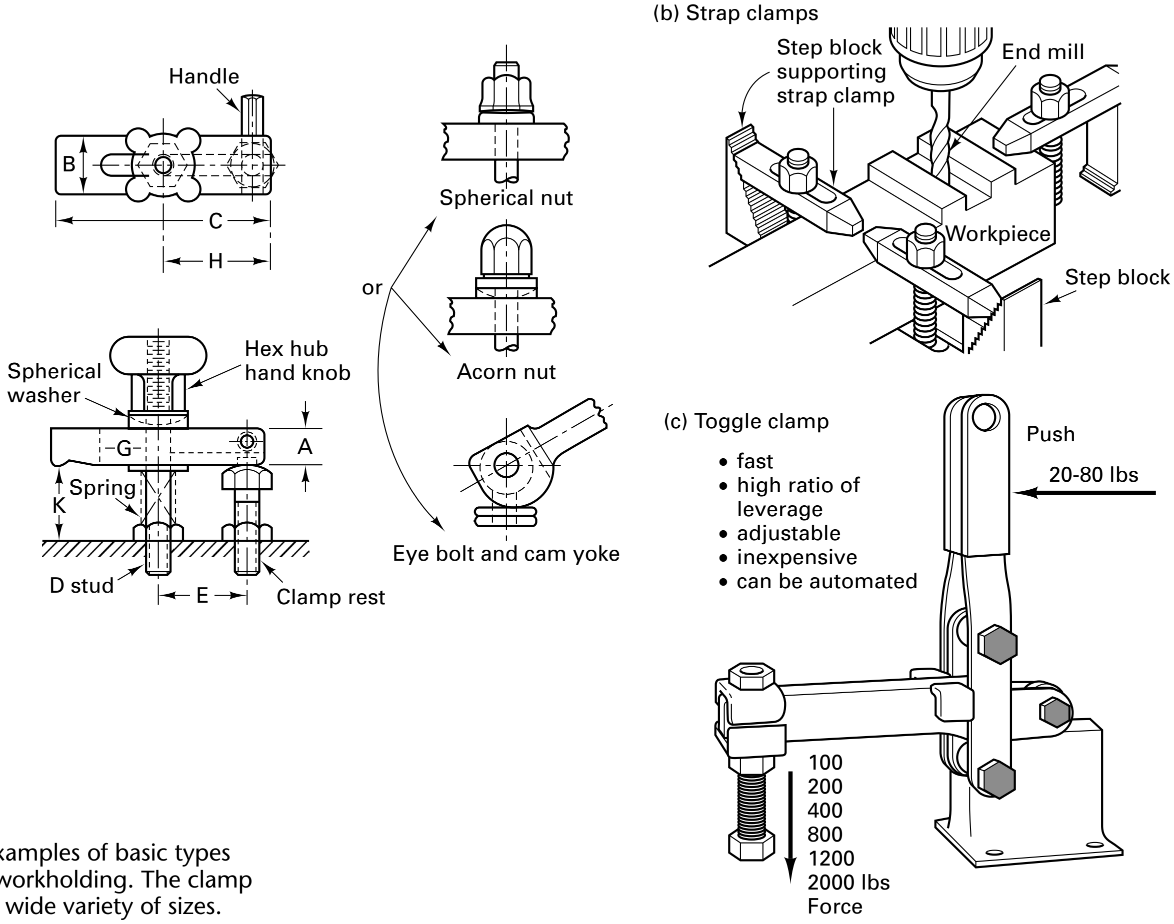

FIGURE 25-17 Examples of basic types of clamps used for workholding. The clamp elements come in a wide variety of sizes.

■ 25.12 CLAMPS

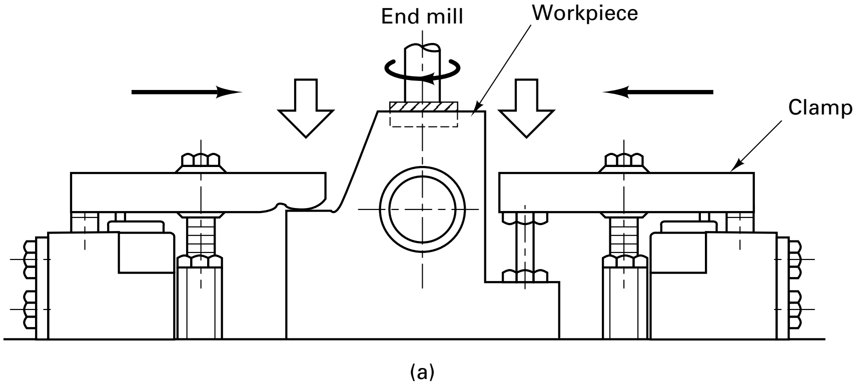
When designing a jig or fixture, there are many choices to be made regarding the clamps. Manual clamps, which include screw, strap, swing, edge, cam, toggle, and C-clamps, each with certain strengths and weaknesses, are usually cheaper but slower. In Figure 25-17 typical types of clamps that are used in fixtures are shown. The *strap clamp* comes in many forms and sizes and is simple, low cost, and flexible. The force can be applied by a hand knob, a cam, or a wrench turning down a nut. A conventional *toggle clamp* accommodates only small thickness variation from part to part yet provides an excellent, consistent clamping force.

Power-actuated clamps (shown in Figure 25-18) provide more consistent clamping forces than do manual clamps, especially in applications that promote operator fatigue. The higher cost must be weighed against the capability for consistent and repeatable operation, automatic adjustment of holding forces, remote actuations, and automating sequencing of clamping actions. *Extending clamps* operate in a manner similar to that of a manual clamp-strap assembly. They extend forward horizontally, then clamp down. *Edge clamps* have a very low profile. They clamp down and forward simultaneously.

■ 25.13 OTHER WORKHOLDING DEVICES

ASSEMBLY JIGS

Because *assembly jigs* usually must provide for the introduction of several component parts and the use of some type of fastening equipment, such as welding or riveting, they commonly are of the open-frame type. Such jigs are widely used in automobile body welding and aircraft assembly. Large jigs of the type are shown in Figure 25-19 are used for the assembly and usually feature automatic clips. This jig is constructed mainly of reinforced concrete.



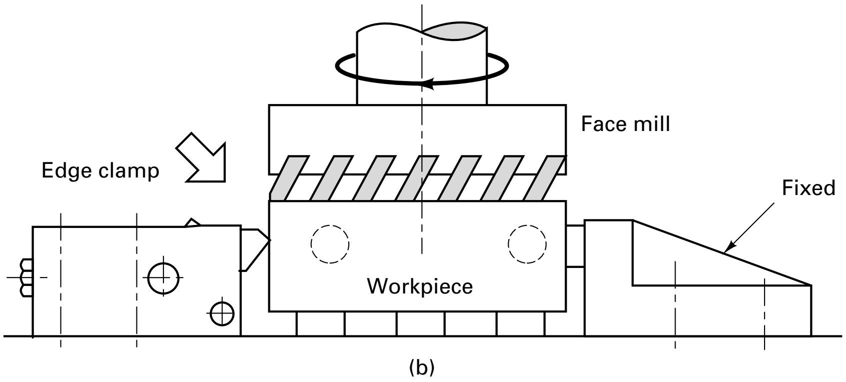


FIGURE 25-18 Examples of power-clamping devices: (a) extending clamp; (b) edge clamp.

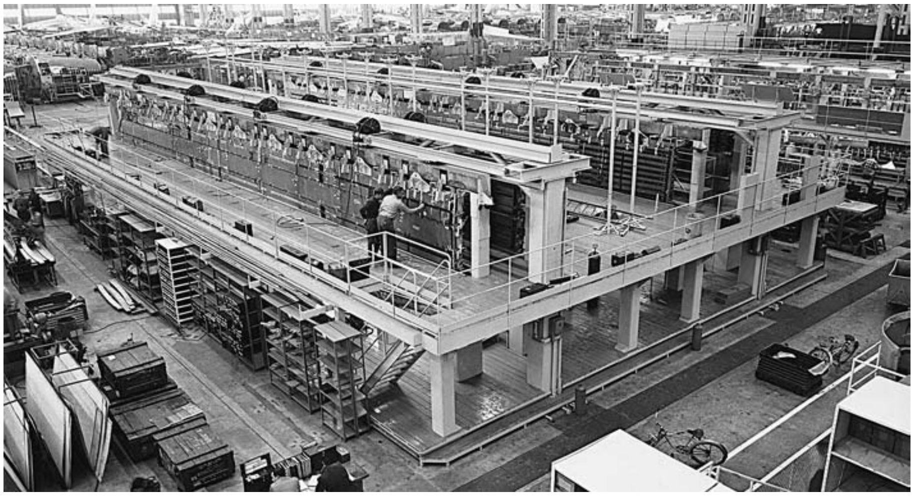

FIGURE 25-19 Example of large assembly jig for an airplane wing. The body of the wing and flap are held in the correct location with each other and then the flap is mechanically attached.

MAGNETIC WORKHOLDERS

Because of the light cuts and low cutting forces, workpieces can be held in a different manner on surface grinders than on other machine tools. *Magnetic chucks* are used for ferromagnetic materials. To obtain high accuracy, it is desirable to reduce clamping forces and distribute them over the entire area of the workpiece. Also, grinding is frequently done on quite thin or relatively delicate workpieces, which would be difficult to clamp by normal methods. In addition, there is often the problem of grinding a number of small, duplicate workpieces. Magnetic chucks solve all these problems very satisfactorily. Magnetic chucks are available in disk or rectangular shapes. Dry-disk rectifiers are used to provide the necessary direct-current power. Some magnetic chucks utilize permanent magnets, as shown in Figure 25-20, and can be tilted so that angles can be ground. Magnetic chucks provide an excellent means of holding workpieces provided that the

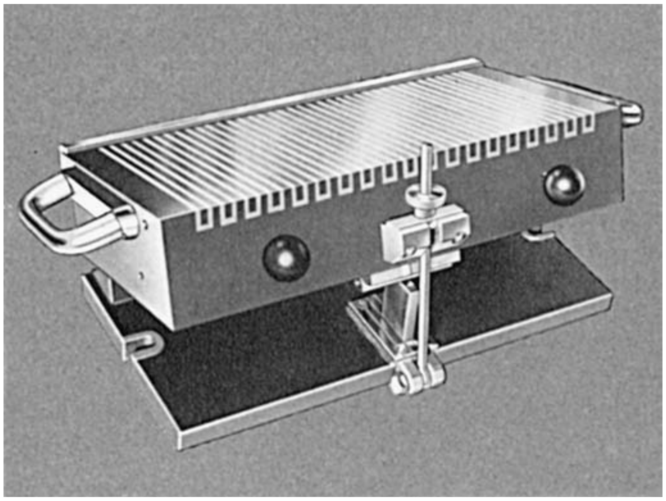

FIGURE 25-20 Example of magnetic chuck. *(Courtesy of O. S. Walker.)*

cutting or inertial forces are not too great. The holding force is distributed over the entire contact surface of the work, the clamping stresses are low, and therefore there is little tendency for the work to be distorted. Consequently, pieces can be held and ground accurately. Also, a number of small pieces can be mounted on a chuck and ground at the same time. Magnetic chucks provide great part-to-part repeatability because the holding power from one part to the next is the same. Initial setup is usually fast, simple, and relatively inexpensive. Parts loading and unloading is also relatively easy.

It often is necessary to demagnetize work that has been held on a magnetic chuck. Some electrically powered chucks provide satisfactory demagnetization by reversing the direct current briefly when the power is shut off.

ELECTROSTATIC WORKHOLDERS

Magnetic chucks can be used only with ferromagnetic materials. Electrostatic chucks can be used with any electrically conductive material. This principle (Figure 25-21) directs that work be held by mutually attracting electrostatic fields in the chuck and the workpiece. These provide a holding force of up to 20 psi (21,000 Pa). Nonmetal parts can usually be held if they are flashed (i.e., coated) with a thin layer of metal. These chucks have the added advantage of not inducing residual magnetism in the work.

VACUUM CHUCKS

Vacuum chucks are also available. In one type, illustrated in Figure 25-22, the holes in the work plate are connected to a vacuum pump and can be opened or closed by means of valve screws. The valves are opened in the area on which the work is to rest. The other type has a porous plate on which the work rests. The workpiece and plate are covered

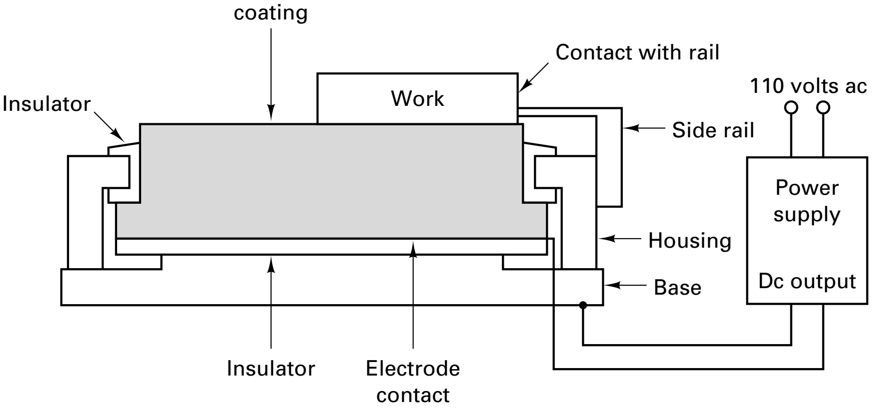

FIGURE 25-21 Principle of electrostatic chuck.

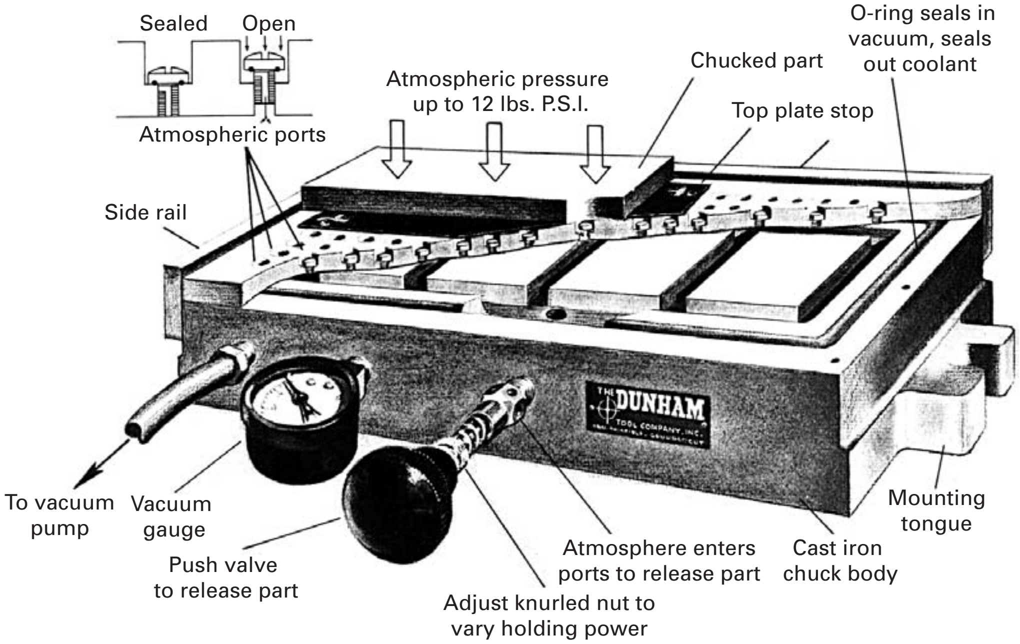

FIGURE 25-22 Cutaway view of a vacuum chuck. *(Courtesy of Dunham Tool Company, Inc.)*

with a polyethylene sheet. When the vacuum is turned on, the film forms around the workpiece, covering and sealing the holes not covered by the workpiece and thus producing a seal. The film covering the workpiece is removed or the first cut removes the film covering the workpiece. Vacuum chucks have the advantage that they can be used on both nonmetals and metals and can provide an easily variable force. Magnetic, electrostatic, and vacuum chucks are used for some light milling and turning operations.

As shown in Figure 25-23, T-slots are provided on milling machine tables so that workpieces can be clamped directly to the table. More often various workholding devices, called *vices* or *fixtures*, are utilized. Smaller workpieces are usually held in a vise mounted on the table. Fixtures designed to specifically hold a part in the correct location with respect to the tool are used for larger volumes. Fixtures reduce the time it takes to put the part in the machine and assure repeatable location with respect to the cutting tools. Fixtures provide clamping forces that counteract the cutting forces.

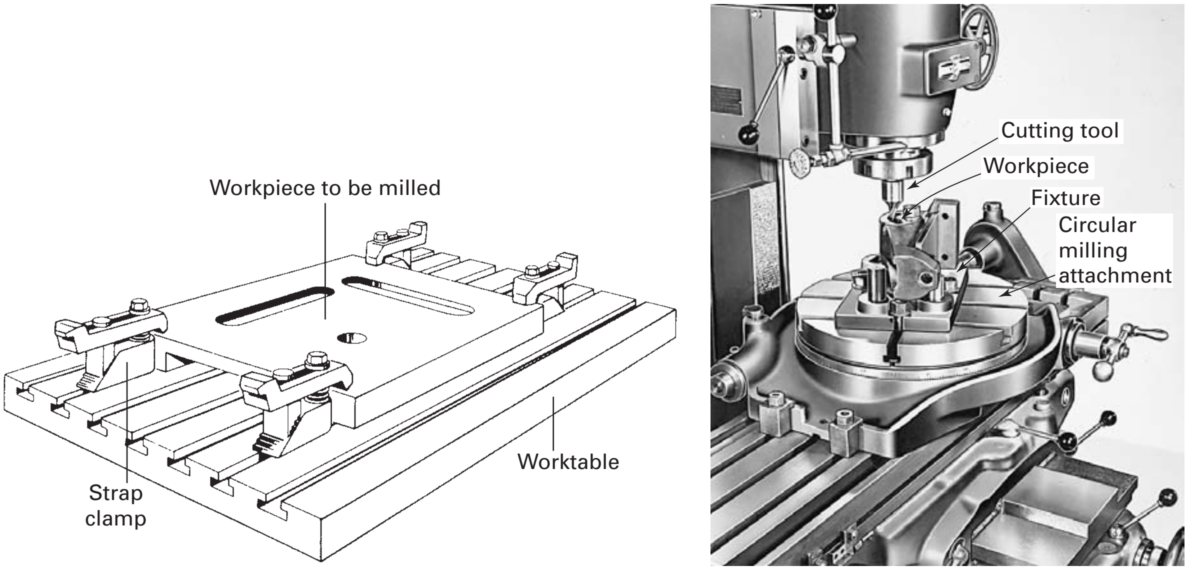

FIGURE 25-23 While the work can be clamped directly to the milling machines table (on the left), the workpiece on the right is located in a fixture mounted in a circular attachment located on the table, so a circular slot can be milled in the workpiece.

25.14 ECONOMIC JUSTIFICATION OF JIGS AND FIXTURES

As discussed previously, workholders are expensive, even when designed and constructed by using standard components. Obviously, their cost is a part of the total cost of production, and one must determine whether they can be justified economically by the savings in labor and machine cost and improvements in quality that will result from their use. Often it is only through the use of such devices that the design specifications can be met and sustained from part to part. To determine the economic justification of any special tooling, the following factors must be considered:

1. The cost of the tooling
2. Interest or profit charges on the tooling cost
3. The savings resulting from the use of the tooling; can result from reduced cycle times or improved quality or lower-cost labor
4. The savings in machine cost due to increased productivity
5. The number of units that will be produced using the tooling

The economic relationship between these factors can be expressed in the following manner:

$$\text{savings per piece (exclusive of tooling costs)} \geq \text{additional cost per piece}$$

$$\left\{\begin{matrix}\text{total cost per piece}\\ \text{without tooling}\end{matrix}\right\} - \left\{\begin{matrix}\text{total cost per piece}\\ \text{using tooling}\\ \text{(exclusive of tooling cost)}\end{matrix}\right\} \geq \text{tooling cost per piece}$$

$$\overbrace{\begin{matrix}\text{labor cost}\\ \text{per piece}\\ \text{without}\\ \text{tooling}\end{matrix} + \begin{matrix}\text{machine and}\\ \text{overhead cost}\\ \text{per piece}\\ \text{without tooling}\end{matrix}} - \overbrace{\begin{matrix}\text{labor cost}\\ \text{per piece}\\ \text{with}\\ \text{tooling}\end{matrix} + \begin{matrix}\text{machine and}\\ \text{overhead cost}\\ \text{per piece}\\ \text{with tooling}\end{matrix}} \geq \overbrace{\begin{matrix}\text{cost}\\ \text{of}\\ \text{tooling}\end{matrix} + \begin{matrix}\text{interest on}\\ \text{tooling cost}\end{matrix}}$$

$$[(R)(t) + (R_m)(t)] - [R_t)(t_t) + (R_m)(t_t)] \geq \frac{C_t + (C_t/2)(n)(i)}{N} \qquad (25\text{-}2)$$

where

R = labor rate per hour, without tooling

R_t = labor rate per hour, using tooling

t = hours per piece, without tooling

t_t = hours per piece, using tooling

R_m = machine cost per hour, including all overhead

C_t = cost of the special tooling

n = number of years tooling will be used

i = interest rate (or what invested capital is worth)

N = number of pieces that will be produced with the tooling

Equation 25-2 can be expressed in a simpler form:

$$(R + R_m)t - (R_t + R_m)t_t \geq \frac{C_t}{N}\left(1 + \frac{n \times i}{2}\right) \qquad (25\text{-}3)$$

This equation assumes straight-line depreciation and computes interest on the average amount of capital invested throughout the life of the tooling.[1] When the time over

---

[1] For the use of more sophisticated economic analysis, see C. S. Park, *Contempory Engineering Economics*, 2nd ed., New York, Wiley, 1999.

which the tooling is to be used is less than one year, companies often do not include an interest cost. If this factor is neglected, the right-hand term of equation 25-3 reduces to C_t/N.

The equations assume that the material cost will be the same regardless of whether or not special tooling is used. This is not always true. Although these equations are not completely accurate for all cases, they are satisfactory for determining tooling justification in most cases, because the life of tooling for machine tools seldom exceeds five years and often does not exceed two years. The equation does not include the cost of poor quality. This can be included by estimating the decrease in the number of defective parts when the workholder is used versus when it is not used.[2]

The following example illustrates the use of equation 25-3 to determine tooling justification for a dedicated jig. In drilling a series of holes on a radial drill, the use of a drill jig will reduce the time from $^1/_2$ hour per piece to 15 minutes per piece. If a jig is not used, a machinist, whose hourly rate is \$18/hr, must be used. If the jig is used, the job can be done by a machinist whose rate is \$12/hr. The hourly rate for the radial drill is \$32/hr.

The cost of making the jig would include \$350 for design, \$150 for material, and 50 hours of toolmaker's labor, which is charged at the rate of \$22/hr to include all machine and overhead costs in the toolmaking department. Investment capital is worth 16% to the company. It is estimated that the jig would last three years and that it would be used for the production of 300 parts over this period. Is the jig justified?

The cost of the jig, C_t, is estimated to be

$$C_t = \$350 + \$150 + \$150 + \$22 \times 50\text{hr} = \$1{,}600$$

Substituting the values given in equation 25-3, we find:

$$(18 + 32)0.5 - (12 + 32)0.25 \geq \$\frac{1600}{300}\left(1 + \frac{3 \times 0.16}{2}\right)$$

$$\text{or } 14.00 \cong 13.76$$

So this jig is not justified based on cost savings.

One could also ask how many parts would have to be produced with the jig to break even (i.e., increased costs just equal savings). By omitting the value 300 in the solution above and solving for N, it is found that at least 1627 pieces would have to be produced annually with the jig for it to break even.

This analysis assumes that the time (of the people and machines) saved by the use of the special tooling can be used for other productive work. If this is not the case, the cost analysis should be altered to take this important fact into account. Otherwise, the tooling justification may be substantially in error.

The application of group technology, NC machines, and lean manufacturing techniques may eliminate the need for designing and building a new jig or fixture every time a new part is designed. New measures of manufacturing productivity that include terms for quality and flexibility are being developed.

---

Review Questions

1. What are the two primary functions of a workholding device?
2. What distinguishes a jig from a fixture?
3. An early treatise defined a jig as "a device that holds the work and guides a tool." Why was this definition incorrect?
4. What modifications do you need to make to an ordinary vise so it can be a fixture?
5. What basic criteria should be considered in designing jigs and fixtures?
6. In any part drawing, what are the critical surfaces of a part (i.e., what makes a part surface critical)? (This question requires an understanding of basic part drawings.)
7. What difficulties can result from not keeping clamping stresses low in designing jigs and fixtures?
8. Explain the 3-2-1 concept for workpiece location in a workholder on a machine tool.
9. Which of the basic design principles relating to jigs and fixtures would most likely be in conflict with the 3-2-1 location concept?
10. What are two reasons for not having drill bushings actually touching the workpiece? How many of the designs shown in this chapter violate this rule? It is not uncommon to have conflicts and trade-offs in fixture design situations.
11. Why does the use of down milling often make it easier to design a milling fixture than if up milling were used?
12. Name another example of the intermediate workholder concept aside from the video cassette.
13. A large assembly jig for an airplane-wing component gave difficulty when it rested on four-point support. The assembled wing components were not consistent in shape. It was satisfactory when only three supporting points were used. Why?
14. Explain why the use of a given fixture may not be economical when used with one machine tool but may be economical when used in conjunction with another machine tool.
15. What are rollover jigs, and what advantages do they offer?
16. In the clamps shown in Figure 25-17, what is the purpose of the spherical washer?
17. What are other common types of clamps?
18. What is the purpose of dimensioning the strap-clamp assembly in Figure 25-17 with letters?
19. Figure 25-8 showed the part sitting on locator buttons. Why not have the part rest on the flat plate?
20. In Figure 25-8, why aren't there three points put on the x-plane, two points on the z-plane, and one point on the y-plane?
21. Which set of locators in Figure 25-8 establishes the A dimension on the part?
22. To prepare the workpiece shown in Figure 25-8, which surface would you have milled first—the bottom, the back, or the front?
23. For the part shown in Figure 25-8, why don't you drill the holes first, then mill? Why mill at all?
24. Notice that the holes in the part in Figure 28-8 need to be countersunk after they are drilled. How must the jig be designed to put the countersinks on the mounting holes while the part is in the jig, or would this operation be done afterward?

Problems

1. Using the following values, determine the number of pieces that would have to be made to justify the use of a jig costing $3000.

   $R = \$5.75$
   $R_t = \$4.50$
   $t_t = 1\,{}^1\!/_4$
   $t = 2\,{}^1\!/_2$
   $I = 10\%$
   $R_m = \$4.50$
   $N = 3$

2. Suppose in the sample problem at the end of this chapter that modular fixturing is used, which reduces the toolmaker's labor to 4 hours and the design cost to $100 (4 hours at $25 per hour), and that the material cost (modular elements) for the subplate structural elements, clamps, and so on was $600. What is the break-even quantity for a modular fixture? (*Note:* The modular fixture is used for the job, then disassembled and returned to the tool room. The parts are reused in other workholders.)
3. Suppose the leaf jig in Figure 25-A could be improved by replacing the screw clamp with swing clamps. See Figure 25-A. Many things are needed to be able to cost justify the improvement in the jig. This problem requires that the engineer estimate or determine the following:
   1. How much time is saved with a swing clamp (in the loading and unloading) cycle?
   2. How much does a swing clamp cost?
   3. How much will it cost to modify the existing jig?

   Currently, for this job, the machining cycle time to drill the hole is 30 sec, the unload/load time is 30 sec, the operator is getting $12/hr, and the machine cost is $30/hr.
4. Examine Figure 25-23. The part has a circular slot in the top. How else could you produce this slot?

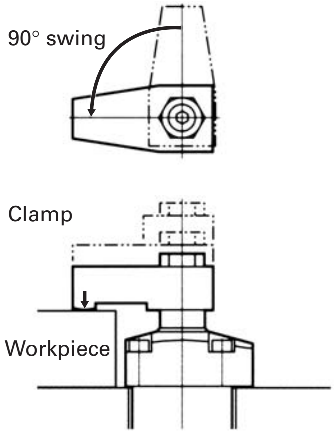

FIGURE 25-A Forces on a 1500-lb work piece produced by face milling.

Chapter 25 CASE STUDY

Fixture versus No Fixture in Milling

Design engineering has sent down to manufacturing engineering a drawing that calls for a surface $4\frac{1}{2}$ inches wide by 10 in. long to be rough milled with a depth of cut of 0.30 in.

A 16-tooth cemented carbide face mill 150 mm (6 in.) in diameter has been selected for the job. The material is medium hard cast iron (220 to 260 Bhn).

This surface is to be milled on a large number of identical pieces. The estimated time to unload and load a piece in a fixture is 0.30 minutes. Here are three possible choices of machine setup you could use to do this job.

1. Face milling on a vertical spindle milling machine (NO fixture, 6 minutes to remove part from table and bolt up a new part).
2. String milling with three pieces 0.6 in. apart in a fixture.
3. Index base milling (0.15 minute required to index the base) on a vertical single spindle mill where the operator is unloading/loading the index table while the alternate piece is being machined (2 fixtures required).

Which arrangement should be selected based on your estimated operation time per piece and your estimated fixture cost per piece?

CHAPTER 26

NUMERICAL CONTROL (NC) AND THE A(4) LEVEL OF AUTOMATION

26.1 INTRODUCTION

The first numerically controlled (NC) machine tool was developed in 1952 at the Massachusetts Institute of Technology (MIT). It had three-axis positional feedback control and is generally recognized as the first NC machine tool. By 1958, the first NC *machining center* was being marketed by Kearney and Trecker. A machining center was a compilation of many machine tools capable of performing many processes (milling, drilling, tapping, and boring), as shown in Figure 26-1. This NC machine had a tool changer and could automatically change tools. Almost from the start, computers were needed to help program these machines. Within 10 years, NC machine tools had become computer numerical control (CNC) machine tools with onboard microprocessors and could be programmed directly.

With the advent of the NC type of machine (and, more recently, programmable robots), two types of automation were defined. *Hard* or *fixed automation* is exemplified by transfer machines or automatic screw machines controlled by a mechanical cam. *Flexible* or *programmable automation* is typified by CNC machines or robots that can be taught or programmed externally by means of computers. The control is in computer software rather than mechanical hardware.

You may not be familiar with the concept of feedback control, where some aspect (usually position) of the process is measured using a detection device (sensor). This information is fed back to an electronic comparator, housed in the machine control unit (MCU), which makes comparisons with the desired level of operation. If the output and input are not equal, an error signal is generated and the table is adjusted to reduce the error.

For a milling machine, Figure 26-2 shows the difference between an open-loop machine and a closed-loop machine, with feedback provided on the location of the table and the part with respect to the axis of the spindle of the cutting tool. Three position control schemes are shown.

In CNC turning machines, the feedback is on the tool tip with respect to the rotating part creating tool paths. Figure 26-3 shows how a part can be turned (machined) from a round bar in a CNC lathe. A program is written that directs the machine to execute the necessary roughing and finishing passes.

$$\text{number of rough passes} = \frac{\text{stock diameter} - \text{minimum diameter} + \text{finish}}{\text{depth of cut} \times 2}$$

In this case, eight roughing passes and one finishing cut were specified.

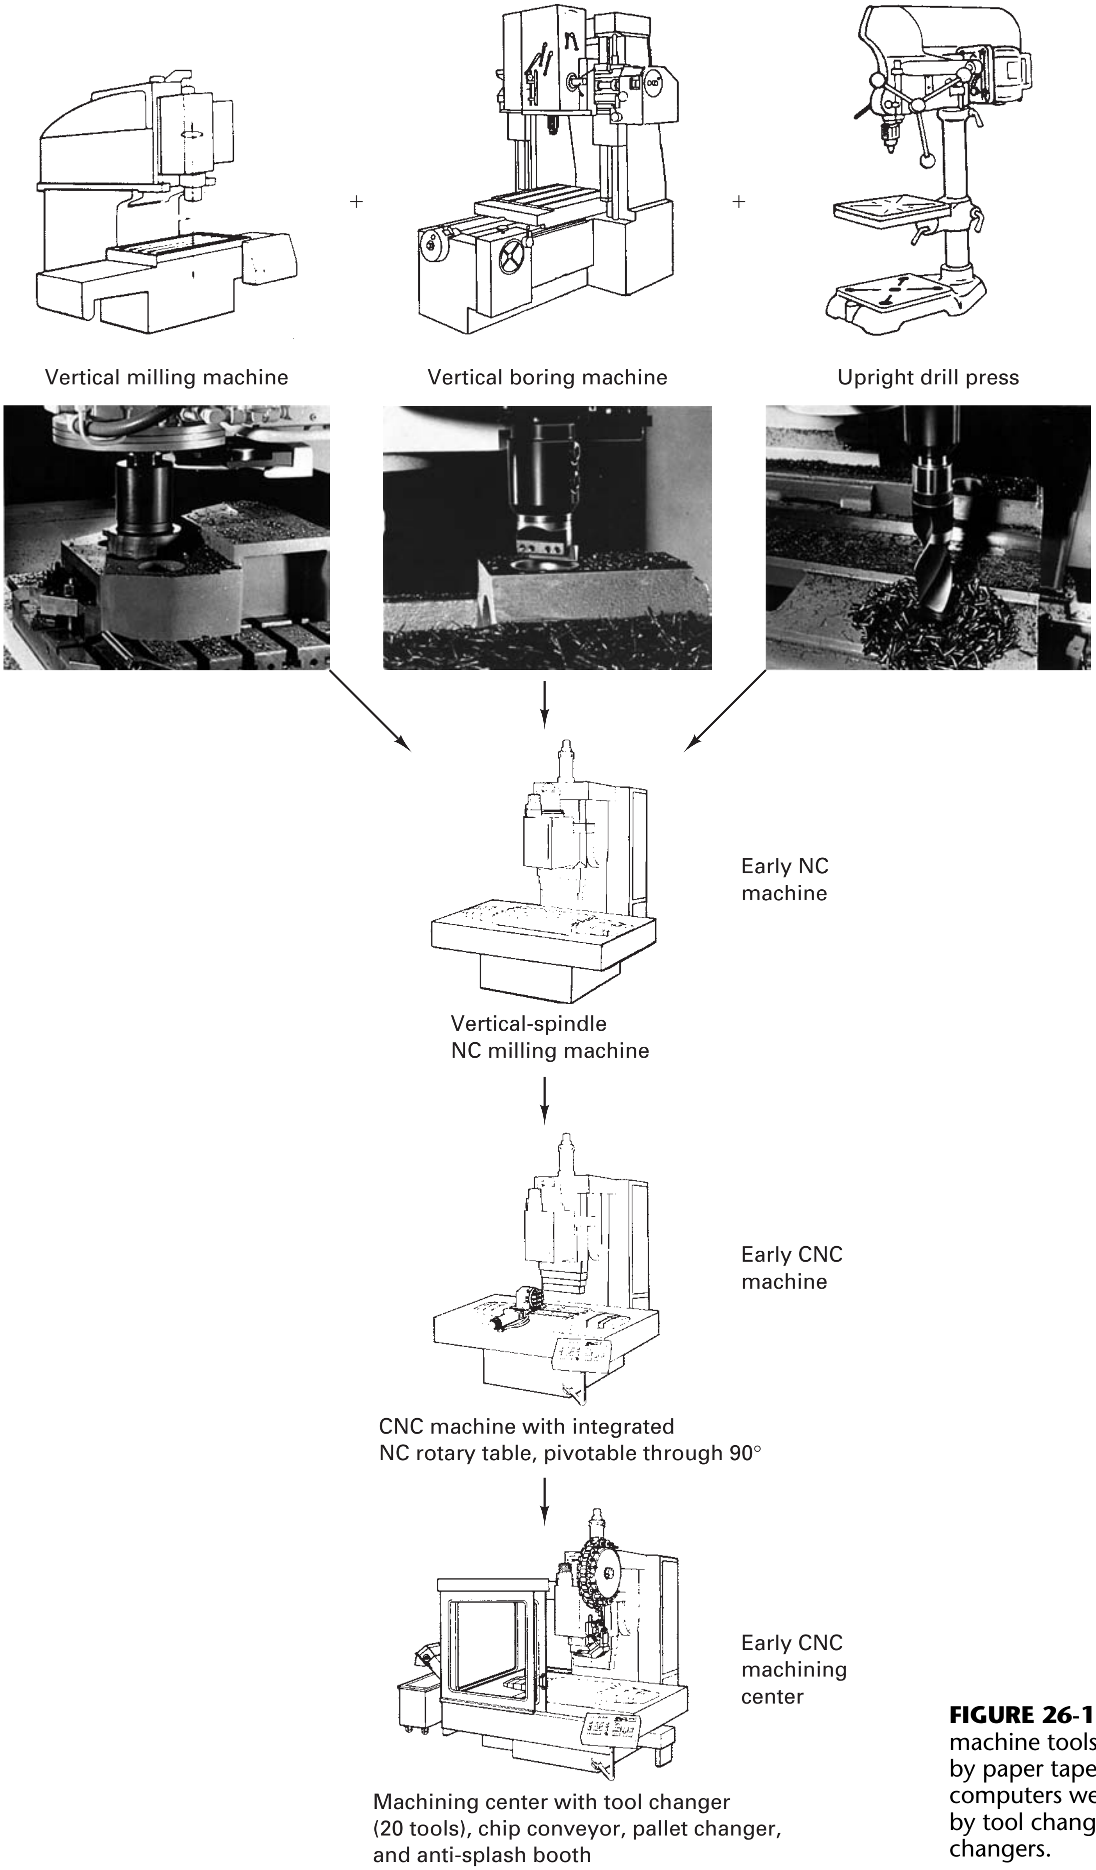

FIGURE 26-1 Early NC machine tools were controlled by paper tape. Soon onboard computers were added, followed by tool changers and pallet changers.

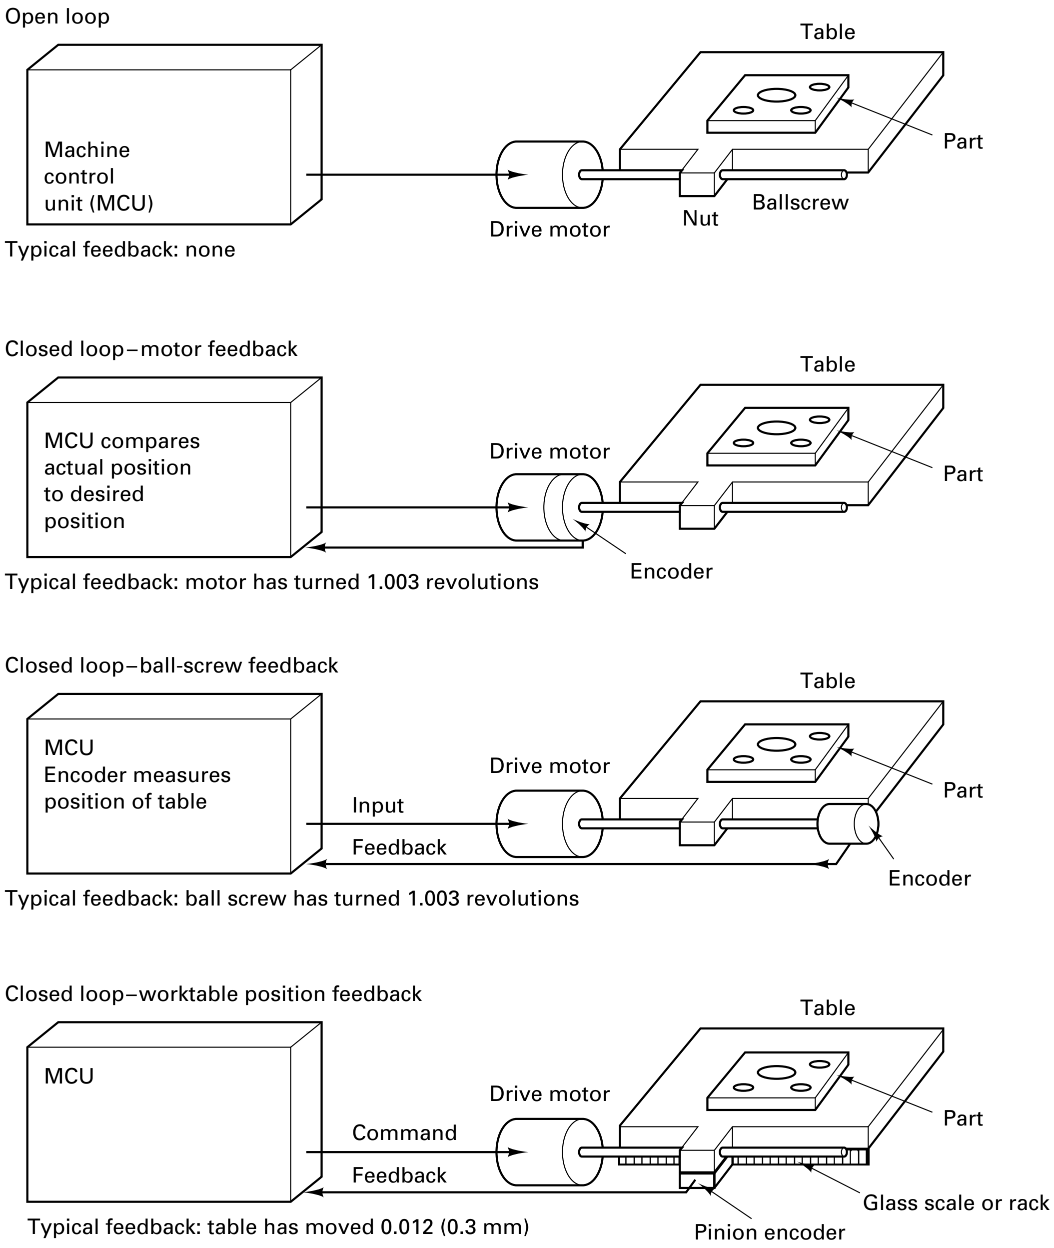

FIGURE 26-2 Open-loop NC versus three position control schemes for NC and CNC machine tools.

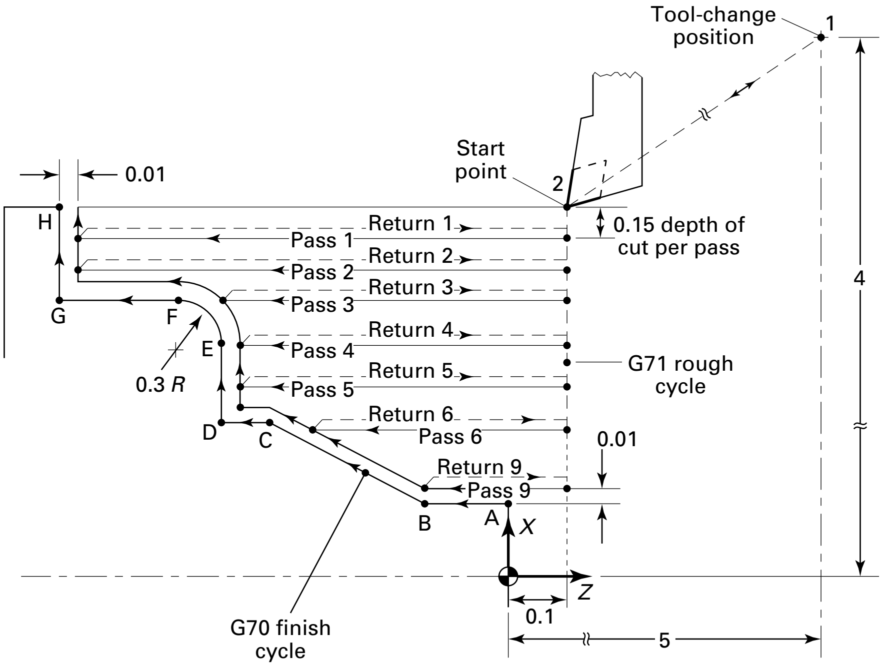
BRIEF HISTORY OF NUMERICAL CONTROL AND FLEXIBLE MANUFACTURING SYSTEMS (FMSs)

The advent and wide scale adoption of numerically (tape- and computer-) controlled machine tools has been the most significant development in machine tools in the past 60 years. These machines raised automation to a new level by providing positional feedback as well as programmable flexibility to machine tools. Numerical control of machine tools created entirely new concepts in manufacturing. Certain operations are now routine that previously were very difficult, if not impossible, to accomplish.

However, NC impacts on machine tools were greater than expected. Machine tools had to be redesigned to sustain more wear and tear on the drives, gears, and motors, and made better (more precise) because the operator no longer controlled the position of the work in respect to the cutting tool. The machines cost more (for controls and precision), with automatic tool changers and pallet changers quickly being added to make the NC machine a "machining center."



Point	X (in.) diameter	Z (in.)
2	4.5	0.1
A	1.8	0
B	1.8	–0.9
C	2.6	–2.6
D	2.6	–2.9
E	3.1	–2.9
F	3.7	–3.2
G	3.7	–3.8
H	4.5	–3.8

FIGURE 26-3 The tool paths necessary to rough and finish turn a part in a CNC lathe are computer generated using G codes.

In earlier years, highly trained NC programmers were required. The development of low-cost, solid-state microprocessing chips resulted in machines that can be quickly programmed by skilled machinists after only a few hours of training, using only simple machine shop language. As a consequence, today almost all manufacturing facilities, from the largest to the smallest job shops, have one or more numerically controlled machine tools in routine use.

NC came into being to fill a need. The U.S. Air Force (USAF) and the airframe industry were seeking a means to manufacture complex contoured aircraft components to close tolerances on a highly repeatable basis. John Parsons of the Parsons Corporation of Traverse, Michigan, had been working on a project to solve this problem; in 1947 he and his engineers developed a machine that would machine templates to be used for inspecting helicopter blades. He conceived of a machine (a jig borer) that was controlled by numerical data to make these templates and took his proposal to the USAF. Parsons convinced the USAF to fund the development of a machine. Subsequently, MIT was subcontracted to build the first NC machine in 1949. The prototype was a conventional two-axis tracer mill retrofitted with servomechanisms. As luck would have it, the servomechanism lab was located next to a lab where one of the very first digital computers (Whirlwind) was being developed. This computer generated the digital numerical data for the servomechanisms, and in 1952 a modified three-axis Cincinnati Hydrotel milling machine was demonstrated.

In 1962, 35 billion was spent on machine tools and NC machines accounted for about 10% of total. Early on, NC machines were continuous-path or contouring machines where the entire path of the tool was controlled with close accuracy in regard to position and velocity, and the large aerospace companies had many home-made NC machines. Today, milling machines, machining centers, laser beam and water-jet cutting machines, and lathes are popular applications of continuous-path control requiring feedback control. Next, point-to-point machines were produced in which the path taken between operations was relatively unimportant and therefore not monitored continuously. Point-to-point machines are used primarily for drilling, milling straight cuts, cutoff, and punching. Automatic tool changers, which require that the tools be precisely set to a given length prior to installation in the machines, permitted the merging of many into

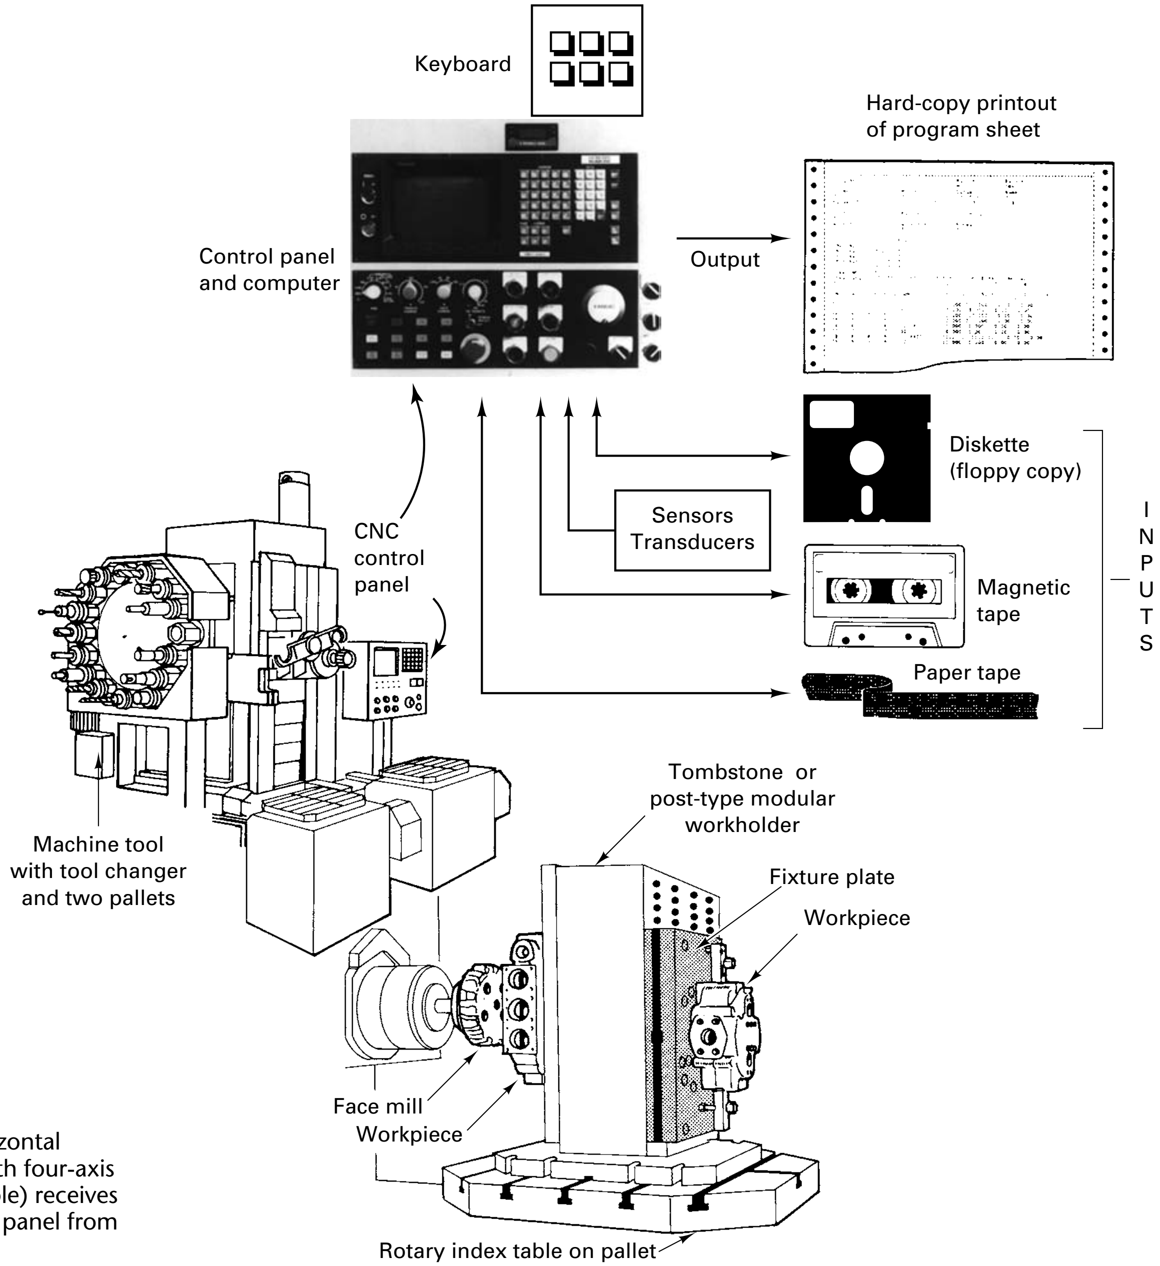


FIGURE 26-4 Horizontal machining center with four-axis control (*X, Y, Z, R* table) receives inputs to the control panel from many sources.

one machine. Modern machines are often equipped with two pallets so that one can be set up while the other is working. The two-sided (or four-sided) "tombstone" fixture shown in Figure 26-4 has multiple mounting and locating holes for attaching part-dedicated fixture plates, which greatly extends the utility of a horizontal machining center.

During the early days of NC, the machine tools had to be programmed using a machine control language, a difficult, time-consuming task prone to error. Many companies developed computer languages to aid the NC programming task, each developing a different language to describe tool geometry, tool movements, and machining instructions. Confusion reigned.

The USAF sponsored the placement of many NC machines in the major aerospace companies. The companies soon concluded that a universally accepted NC programming language was needed. Under the auspices of the Aerospace Industries Association (AIA), these companies, with the USAF, sponsored additional research at MIT to develop a computer language that would use simple English-like statements to produce an output that would control the NC machines. This language, called *APT* (automatically programmed tools), was introduced by MIT in 1959, when computer technology was in its adolescence. Hundreds of thousands of parts have been programmed using APT, running initially on large mainframe computers. The output from the APT program had to be converted to the language of a particular machine. This was called *postprocessing*. Traditional postprocessing yields NC workpiece programs that are not exchangeable. To machine an identical workpiece on another machine, the program must be postprocessed again unless the machine and control are exactly the same.

With the arrival of high-resolution *computer-aided design* (CAD) graphics, many people thought that APT would be phased out. But when complex tool control is required for complex parts, APT or one of its many offspring is still used. The chief problems in NC programming were tool radius compensation and tool path interpolation (discussed later). Computer software with the capability to perform linear, circular, parabolic, and other kinds of interpolations were developed. The capabilities were included in APT, and such software programs are now routinely available on CNC machines.

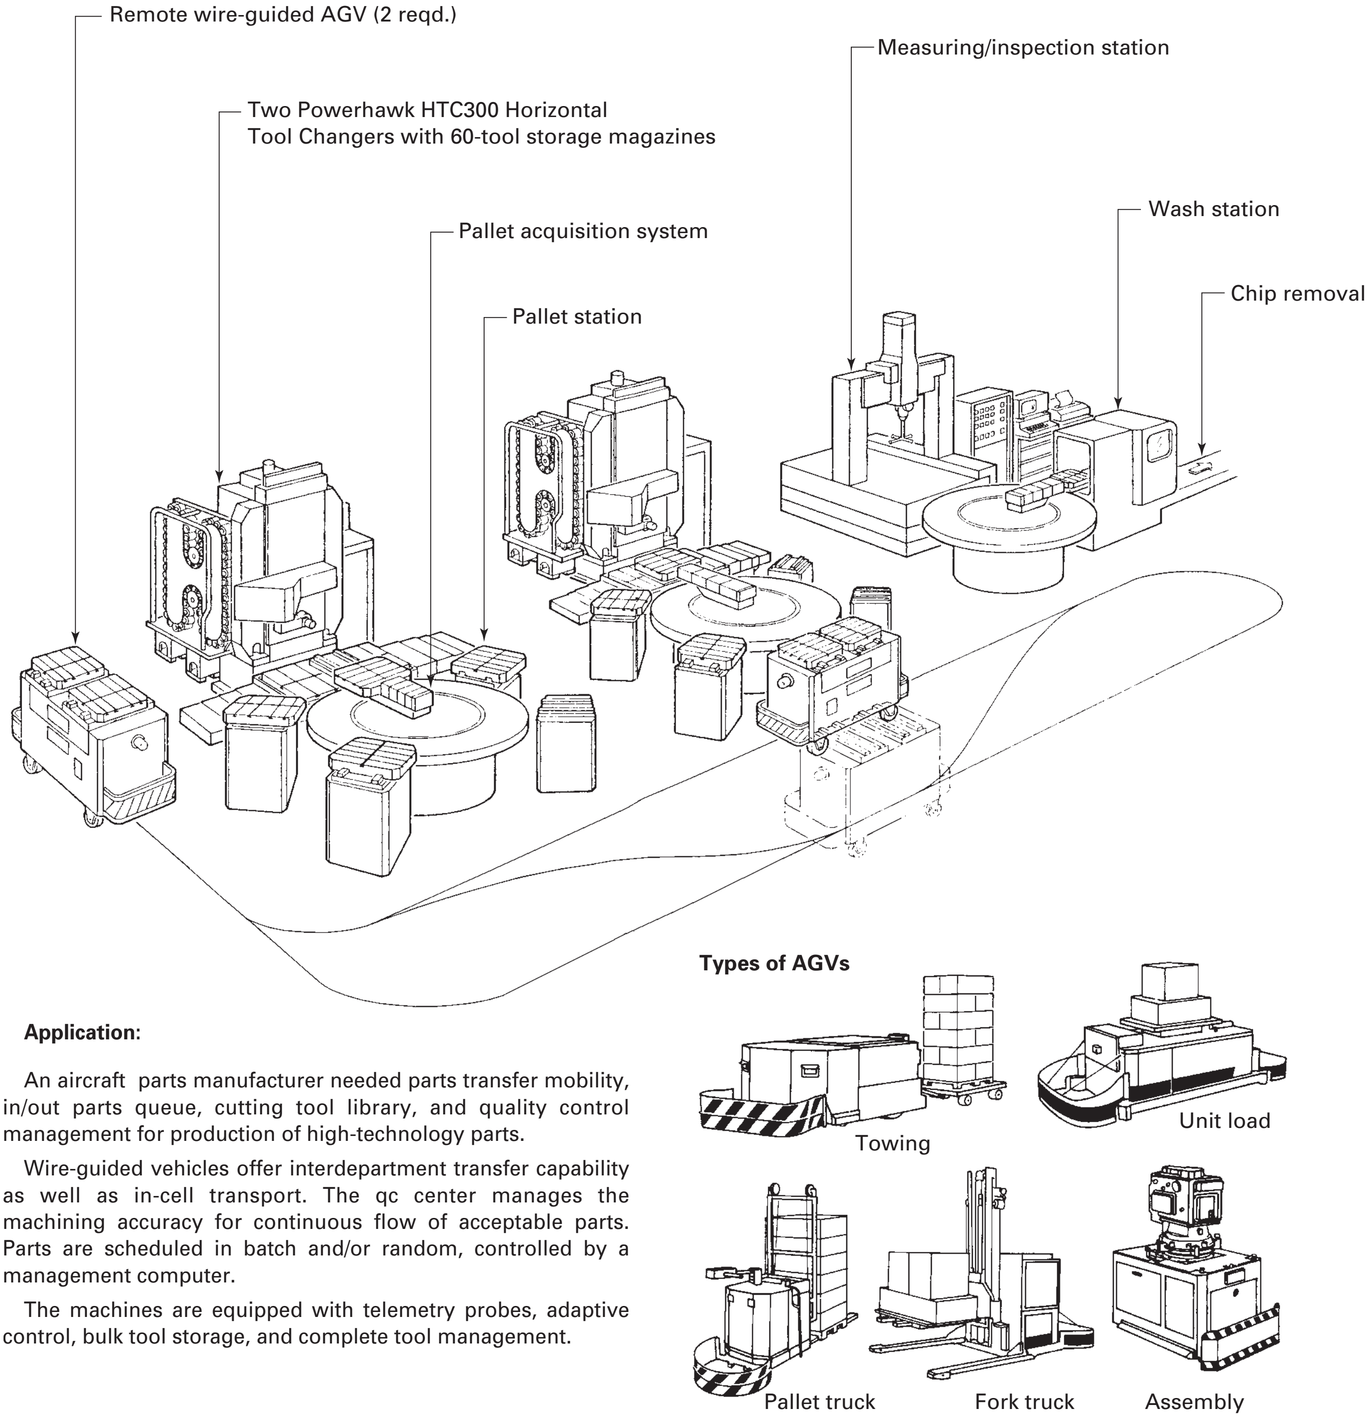
In the 1960s, it was envisioned that a large computer could be used directly to control, in real time, a number of machines. A limited number of *direct numerical control* (DNC) systems were developed, with the idea that the programs were to be sent directly to the machines (eliminating paper tape handling). The mainframe computer would be shared on a real-time basis by many machine tools. The machine operator would have access to the main computer through a remote terminal at the machine, while management would have up-to-the-minute data on production status and machine utilization. This version of DNC had very few takers. Instead, NC machines became *computer numerical control* (CNC) machines through the development of small, inexpensive computer microprocessors with large memories. These onboard computers have every sort of input imaginable coupled with functions such as program storage, tool offset and tool compensation, program-editing capability, various degrees of computation, and the ability to send and receive data from a variety of sources, including remote locations. The computer can store multiple-part programs, recalling them as needed for different parts. As the software and controllers developed, it was immediately found that the machine tool operator could readily learn how to program these machines (manually) for many component parts, often eliminating the need for a part programmer.

In recent years the DNC concept has been revived with the small but powerful computers on the machine tools being networked to a larger computer to provide enhanced computer memory and computational capacity. Therefore, DNC now means *distributed numerical control,* with the distribution of NC programs by a central computer to individual CNC units. And so emerged a special type of manufacturing system called the flexible manufacturing system, or FMS. Historically speaking, the first examples of FMS systems appeared in the late 1960s, but few companies adopted them because of their high initial cost.

FLEXIBLE MANUFACTURING SYSTEMS

The development of FMSs began in England and the United States simultaneously in the 1960s. By combining the repeatability and productivity of the transfer line with the programmable flexibility of the NC machine, a variety of parts could be produced on the same set of machines. In the United States the first systems were called variable mission or flexible manufacturing systems. In the late 1960s Sundstrand installed a system for machining aircraft speed drive housings that was used for over 30 years. Overall, however, very few of these systems were sold until the late 1970s and early 1980s, when a worldwide FMS movement began. But even today international trade in FSM is not significant, and there are fewer than 2000 systems in the world (less than 0.1% of the machine tool population). There is also some evidence that the market for these large, expensive systems became saturated around the mid-1980s.

Essentially, the FMS permits (schedules) the products to take random paths through the machines. This system is fundamentally an automated, conveyorized, computerized job shop so the system is complex to schedule. Because the machining time for different parts varies greatly, the FMS is difficult to link to an integrated system and often remains an island of very expensive automation.



Application:

An aircraft parts manufacturer needed parts transfer mobility, in/out parts queue, cutting tool library, and quality control management for production of high-technology parts.

Wire-guided vehicles offer interdepartment transfer capability as well as in-cell transport. The qc center manages the machining accuracy for continuous flow of acceptable parts. Parts are scheduled in batch and/or random, controlled by a management computer.

The machines are equipped with telemetry probes, adaptive control, bulk tool storage, and complete tool management.

FIGURE 26-5 An example of a sophisticated FMS developed for machining aircraft parts. A wire-guided cart called an AGV (automated guided vehicle) is used to transport pallets from the unload/load station to the machines.

About 60 to 70% of FMS implementations are for components consisting of nonrotational (prismatic) parts such as crankcases and transmission housings. Figure 26-5 depicts an FMS with two machine tools serviced by a pallet system and an automated guided vehicle (AGV). The balance of FMS installations are for rotational parts or a mixture of both types of parts.

The number of machine tools in an FMS varies from 2 to 10, with 3 or 4 being typical. Annual production volumes for the systems are usually in the range of 3000 to 10,000 parts, the number of different kinds of parts ranging from 2 to 20, with 8 being typical. The lot sizes are typically 20 to 100 parts, and the typical part has a machining time of

TABLE 26-1 Common Features of Flexible Manufacturing Systems

Pallet changers
Multiple machine tools: NC or CNC
Automated material handling system (to deliver parts to machines)
Computer control for system: DNC
Multiple parts: Medium-sized lots (200–10,000) with families of parts
Random sequencing of parts to machines (optional)
Automatic tool changing
Inprocess inspection
Parts washing (optional)
Automated storage and retrieval (optional, to deliver parts to system)

about 30 minutes with a range of 6 to 90 minutes per part. Each part typically needs two or three chuckings or locating positions and 30 or 40 machining operations. Early on, NC machining centers were used, but in recent years, CNC machine tools have been favored, leading to a considerable number of systems being operated under direct numerical control. The machining centers always have tool changers. To overcome the limitation of a single spindle, some systems are being built with head changers. These are sometimes referred to as modular machining centers.

Common features of FMSs (see Table 26-1) are *pallet changers,* underfloor conveyor systems for the collection of chips (not shown), and a conveyor system that delivers parts to the machine. This is also an expensive part of the system, as the conveyor systems are either powered rollers, mechanical pallet transfer conveyors, or AGVs operating on underground towlines or buried guidance cables. The carts are more flexible than the conveyors. The AGVs also serve to connect the islands of automation, operating between FMSs and replacing human guided vehicles (forklift trucks).

Pallets are a significant cost item for the FMS because the part must be accurately located on the pallet and the pallet accurately located in the machine. Since many pallets are required for each different component, a lot of pallets are needed and they typically represent anywhere from 15 to 20% of the total system cost. FMSs cost about $1 million per machine tool. Thus the seven-machine FMS costs $6 million for hardware and software, with the transporter costing over $1 million.

Computer Control in FMS. The CNC machines receive programs as needed from a host minicomputer, which acts as a supervisory computer for the system, tracking the status of any particular machine in the system. In recent years, in-process inspection, detection, and automatic tool position correction for tool wear and breakage have been added because a very common problem with these systems is the monitoring of the tool condition and performance. Most installations also incur problems in the performance and reliability of the software and the control systems. Because it may take just as long to debug software as it does to debug hardware, delays of two to six months in startup are not uncommon.

However, operators are typically needed to load workpieces, unload finished parts, change worn tools, and perform equipment maintenance and repairs. CNC and DNC functions are often incorporated into a single FMS. The system can usually monitor piece-part counts, tool changes, and machine utilization, with the computer also providing supervisory control of the production. The workpieces are launched randomly into the system, which identifies each part in the family and routes it to the proper machines. The systems generally display reduced manufacturing lead time, low in-process inventory, and high machine tool utilization, with reduced indirect and direct labor. The materials-handling system must be able to route any part to any machine in any order and provide each machine with a small queue of "banked parts" waiting to be processed so as to maximize machine utilization. Convenient access for loading and unloading parts, compatibility with the control system, and accessibility to the machine tools are other necessary design features for the material handling system.

The computer control system for an FMS typically has three levels. The master control monitors the entire system for tool failures or machine breakdowns, schedules the work, and routes the parts to the appropriate machine. The DNC computer distributes programs to the CNC machines and supervises their operations, selecting the required programs and transmitting them at the appropriate time. It also keeps track of the completion of the cutting programs and sends this information to the master computer. The bottom level of computer control is at the machines themselves.

It is difficult to design an FMS because it is, in fact, a very complex assembly of elements that must work together. Designing the FMS to be flexible is also difficult. Many companies have found that between the time they ordered their system and the time they had it installed and operational, design changes had eliminated a number of parts from the FMS. That is, the system was not as flexible as they thought. Figure 26-6 shows some typical FMS designs. Today a popular system has only one (or two) machining centers, with an automatic storage and retrieval system (ASRS) to provide the machine with a continuous supply of parts during all three shifts. This design is called a flexible manufacturing cell (FMC). FMSs are, in fact, classic examples of supermachines. Such large, expensive systems must be examined with careful and complete planning. It is important to remember that even though they are often marketed and sold as a *turnkey* installation (the buyer pays a lump sum and receives a system that can be turned on and run), this is only rarely possible with a system that has so many elements that must work together reliably. Taken in the context of integrated manufacturing systems, large FMSs may be difficult to synchronize to the rest of the system. The flexibility of the FMS requires variable speeds and cycles, numerical control, and a supervisory computer to coordinate cell operation. In the long run, smaller manned or unmanned cells may well be the better solution, in terms of system flexibility. Perhaps a better name for these systems would be *variable mission* or *random-path manufacturing systems.*

Many companies elect to identify the families of parts around which the FMS is designed, which greatly improves the utilization of the FMS. One might say that FMSs were developed before their time, since they are being more readily accepted since group technology has been used (at least conceptually) to identify families of parts for the system to produce.

As an FMS generally needs about three or four workers per shift to load and unload parts, change tools, and perform general maintenance, it cannot really be said to be self-operating. FMS systems are rarely left untended, as in third-shift operations. Other than the personnel doing the loading and unloading, the workers in the FMS are usually highly skilled and trained in NC and CNC. Most installations run fairly reliably (once they are debugged) over three shifts, with uptime ranging from 70 to 80%, and many are able to run on one shift untended.

■ 26.2 BASIC PRINCIPLES OF NUMERICAL CONTROL

NC uses a processing language to control the movement of the cutting tool or workpiece or both. The programs contain information about the machine tool and cutting tool geometry, the part dimensions (from rough to finish size), and the machining parameters (speeds and feeds and depth of cut). Thus NC machines can duplicate consecutive parts, and a part made at a later date will be the same as one made today. Repeatability and quality are improved over conventional (job shop) machines. Workholding devices can be made more universal, and setup time can be reduced, along with tool-change time, thus making programmable machines economical for producing small lots or even a single piece. When combined with the managerial and organizational strategies of group technology (GT) and cellular manufacturing, programmable machines lead to tremendous improvements in quality and productivity. GT basically leads to the creation of families of parts made in machining cells containing flexible, programmable machines. The compatibility of the components (similarly in process and sequences of processes) greatly enhances the productivity (utility) of the programmable equipment.

A side result has been the decrease in the non-chip-producing time of machine tools. The operator was relieved of the jobs of changing speeds and feeds and locating

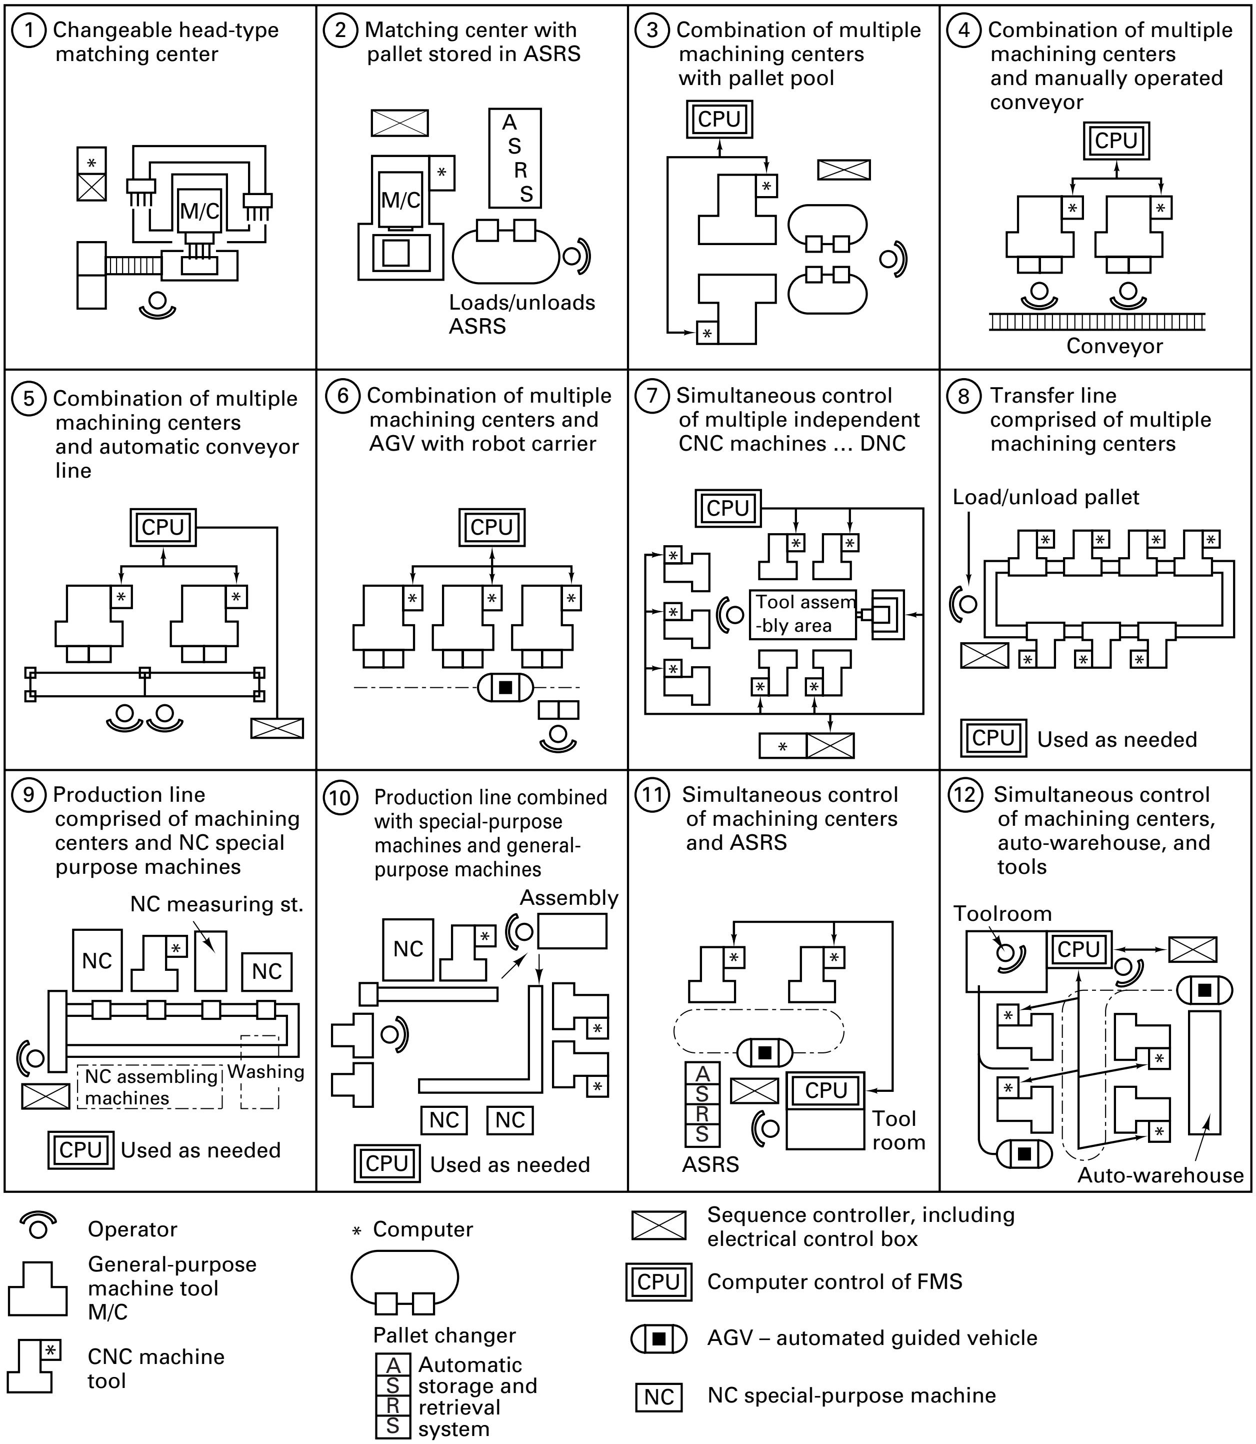


FIGURE 26-6 Examples of machining centers—FMC and FMS designs.

the tool relative to the work. Even simple forms of NC and digital readout equipment have provided both greater productivity and increased accuracy. Most early NC machine tools were developed for special types of work where accuracies of as much as 0.00005 in. were required, and many NC machines are built to provide accuracies of at least 0.0001 in., regardless of whether or not it is needed. This forced many machine tool builders to redesign their machines and improve their quality because the operator was not available to compensate for the machine (positioning) error. While most NC machine tools today will provide greater accuracy than is required for most jobs, the trend is toward greater accuracy and precision (i.e., better quality) but at no increase in cost.

Therefore, NC machines will continue to be the very backbone of the machine tool business. Hopefully, all builders will one day arrive at a common language, so that if one can program one machine, one can program them all.

As the name implies, *numerical control* is a method of controlling the motion of machine components by means of numbers or coded instructions. Assume that three 1-in. holes in the part shown in Figure 26-7 are to be drilled and bored on a vertical-spindle machine. The centers of these holes must be located relative to each other and with respect to the left-hand edge (X direction) and the bottom edge (Y direction) of the workpiece. The depth of the hole will be controlled by the Z- (or W-) axis. For this part, this is the zero reference point for the part.

The holes will be produced by center drilling, hole drilling, boring, reaming, and counterboring (five tool changes). If this were done conventionally or in manned cells, three or four different machines might be required. On the NC machining center, it only requires changing the tool automatically. The movements of the table are controlled by coordinate systems for each direction. The machine tool has a zero point. The accurate positioning of the cutting tool with respect to the work is established by these zero points. The center of the table or a point along the edge of the traverse range is commonly used. The workpiece is positioned on the table with respect to this zero point on the table. For our example, the lower left-hand corner of the part is placed on the table 12 in. in the $X+$ direction, 4 in. in the $Y+$ direction, and 2 in. in the $Z+$ direction with respect to the machine zero point.

A software program is written that instructs the table to move with respect to the axis of the spindle to bring the holes to the correct location for machining. The machine shown in Figure 26-7 is called a five-axis machine because it has five movements (shown by the dark arrows) under numerical control. No fixture is shown in this example, but one would typically be used to obtain quick and repeatable location of the part on the table.

HOW CNC MACHINES WORK

NC and CNC machines can be subdivided into two types, shown in Figure 26-8. In *point-to-point machines,* the tool path is not controlled but tools can be moved in straight lines or parallel traverses at desired table feed rates, but only one axis drive is operated at a time. *Contouring* permits two or three axes to be controlled simultaneously, permitting two- or three-dimensional geometries to be generated. Another term for contouring is *continuous path*. Most milling and turning machining centers have contouring capability and are closed loop. The point-to-point machines can be open loop rather than closed loop.

The X-axis of the three-axis vertical spindle CNC machine tool shown in Figure 26-7 will be used to explain how the closed-loop positional control works.

Controlling a machine tool using variable input, such as a punched tape or a stored program, is known as numerical control and is defined by the Electronic Industries Association (EIA) as “a system in which actions are controlled by direct insertion of a numerical data at some point (the measured data is call the parts program). The system must automatically interpret at least some portion of the data.”

Traditionally, NC machine tool has a *machine control unit* (MCU). The MCU is further divided into two elements: the data-processing unit (DPU) and the control-loops unit (CLU). The DPU processes the coded data that are read from the tape or some other input medium that it gives to the CPU, specifically the position of each axis, its direction of motion feed, and its auxiliary-function control signals. The CLU operates the drive mechanisms of the machine.

The CNC control system, shown schematically in Figure 26-9, uses a resolver or encoder to provide axis-position feedback to the MCU. A closed-loop control requires a transducer or sensing device to detect machine table position (and velocity for contouring) and transmit that information back to the MCU to compare the current status with the desired state. If they are different, the control unit produces a signal to the drive motors to move the table, reducing the error signal and ultimately moving the table to the desired position at the desired velocity. At this point, the command counter reaches zero, meaning that the correct number of pulses has been sent to move the table to the desired position. In a closed-loop system, a comparator is used to compare

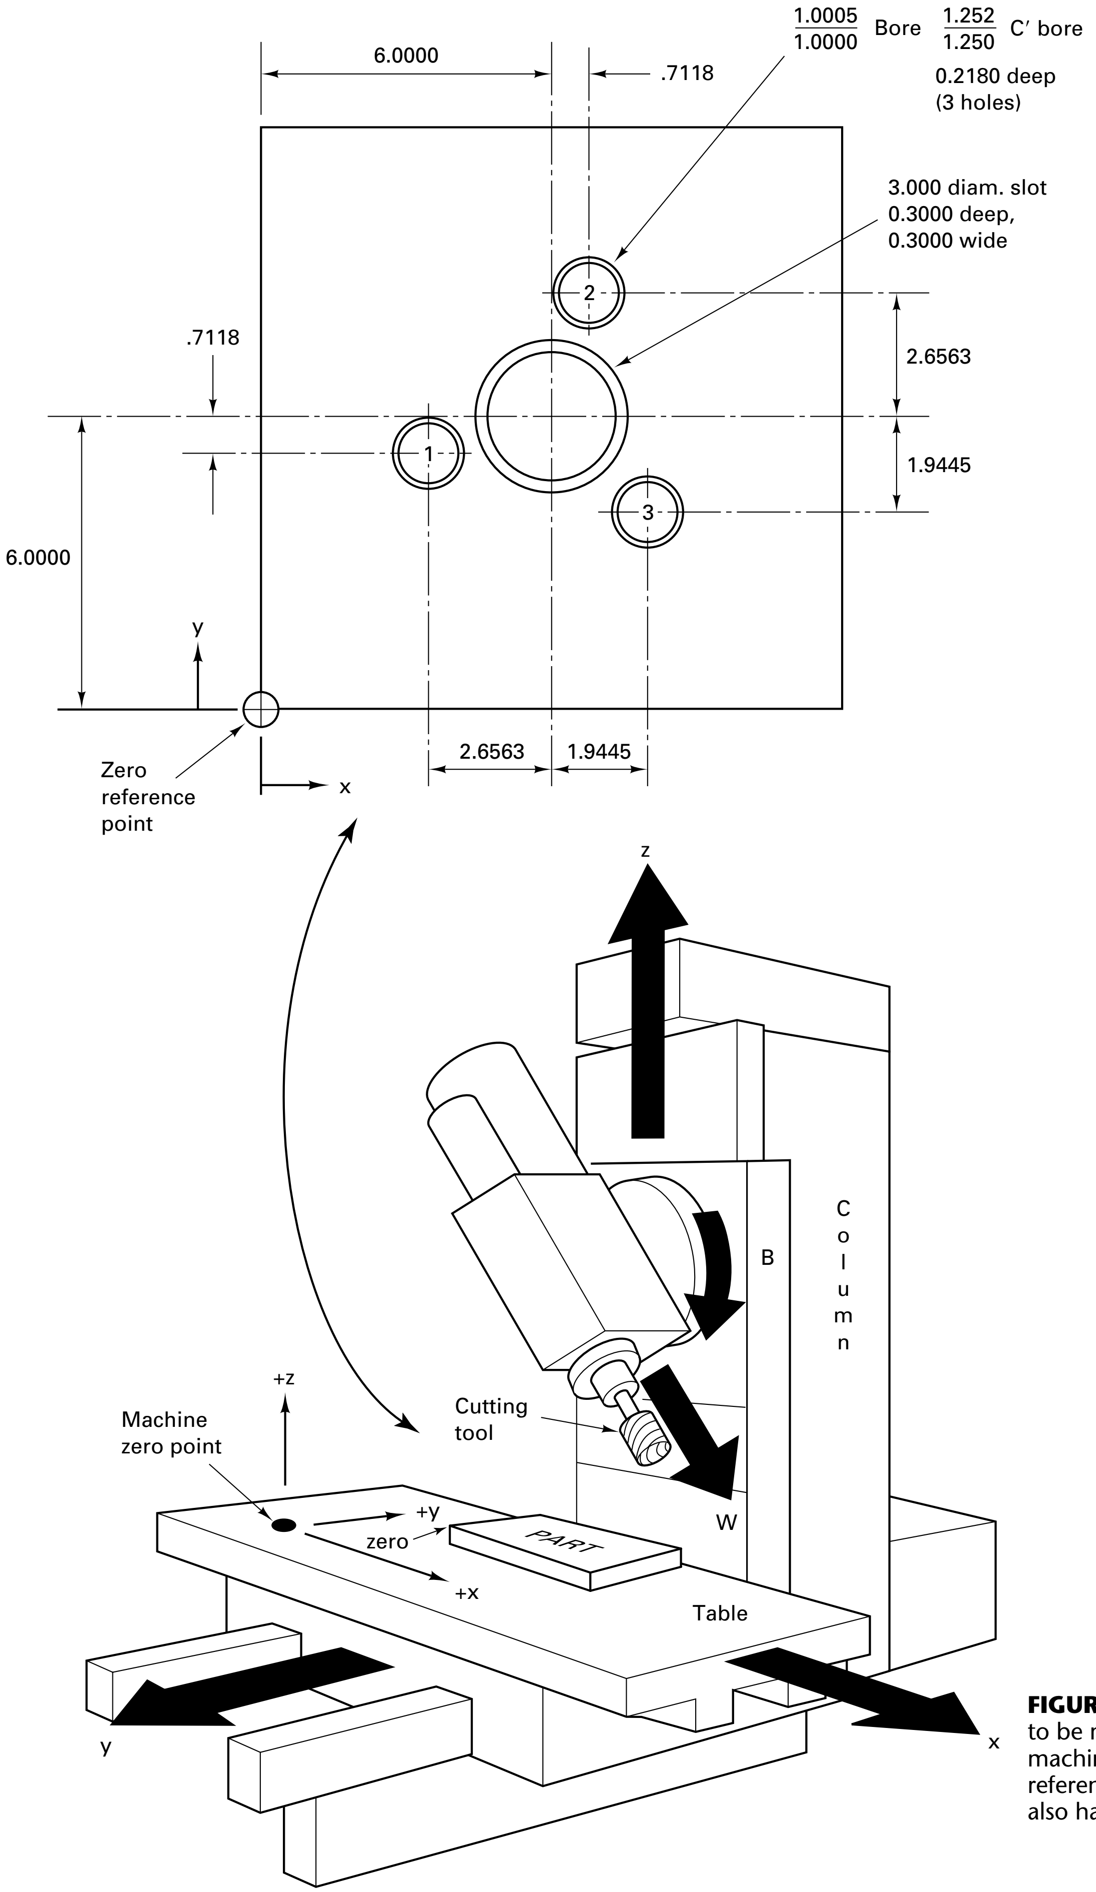

FIGURE 26-7 The part (above) to be machined on the NC machine (below) has a zero reference point. The machine also has a zero reference point.

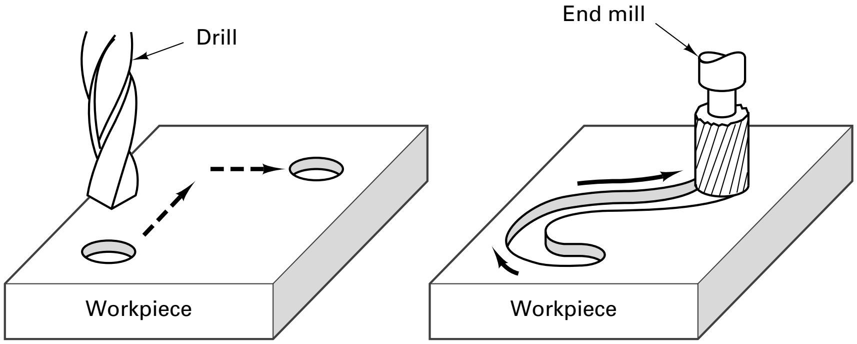

Point-to-point control (milling machines, welding)

Contouring control (machining centers)

FIGURE 26-8 NC and CNC systems are subdivided into two basic categories: point-to-point controls or contouring controls.

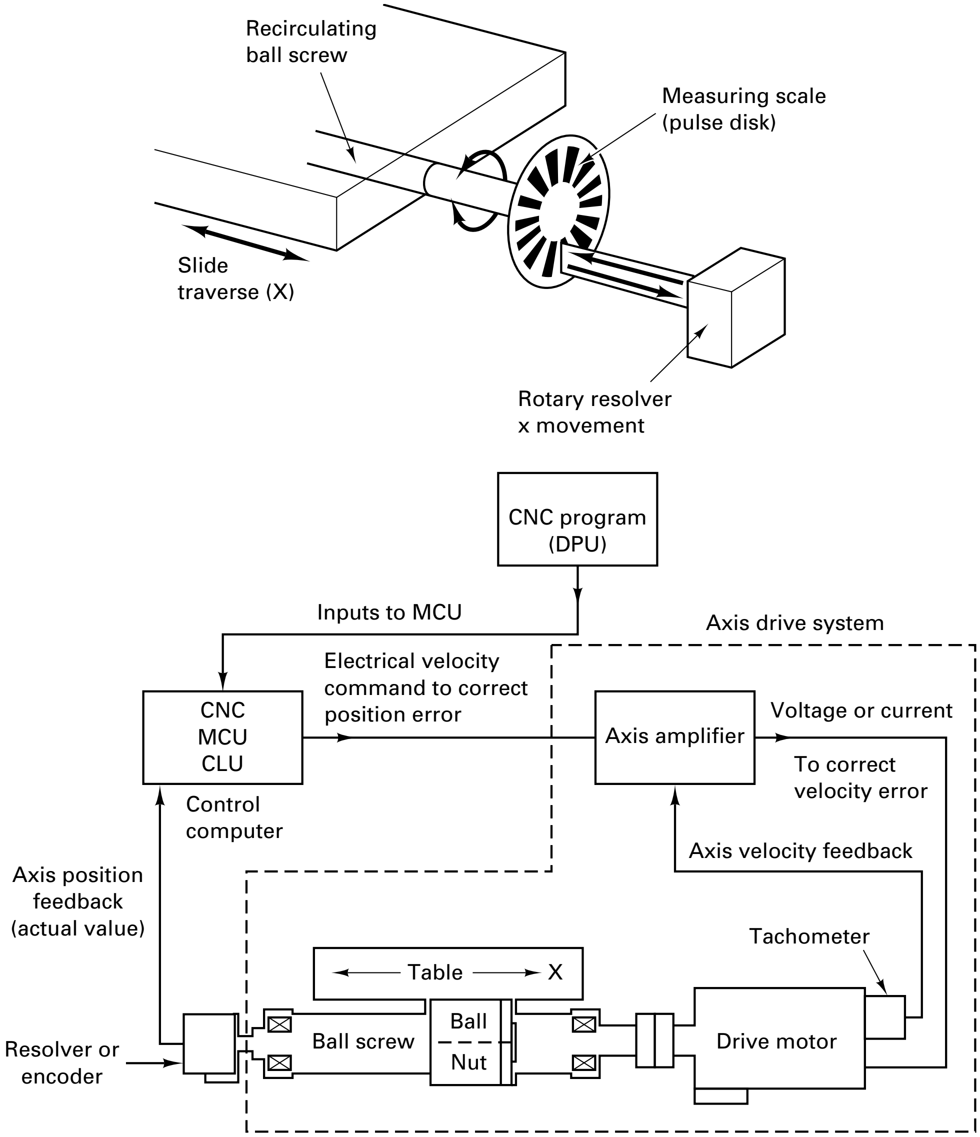

FIGURE 26-9 The table of the CNC machine (above) is translated with a ball screw mechanism, and its location is detected with a resolver. The schematic below shows how the table is located with respect to the spindle axis of the machine tool.

feedback pulses with the original value, generating an error signal. Thus, when the machine control unit receives a signal to execute this command, the table is moved to the specified location, with the actual position being monitored by the feedback transducer. Table motion ceases when the error signal has been reduced to zero and the function (drilling a hole) takes place. Closed-loop systems tend to have greater accuracy and respond faster to input signals but may exhibit stability problems (oscillating about a desired value instead of achieving it) not found in open-loop machines.

For most NC controls, the feedback signals are supplied by transducers actuated either by the feed screw or by the actual movement of the component. The transducers may provide either *digital* or *analog* information (signals). The resolver in Figure 26-9 measures (indirectly) the movement of the table by the rotation of the ball screw. A pulse disk on the end of the ball screw converts analog movement back into digital pulses, which are used to calculate table movement. The tachometer on the drive motor measures the table velocity.

Two basic types of digital transducers are used. One supplies *incremental* information and tells how much motion of the input shaft or table has occurred since the last time. The information supplied is similar to telling newspaper carriers that papers are to be delivered to the first, fourth, and eighth houses from a given corner on one side of the block. To follow the instructions, the carriers would need a means of counting the houses (pulses) as they passed them. They would deliver papers as they counted 1, 4, and 8. The second type of digital information is *absolute* in character, with each pulse corresponding to a specific location of the machine components. To continue the carrier analogy, this would correspond to telling the carriers to deliver papers to the houses having house numbers 2400, 2406, and 2414. In this case it would only be necessary for the carriers (machine component) to be able to read the house numbers (addresses) and stop to deliver a paper when arriving at a proper address. This *address* system is a common one in numerical control systems, because it provides absolute location information relative to a machine zero point.

When analog information is used, the signal is usually in the form of an electric voltage that varies as the input shaft is rotated or the machine component is moved, the variable output being a function of movement. The movement is evaluated by measuring, or matching, the voltage, or by measuring the ratios between the applied and feedback voltages; this eliminates the effect of supply-voltage variations.

The input information (i.e., the location of the holes) is given in binary form to the machine control unit in the form of a punched tape—a magnetic tape in a cassette on old machines or disks, as shown, on newer machines. The data are input directly via the control panel or a computer program. This command signal is converted into pulses by the machine control unit, which in turn drives the servomotor or stepper motor.

Alternating-current servomotors are rapidly replacing direct-current motors on new CNC machine tools. The reasons for change are better reliability, better performance-to-weight ratio, and lower power consumption.

If the system is point-to-point (or positioning), the control system disregards the paths between points. Some positioning systems provide for control of straight cuts along the machine axes and produce diagonal paths at 45° to the axes by maintaining one-to-one relationships between the motions of perpendicular axes. Contouring systems require directional changes at controlled velocity. Any lost motion in the system can distort the part. In contouring, it is usually necessary to control multiple paths between points by interpolating intermediate coordinate positions. As many of these systems as desired can be combined to provide control in several axes—two- and three-axis controls are most common, but some machines have as many as seven. In many, conversion to either English or metric measurement is available merely by throwing a switch.

The components required for such a numerical control system are now standardized items of hardware. In most cases the drive motor is electric, but hydraulic systems are also used. They are usually capable of moving the machine elements, such as tables, at high rates of speed, up to 200 in./min being common. Thus exact positioning can be achieved more rapidly than by manual means. The transducer can be placed on the drive motor or connected directly to the leadscrew, with special precautions being taken, such as the use of extra-large screws and ball nuts, to avoid backlash and to assure accuracy. In other systems, the encoder is attached to the machine table, providing direct measurement of the table position. Various degrees of accuracy are obtainable. Guaranteed positioning accuracies of 0.001 or 0.0001 in. are common, but greater accuracies can be obtained at higher cost. Most NC systems are built into the machines, but they can be retrofitted to some machine tools.

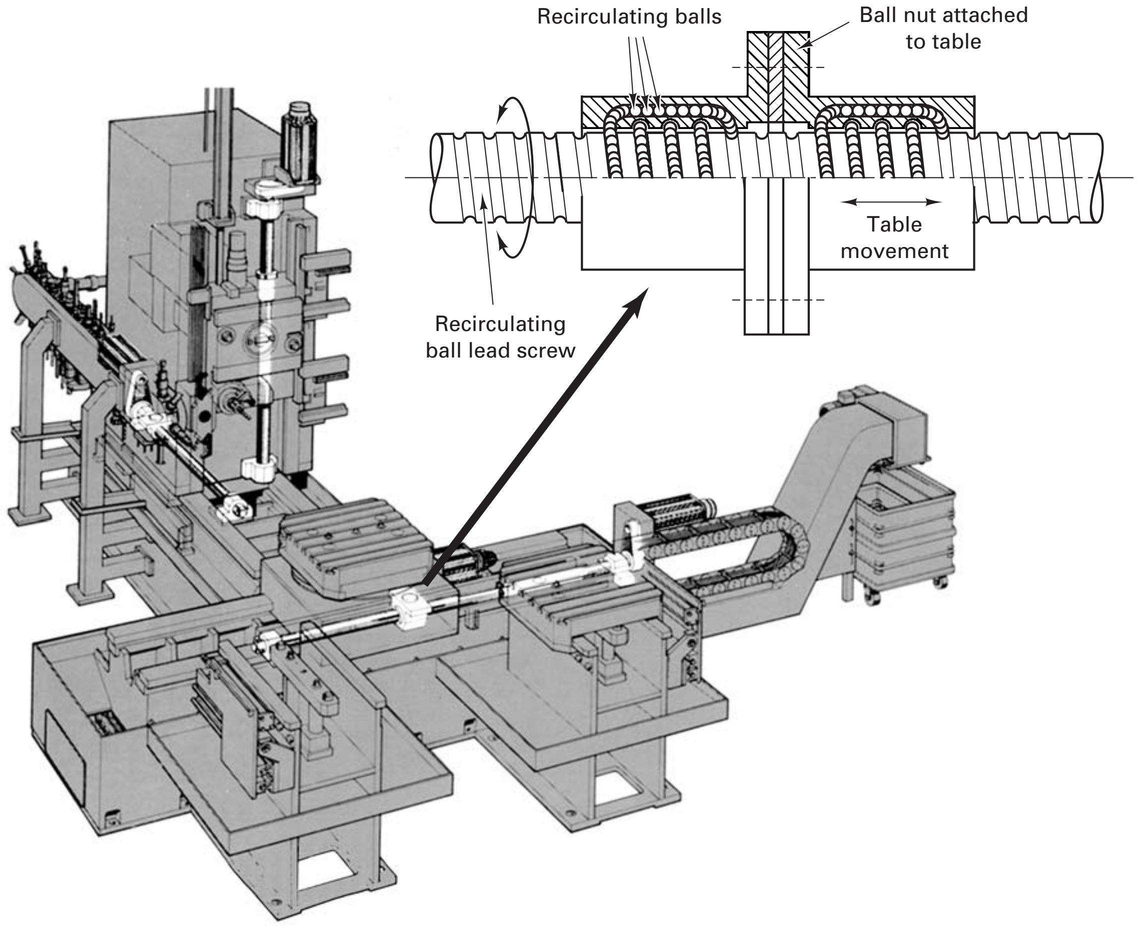

FIGURE 26-10 The ball lead screw shown in detail provides great accuracy and position to NC and CNC machine tools.

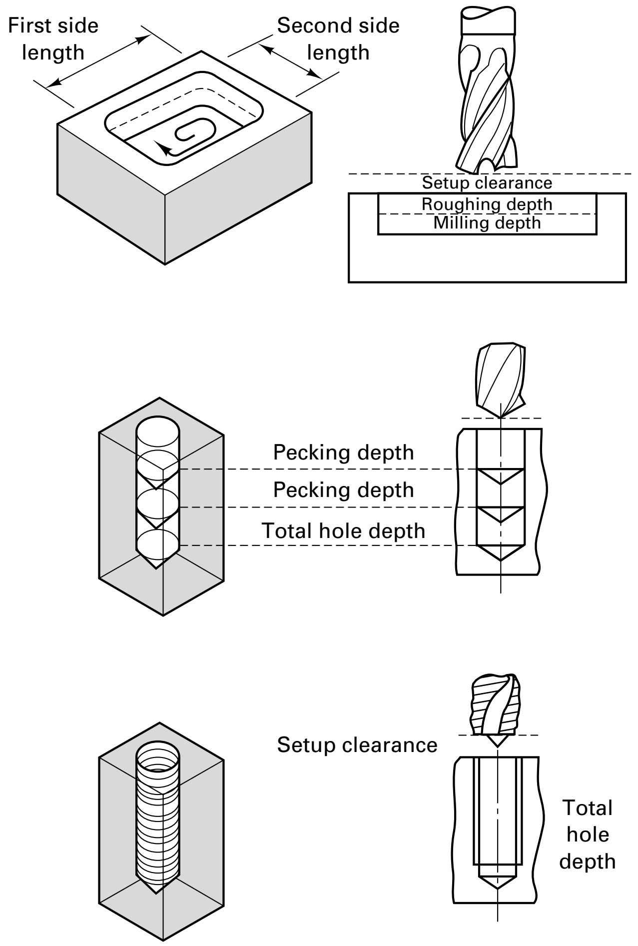
Initially, NC machines provided tool change; tool setting; and speed, feed, and depth-of-cut settings for positioning the work relative to the tool, with the remaining functions controlled by the operator. Gradually, the functions were incorporated into the control system so that the machines could change the tools automatically, change the speeds and feeds as needed for different operations, position the work relative to the tools, control the cutter path and velocity, reposition the tool rapidly between operations, and start and stop the sequence as needed.

Tables and tools are positioned using recirculating ball-screw drives (see Figure 26-10), or linear accelerators, which greatly reduce the backlash in the drive systems, helping to eliminate problems of servoloop oscillation and machine instability. Using such hardware, NC machines are manufactured with greater accuracy and repeatability and more rapid table movements than is possible for conventional machines.

Some of the functions in programmable machines require feedforward or preset loops. The machine must know in advance the rough dimensions of a casting or a forging so that it can determine how many roughing cuts are needed prior to the finishing cut. However, for most CNC work, the operator (or part programmer) still plans the sequence of operations; selects the cutting tools and workholding devices; and selects the speeds, feeds, and depths of cut. Common machining routines such as pocket milling or peck drilling have been programmed into many CNC machines. These are called *canned cycles*. As shown in Figure 26-11, the operator merely supplies the information requested by the control menu, and the machine fills in the necessary data for the previously written program to perform the desired machining routines.



Rectangular pocket milling
Control menu asks for:
- Setup clearance
- Milling depth
- Roughing depth
- Feed rate for roughing
- First side length
- Second side length
- Feed rate
- Direction or rotation

Peck drilling
Control menu asks for:
- Setup clearance
- Total hole depth
- Pecking depth
- Dwell time (seconds)
- Feed rate

Tapping
Control menu asks for:
- Setup clearance
- Total hole depth
- Dwell time (seconds)
- Feed rate

FIGURE 26-11 Canned or preprogrammed machining routines greatly simplify programming CNC machines. *(Courtesy of Heidenkain Corporation, Elk Grove Village, ILL.)*

Source: Heidenhain Corp. (Elk Grove Village, IL.)

To ensure accurate machining of a workpiece on a CNC machine, the control system has to *know* certain dimensions of the tools. These *tool dimensions* are referenced to a fixed *setting point* on the tool holder. For the milling cutter, the dimensions are length *L* and cutter radius. For the turning tool, the dimensions are length *L* and transverse overhang. These dimensions are part of the information given to the operator on the setting sheet (see Figure 26-12). The program assumes that the tools will have the specified dimensions.

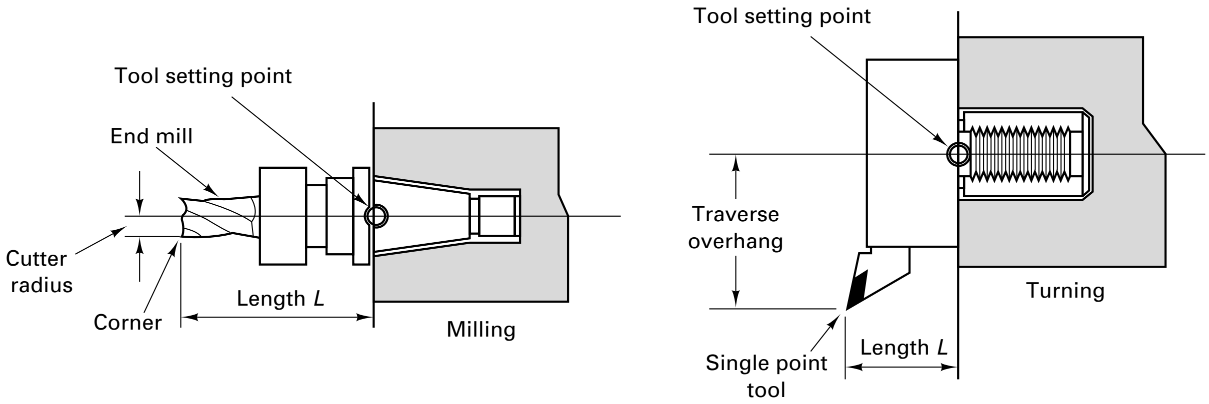


FIGURE 26-12 The location of the corner of the end mill (left) or the tip of a single-point tool (right) must be known with respect to the tool setting points so that tool dimensions are accurately set.

FIGURE 26-13 Example of programming a part in a vertical-spindle NC machine.

PART PROGRAMMING

Obviously, the preparation of the control program for use in NC machines is a critical step. Many standard languages and programs have been developed by the machine tool builders, and only the very basic aspect can be presented here.

The basic steps can be illustrated by reference to the part shown in Figure 26-13. The first step is to modify the drawing received from design engineering to establish the zero reference axes: the *X* and *Y* directions. The zero reference point is the lower left-hand corner of the part. The hole labeled 1 is located +3.3437 in the *X* direction and ±5.2882 in the *Y* direction, with respect to its zero point. The part should be dimensioned with respect to its zero reference point. This may require redrawing and redimensioning the part. Obviously, this step can be avoided if the original drawing is made in the desired form or a CAD design is used. The setup instructions given to the operator establish the position of the workpiece properly on the machine table with respect to the axis of the spindle or the machine zero reference point.

The second step is to develop a *part program*. The program (1) defines the sequence of operations required to fabricate the part; (2) gives the *x*, *y*, and *z* coordinate positions of the operations; and (3) specifies the spindle traverse that determines the depth of the cut, the spindle speed, and the feed rate, and also determines whether the same tool can continue the next operation or whether a tool change is required. The last four items are specified by code symbols, or NC words (see Table 26-2). The NC words are put together in a specified order to define a *block* of information needed to execute an operation. By convention, the data are usually arranged in blocks in the sequential order shown in the table.

Before starting with programming tool movements, the table movements and the workpiece drawing are studied. As a first step, the workpiece zero point is established. The workpiece drawing, two views, is redone into a coordinate system. In Figure 26-8 the workpiece zero point is located at the bottom left-hand corner of the workpiece drawing.

The three axes of the machine coordinate system is established in relation to the workpiece as follows:

- The *x*- and *y*-axes are used to show the workpiece geometry in the *XY*-plane.
- The *z*-axis shows the down feed or depth.

All the coordinates of the most important points on the part (in this case the points P1–P11) have been collated in the form of a table:

	P1	P2	P3	P4	P5	P6	P7	P8	P9	P10	P11
x	190	190	100	100	70	70	10	10	20	160	130
y	10	130	130	105	105	130	130	20	10	100	45
z	20	20	20	20	20	20	20	20	20	20	10

Preparation of the program includes the selection of the cutting tools (a 10-mm-diameter end mill) and the selection of desired cutting speeds and feed per tooth. As discussed in Chapter 25, these parameters, along with the depth of cut and depth of immersion, determine the spindle rpm and table feed rates.

For determining the outer contour, the tool radius must be considered because the path of the milling cutting along the outer contour is input into the control program, not the actual perimeter of the parts. To ensure that the control system can in fact control the milling cutter center axis correctly, the size of the milling cutter (radius or diameter) has to be known beforehand, as does the side of the finished contour (relative to the machining direction) on which the milling cutter is located. How these two items of information are input is not standardized for all machine tools, and it is therefore assumed here that the control system has already received this information.

Machining the outer contour begins with the milling cutter moving at rapid traverse rate—that is, function G00 X190 Y-5 to the starting point adjacent to the workpiece—whereupon down feed takes place with function G00 Z20 after switching on the spindle rotation.

Machining of the outer contour is then accomplished with the following G functions: The supplementary function F produces the necessary feed rate in mm/min. The down feed depth is taken up by the milling cutter at the starting point.

G01	Y130	F200			Straight line from starting point to P2
G01	X100				Straight line from P2 to P3
G01	X105	F150			Straight line from P3 to P4
G02	X70	Y105	R15		Radial arc, clockwise, with 15 radius
G01	Y130	F200			Straight line from P5 to P6
G01	X10				Straight line from P6 to P7
G01	Y20				Straight line from P7 to P8
G03	X20	Y10	R10	F150	Radial arc, counterclockwise with 10 radius
G01	X190	F200			Straight line from P9 to P1

TABLE 26-2 Definitions of Common NC Words

NC Word	Use
N	*Sequence number:* identifies the block of information
G	*Preparatory function:* requests different control functions, including preprogrammed machining routines
X, Y, Z, B	*Dimensional coordinate data:* linear and angular motion commands for the axis of the machine
F	*Feed function:* sets feed rate for this operation
S	*Speed function:* sets cutting speed for this operation
T	*Tool function:* tells the machine the location of the tool in the tool holder or tool turret
M	*Miscellaneous function:* turns coolant on or off, opens spindle, reverses spindle, tool change, etc.
EOB	*End of block:* indicates to the MCU that a full block of information has been transmitted and the block can be executed

For milling the slot, the milling cutter is first retracted by G01 Z35 from the workpiece to point P1 shown in Figure 26-13d.

Because the width of the slot is equal to the cutter diameter, the path of the cutter is easy to program. The tool radius compensation feature is switches off (by G40) so the following traverse instructions refer to the cutter center line axis.

Milling of the slot is accomplished by the following instructions:

G00	X160	X100		Rapid traverse to point P10
G01	Z20	F150		Down feed at point P10
G01	X130	Y45	Z10	Straight line from P10 to P11
G01	Z35	F200		Retraction from workpiece
G00	X300	Y300		Rapid traverse away from workpiece

After the program has been written, it is *verified*, which means the steps in making the part are graphically simulated. The verification step can use the computer monitor, which simulates the part being made by tracing all the toolwork paths as they would occur on the machine tool. Sometimes a sample part is machined in plastic or machinable wax for checking the part specifications from the drawing against the real part.

The program can be directly entered into the control panel of a CNC machine. Usually, longer programs are entered by tape or disk and short programs are entered manually. The inputs may be in binary code (in older machines) or in arabic numbers with verbal commands that the machine understands.

Historically, punched tape was used to control the movements. The idea came from the old player-piano roll, which was a form of tape control, and punched cards had been used for many years for controlling complicated weaving and business machines. Thus tape control of machine tools was an extension of an existing basic concept in which holes, representing information that has been punched into the tape, are read by sensing devices and used to actuate the devices that control various electrical or mechanical mechanisms.

Over the years, four basic types of tape format have been used for NC input to communicate dimensional and nondimensional information: *fixed-sequential format, block-address format, tab-sequential format,* and *word-address* format. Most new NC or CNC systems use the word-address format, which allows the words to be presented in any order and is the most flexible.

Today, CNC machines permit the user to program the interface between the machine tool and the control, greatly reducing the number of machining system components and interconnections. Current CNCs have extensive self-diagnostics and performance-monitoring systems. The greatest advances in CNC technology, however, are in part programming, where easy-to-use, menu-driven software makes programming almost as simple as setting up the machine manually. With older NC machines, the operator could override the program when necessary but could not reprogram the machine unless a new program was written. The CNC machine has the capability of reading a program into its computer memory, and the program can be modified at the machine like any other computer program.

On CNC machines, the machine tool operator may perform all the programming steps right at the console of the machine, programming the processing steps for the part directly into the computer memory. The program can be saved by having the machine print out a copy of the program, which can be used later for reorders of the same part. Features such as program edit, canned routines, program storage, diagnostics, constant surface speed, and tape punch are common on today's CNC machines.

As more and more design work is done on the computer (CAD) using databases and software that are compatible to the machine tools, there will be less dependence on tape for program storage and more utilization of floppy disks, hard disks, and other typical computer storage means. For example, a machining cell composed of NC machine tools designed for a family of 10 component parts is able to make the 10 different parts without needing retooling or refixturing, but it will still have 10 different programs for these parts for each machine. If the programs are stored in the computer, they can be readily accessed, but if they are stored on disk, delays will occur in dumping the different programs into or out of the control computer.

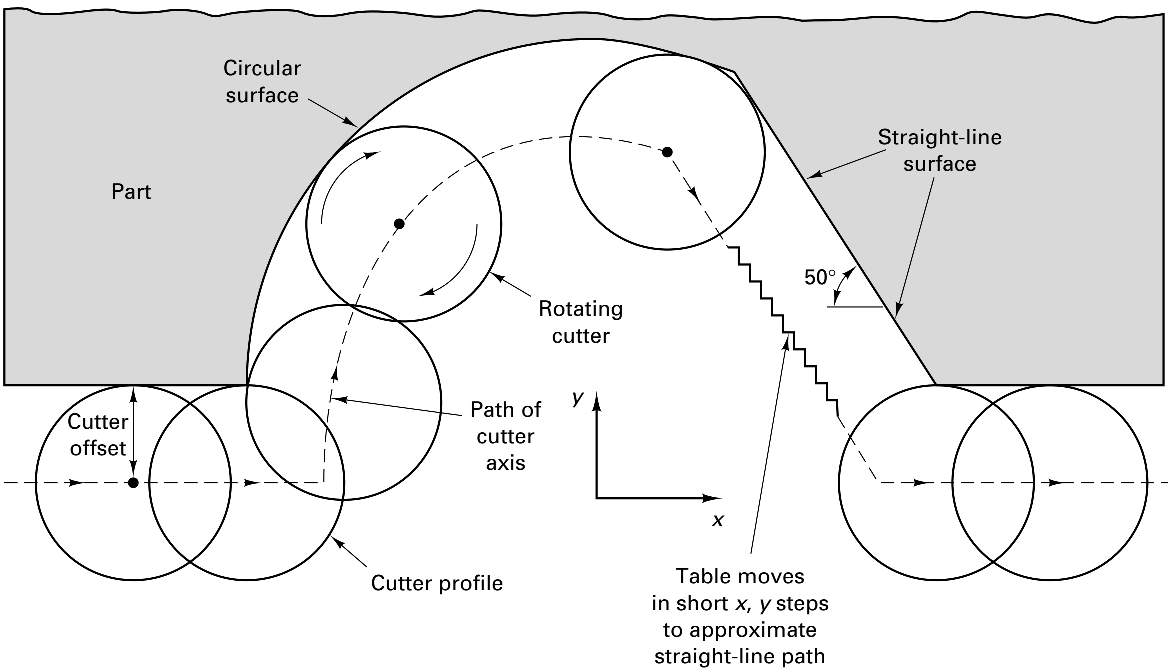

FIGURE 26-14 Two classic problems in NC programming are the determination of cutter offset and interpolation of cutter parts.

Cutter Offset and Interpolation in Numerical Control. Although the majority of NC and tape-controlled machine tools do not provide for machining contoured surfaces, most CNC and DNC machines do. The required curves and contours are generated approximately by a series of very short straight lines or segments of some type of regular curves, such as hyperbolas. This is called *interpolation*. The program fed to the machine is arranged to approximate the required curve within the desired accuracy. Figure 26-14 illustrates how a desired straight-line or curved surface can be approximated by means of short segments. Interpolation refers to the fact that curved surfaces as generated by machine tools must be approximated by a series of very short, straight-line movements in the x,y, and z directions. The length of the segment must be varied in accordance with the deviation permitted. Most NC machine tools with contouring capability will produce a surface that is within 0.001 in. of the one desired, and many will provide considerably better performance. Most contouring machines have either two- or three-axis capability, but five-axis capability as shown in Figures 26-7 and 26-15 are readily available.

In milling machines, the centerline of the cutter is offset from the desired surface by the radius of the cutter. The path that the cutter needs to take to generate the desired geometry is not simply the perimeter or profile of the part. Thus cutter offset programs must be included in the software. Obviously, contour machining (with cutter offset and interpolation) requires that complex information be entered into the computer because the number of straight-line or curved segments may be quite large. Manual programming of the tape can be quite laborious. Computer programming can translate simple commands into the complex information required by the machine.

■ 26.3 MACHINING CENTER FEATURES AND TRENDS

Computer numerical control is used on a wide variety of machine tools. These range from single-spindle drilling machines, which often have only two-axis control and can be obtained for about \$10,000, to machining centers, such as shown in Figure 26-15. The machining center can do drilling, boring, milling, tapping, and so on, with four- or five-axis control. It can automatically select and change 40 to 180 preset tools. The table can move left/right and in/out, and the spindle can move up/down and in/out, with positioning accuracy in the range 0.00012 in. with repeatability to ±.00004 in. over 40 in. of travel.

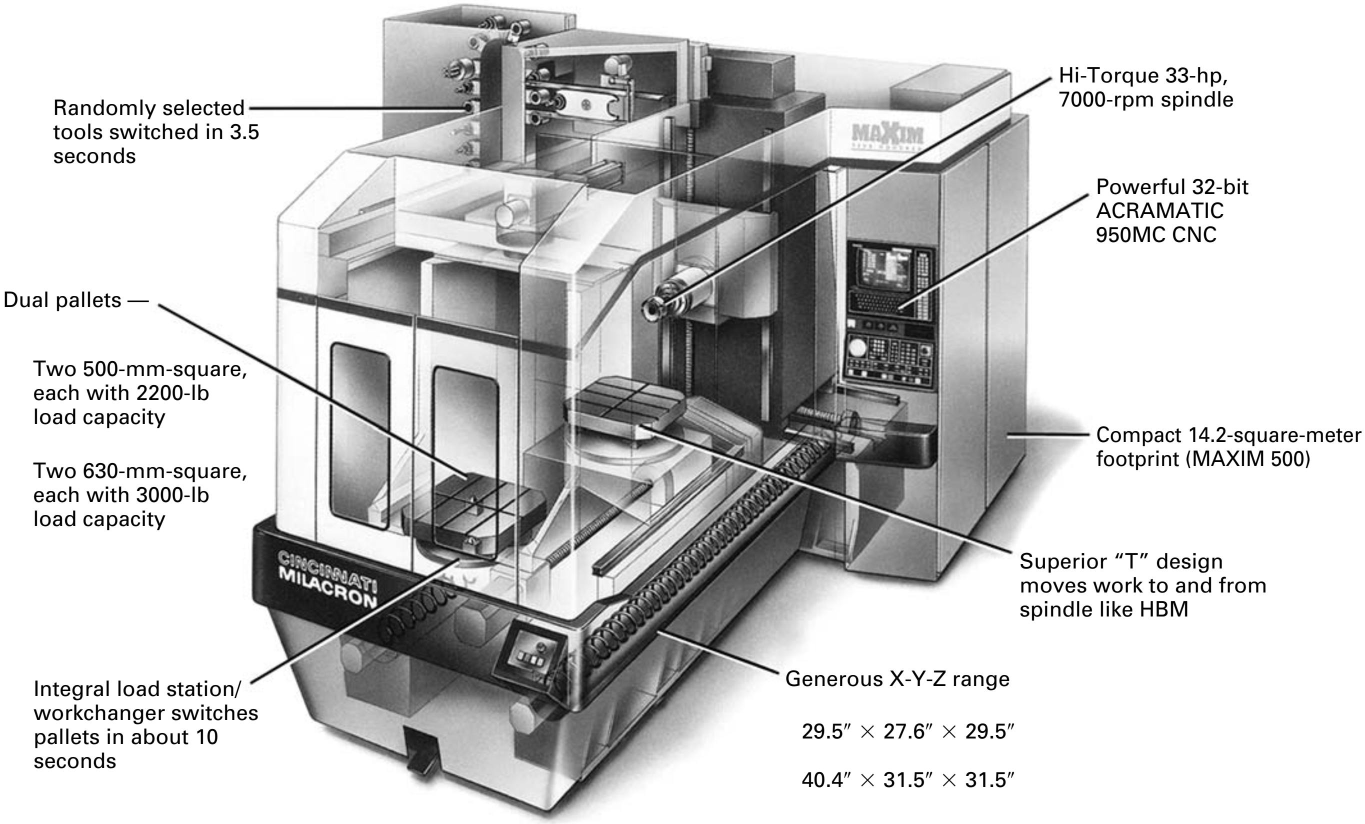

FIGURE 26-15 Modern machining centers will typically have horizontal spindles with rpms up to 15,000, dual pallets, and cutting-tool magazines holding 40 to 100 tools.

Beyond accuracy and repeatability and the number of controlled axes, CNC machines are also categorized by spindle speed, horsepower, and the size of the workpiece. The accuracy and repeatability (precision) result from a combination of factors including the resolution of the control instrumentation and the accuracy of the hardware. The control resolution is the minimum length distinguishable by the control unit. It is called the base length unit (BLU) and is mainly a factor of the axis transducer and the quality of the leadscrew or linear translator. There are many sources of error in a machine, including wear in the machine sliding elements, machine tool assembly errors, spindle runout (wear), and leadscrew backlash.

Tool deflection due to the cutting forces produces dimensional error and chatter marks. Thermal error, caused by the thermal expansion of machine elements, is not uniform and is normally the greatest source of machine error. Methods used to remove heat from a machine include cutting fluids, locating drive motors away from the center of a machine, reducing friction from the ways and bearings, and spray cooling control element of the machine.

Most modern machining centers have automatic tool-change and automatic work-transfer capability, so that workpieces can be loaded and unloaded while machining is in process. Such a machine can cost over $200,000. Between these extremes are numerous machine tools that do less varied work than the highly sophisticated machining centers but that combine high output and minimum setup time with remarkable flexibility (large number of tool motions provided).

CNC TURNING CENTERS

The modern lathe has CNC control and tools mounted in turrets on slanted beds. The tailstock has been replaced by a live, powered spindle and chuck. On some lathes the concept of automatic tool changing has been implemented. The tools are held on a rotating tool magazine, and a gantry-type tool changer is used to change the tools. Each magazine

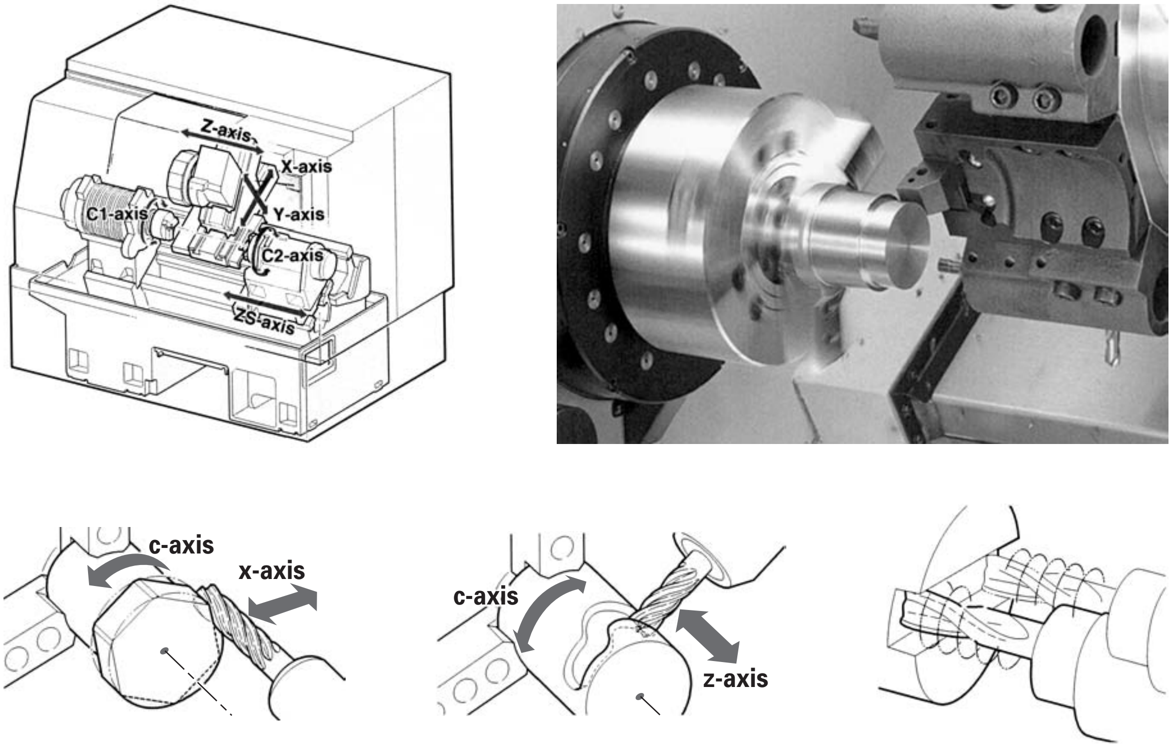

FIGURE 26-16 This CNC turning center has a multiple-axis capability with two spindles and a 12-tool turret with X, Y, and Z control as well as axis control of the spindles.

holds one type of cutting tool. This is an example of the trend of providing greater versatility along with high productivity in lathes. The versatility is being further increased by combining both rotary-work and rotary-tool operations—turning and milling in a single machine. Live, powered, or driven tools replace regular tools in the turrets and perform milling and drilling operations when the spindle is stopped. See Figure 26-16.

OTHER NC MACHINES

Numerical control has been applied to a wide variety of other production processes. NC turret punches with X-Y control on the table, CNC wire EDM machines, laser and water-jet abrasive machining, flame cutters, and many other machines are readily available. Some new trends are being observed in the development of machining centers, such as smaller, compact machining centers with higher spindle speeds. Machines with four- and five-axis capability are readily available. Modern machining centers have contributed significantly to improved productivity in many companies. They have eliminated the time lost in moving workpieces from machine to machine and the time needed for workpiece loading and unloading for separate operations. In addition, they have minimized the time lost in changing tools, carrying out gaging operations, and aligning workpieces on the machine.

The latest generation of machining centers is aimed at further improving utilization by reducing the time when machines are stopped, either during pauses in a shift or between shifts. Delays are caused by tool breakage, unforeseen tool wear, a limited number of tools, or an inadequate number of available workpieces. Machines are fitted with tool breakage monitors, tool wear compensating devices, and means for increasing the number of tools and workpieces available.

Probes on CNC machines can greatly improve the process capability of the machine tool. There is a big difference between the claimed program resolution for an NC machine and the accuracy and precision (the process capability) of the actual parts. As shown in Figure 26-17, true positioning accuracy and precision are affected by machine alignment, machine and fixture setup, variations in the workholding device, raw material variations, workpiece location in the fixture variations, and cutting-tool tolerances.

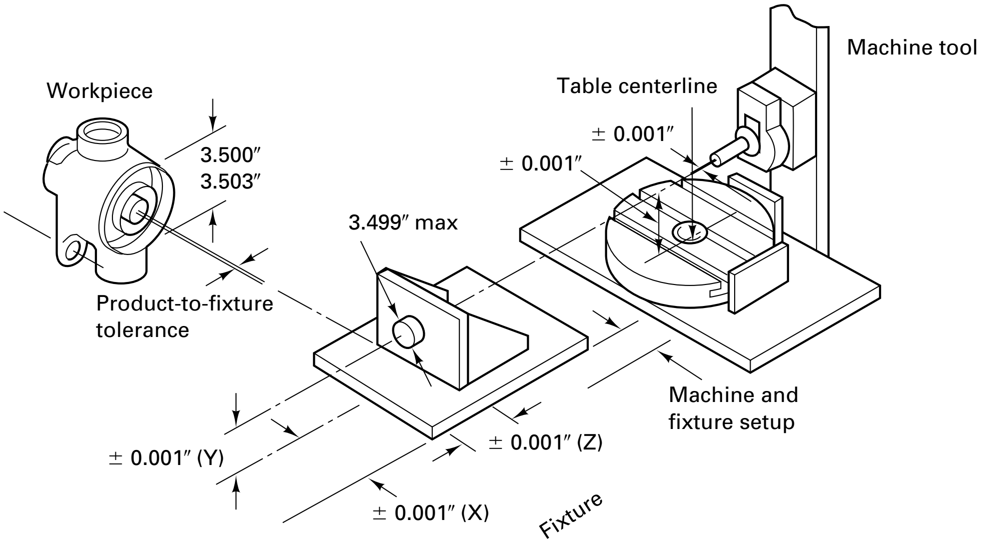

FIGURE 26-17 Process capability in NC machines is affected by many factors.

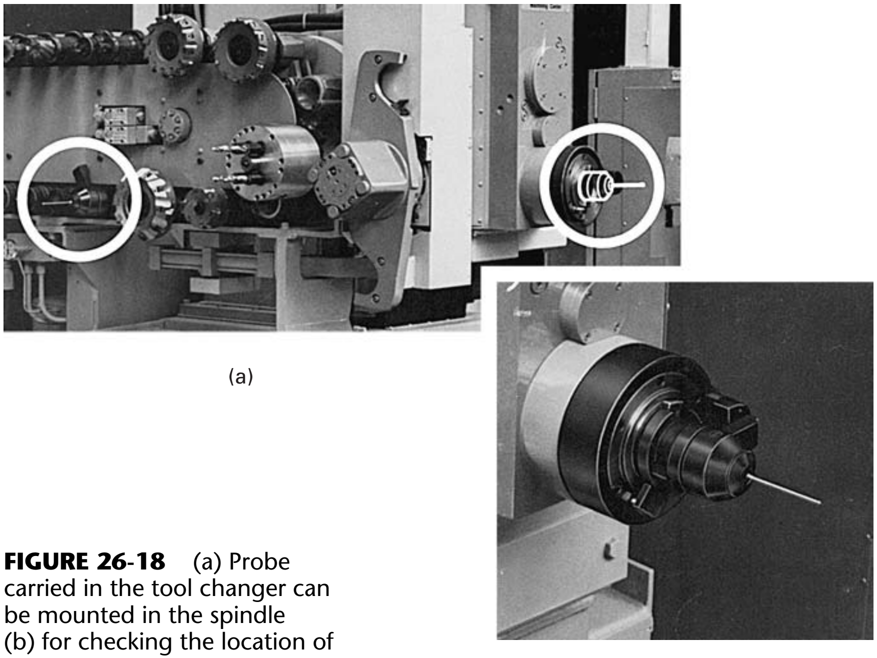
Thus the finished workpiece may be unacceptable even though the machine is more than capable of producing the part to the design specifications. The part program has no assurance that the part is properly located in the fixture or that the fixture is properly located on the table of the machine. However, a probe, carried in the tool storage magazine and mounted when needed in the spindle like a cutting tool, can establish the location of the surface features relative to each other and to the spindle axis within 0.0005 in. (Figure 26-18). The machine controller, using the probe data, will then shift the program reference data accordingly. The probe can be used to determine the amount of material on a rough casting, locate a corner of a part, define the center of a hole, or check for the presence or absence of a feature. All of the variability described in Figure 26-17 can be compensated for except for variations in the cutting-tool geometry or tool wear. A probe mounted on the machine tool can be used to automatically update tool-offset data in the control computer. Thus the machine tool can function as a coordinate measuring machine. By comparing the actual touched location with the programmed location, the measuring routine determines appropriate compensation.



(a)

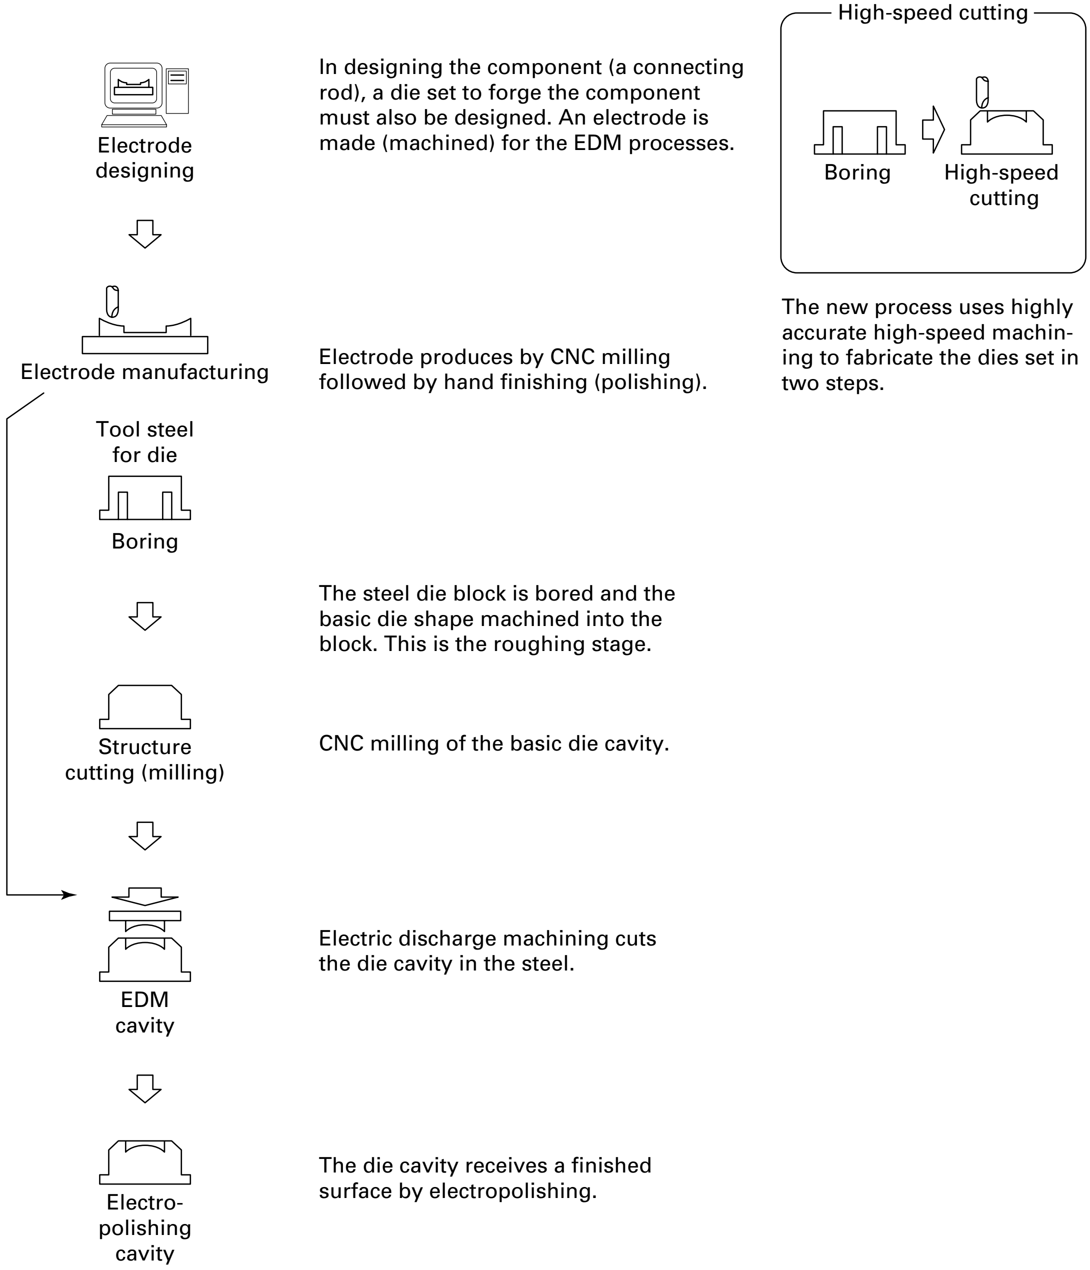
(b)

FIGURE 26-18 (a) Probe carried in the tool changer can be mounted in the spindle (b) for checking the location of part features accurately.

Many of the new machining centers are equipped with novel automatic pallet changers and workpiece loading and unloading devices. Robots are increasingly being applied for workpiece handling in machine groups, including manufacturing cells. In some cases the robot is also used for tool-changing functions.

26.4 ULTRA-HIGH-SPEED MACHINING CENTERS (UHSMCS)

Anyone involved in the product development process knows that the longest lead-time path from a new product (like a car) design to a finished product coming off the final assembly line always includes the die-making process. For example, in the automotive industry, each new car design may have many die sets for forged and sheet metal parts. Machining of the dies is a key process in the conventional die-making process (see Figure 26-19), where the major steps are milling, electronic discharge machining (EDM), polishing, die assembly, tryout, and modification.



In designing the component (a connecting rod), a die set to forge the component must also be designed. An electrode is made (machined) for the EDM processes.

Electrode produces by CNC milling followed by hand finishing (polishing).

The steel die block is bored and the basic die shape machined into the block. This is the roughing stage.

CNC milling of the basic die cavity.

Electric discharge machining cuts the die cavity in the steel.

The die cavity receives a finished surface by electropolishing.

The new process uses highly accurate high-speed machining to fabricate the dies set in two steps.

FIGURE 26-19 The process to manufacture dies for forging processes is shown on the left. Using ultra-high-speed machining centers reduces the sequence to two steps.

Ultra-high-speed machining centers (UHSMCs) are available to shorten the die-making process lead time. The new machining centers have highly accurate high-speed spindles capable of rpms of 30,000 to 50,000, cutting feed rates of 60 m/min, and cutting feed accelerations of 9.8 m/sec^2. The machine requires a spindle with high stiffness utilizing ceramic ball bearings with a constant-pressure preload mechanism and jet lubrication for superior performance.

Robust machining centers of this sort are capable of very high metal removal rates, particularly in materials like aluminum. However, before investing in a high-speed machining center (HSMC), many issues must be addressed. The new machine will usually require the purchase of new cutting tools and tool holders. At the higher rpms and feed rates, smaller-diameter tools are easier to balance. Tungsten carbide is the primary tool material. Make sure the insert retention mechanism is adequate in case of a failure. Other major problems will include chatter and removal of the large volume of chips.

UHSMCs require exceptionally accurate, stiff spindles using ceramic ball bearings, raising the possible rpm as compared to regular ball bearings, air bearings, or magnetic bearings. As shown schematically in Figure 26-20, synchronized sets of ball screws are used to feed the tool in the X and Y directions to reduce the errors caused by distortion in the frame during rapid acceleration of the tool. These machines have usually four or five axes under control and represent the pinnacle of machine tool development at this time.

26.5 SUMMARY

Numerical control machines, robots, FMSs, and computers are critical elements of the advanced manufacturing technologies available for the next decade, which is being touted as the time when computer-integrated manufacturing (CIM) will become a widespread

reality. Computer technology abounds: computer-aided design; computer-aided manufacturing with NC, CNC, or A/C and DNC; computer-aided process planning; computer-aided testing and inspection (CATI); artificial intelligence; smart robots; and much more. But a word of caution: Any company can buy computers, robots, and other pieces of automation hardware and software. The secret to manufacturing success lies in the design of a simple, unique manufacturing system that can achieve superior quality at low cost with on-time delivery and still be flexible. Flexibility means the system can readily adapt to changes in the customer demand (both volume and mix) while quickly implementing design changes. This requires a visionary management team and a change in culture at all levels, starting on factory floor with an empowered and involved workforce. Changing how people work in a manufacturing system means you have to redesign the system. No better example of this can be found than the Toyota Motor Company. Led by their vice president for manufacturing, Taiichi Ohno, who conceived, developed, and implemented Toyota's unique manufacturing system, this company has emerged as the world leader in car production. The implementation of this system has saved many companies (Harley Davidson, for example) and carried many others to the top position in their industry. The Toyota system is unique and as revolutionary today as were the American Armory System (job shops) and the Ford system (flow shops) in their day. It is significant that virtually every manufacturing system or technology cited in this chapter is practiced at Toyota. This new system is now being called *lean production* (to contrast it to mass production). Toyota does not use the word *CIM* because the computer is only a tool used in their system, a manufacturing system design that recognizes people as the most flexible element (Black and Hunter, 2003). Students of industrial, mechanical and manufacturing engineering are well advised to be knowledgeable of this new unique system.

■ Review Questions

1. What human attribute is replaced by an NC machine?
2. Give an everyday example of a household device or appliance that exhibits feedback in its control system.
3. Explain how a toaster could be made a closed-loop device.
4. The first NC machines were closed-loop control. Later some machines were open loop. What change did this require on the part of machine tool builders?
5. Can a continuous-path NC machine be open loop? Why or why not?
6. How is a machining center different from a milling machine?
7. What role did John Parsons play in the development of NC?
8. What was DNC as first practiced, and what does DNC usually mean today?
9. Many manufacturers have purchased large machining centers tied to an ASRS. Go on the Internet to find an example of an ASRS, and explain how such a system works.
10. How does feedforward differ from feedback in a process control system?
11. Why was it necessary for machine tool builders to improve the leadscrews on their machines when they made them into NC machines?
12. Explain what is meant by *interpolation* in NC programming.
13. Explain the problem of cutter offset in NC programming by making a sketch showing an end mill cutting a perimeter on a square plate.
14. Some of the functions performed by the operator in piece-part manufacturing are very difficult to automate completely. Name the functions and explain why.
15. Why do you think there are no NC shapers?
16. Why isn't manual programming used for continuous-path NC?
17. What are the three basic closed-loop feedback A(4) schemes used on CNC machines.
18. Which method for position feedback is the most accurate?
19. What is the difference between the zero reference point and the machine zero point?
20. What is an encoder?
21. What is a peck-drilling subroutine for a CNC machine?
22. What is pocket milling, and what kind of milling cutter is usually used to perform it?
23. How are probes used in CNC machines to improve process capability?
24. What are G words used for in NC?

25. Flexible manufacturing systems use CNC machines for processing and AGVs, robots, or conveyors to transport parts. So what differentiates the FMS from a transfer line?
26. What major changes are being introduced into UHSMCs?

■ Problems

1. What are the X and Y dimensions for the center position of holes 1, 2, and 3 in the part shown in Figure 26-7?
2. Configurations obtained from continuous-path machining are the result of a series of straight-line, parabolic-span or higher-order curves. The degree to which curved surfaces correspond to their design depends on how many lines or spans are used. Four equal chords in a circle describe a square (Figure 26-A). Six make a hexagon, and, as the number increases, the lines themselves come closer to a perfect circle. The number of lines needed is determined by a maximum tolerance allowed between the design of the curved section and the actual chord programmed. This is the dimension T. The program for a parabolic-span control unit requires enough spans for any deviation to stay within an acceptable tolerance. For a tolerance of $T = 0.001$ in., how long should the span be for a curve with a 5-in. radius.? Assume that the arc is part of a circle. What is the span angle here, in degrees?

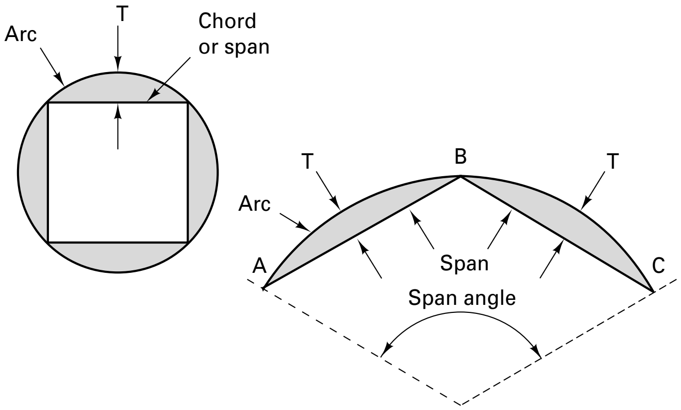

FIGURE 26-A

3. In Problem 2, suppose that the acceptable tolerance was 0.0001 in. Determine the span angle.
4. Suppose that the plate shown in Figure 26-B was to be profile milled around the periphery with a 1-in.-diameter end milling cutter. The dashed line is the cutter path. The programmer must calculate an offset path to allow for cutter diameter. Since the programmed points are followed by the cutter centerline and the profile is made at the tool's periphery, the programmer called for a $^{1}/_{2}$-in. cutter offset. Working with computer assistance, the programmer would describe the part profile to be machined and specify the cutter. The computer would generate the cutter path. Complete the table below to specify the cutter path, starting with the origin at the zero reference point. Move the tool around the plate counterclockwise.

Programmed Point Locations

PT	*X*	*Y*
1		
2		
3		
4		
5		
1		

5. Suppose that surface finish is very important for the profile milling job described in Problem 4. Thus down milling is going to be used. Rewrite the NC program points to accommodate this requirement. Show the new path on a sketch such as Figure 26-B. (Up versus down milling is discussed in Chapter 25.)
6. You have received the part drawing for a typical lathe part that will require turning, facing, grooving, boring, and threading as it is machined from a casting. See Figure 26-C. Unfortunately, you do not yet know how many of these parts will be ordered this year, so you do not know what the build quantity will be. To be prepared, you have developed some cost data for the manufacture of the part by four different lathe processes (see Table 26-A). Complete the table by determining the run cost per batch, the cost per unit at the various quantities, and the total cost per batch. Answer the following questions regarding this situation:

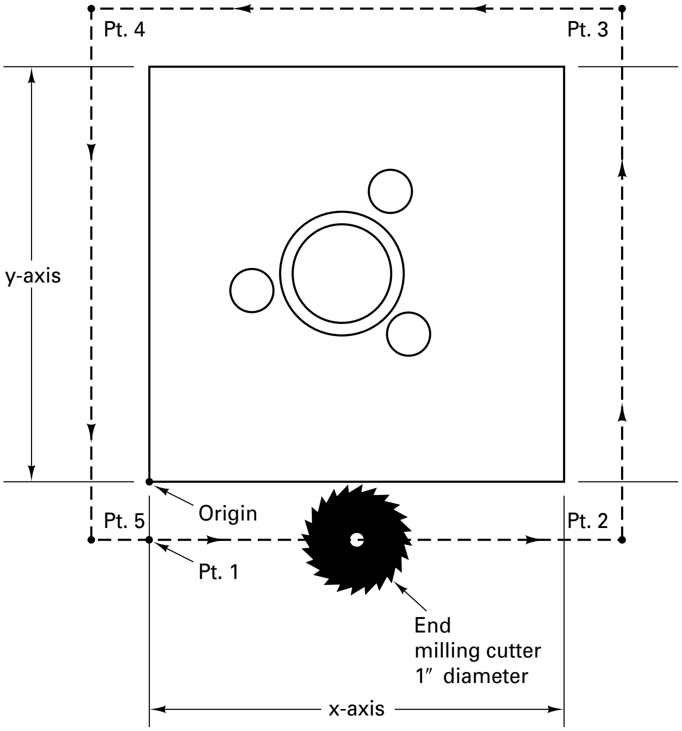

FIGURE 26-B

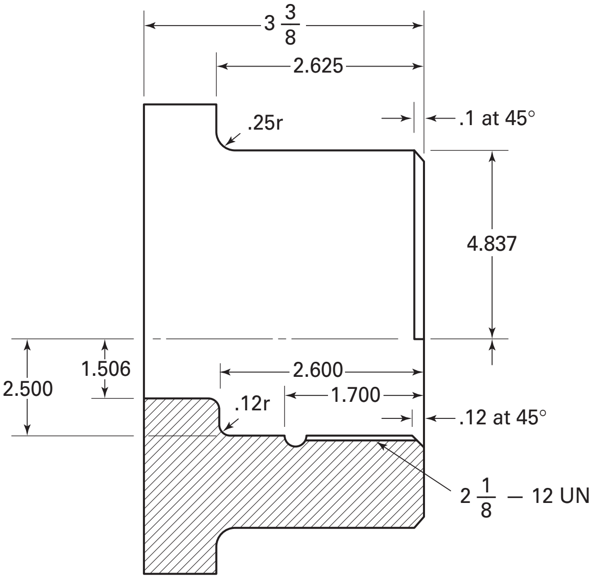

FIGURE 26-C

1. Of the four costs listed for each process, which costs are fixed and which are variable?
2. What is included in the cost per unit? Do you need to estimate the machining time per piece and the cycle time per piece, including the time to change parts and setups in order to compute run cost?
3. How would you go about estimating this time, and what time elements might be included in the cycle time in addition to the machining time?
4. How would you use this estimate of time in the cost table? Show the calculation.
5. Make a plot of cost in dollars versus quantity, with all four methods on one plot.
6. Make a plot of cost per unit versus quantity, again with all four methods on one plot. Find the break-even quantities. (*Hint:* Did you plot the data on log paper?)
7. Discuss the break-even quantities that you found in part 5 versus part 6. (They should be the same.)
8. When would you use the NC lathe? The turret lathe? When would you use the turret lathe if you have no NC lathe?

TABLE 26-A Cost Data for Lathe Processes

	Make Quantity				
	10,000 Units	1,000 Units	100 Units	10 Units	1 Unit
Cost to produce on six-spindle automatic					
Total cost of batch	—	—	—	—	—
Engineering 2.5 hr at $40 /hr	50.00	50.00	50.00	50.00	50.00
Tooling (cutting tools and workholders)	600.00	600.00	600.00	600.00	600.00
Setup 8 hr at $15/hr	120.00	120.00	120.00	120.00	120.00
Run cost per batch: 50 per piece	5000.00	500.00	50.00	5.00	0.5
Cost each	—	—	—	—	—
Cost to produce on turret lathe

Cost each	—	—	—	—	—

Chapter 26 CASE STUDY

Process Planning for the MfE

Figure CS 26a shows a part design for a small flange to be made out of 1020 steel. Prepare a sequence of operations or process plan to make this part. Note that you need to machine the top, bottom, and all the holes. Specify the machines and the tools you would use assuming you select bar stock as your raw material. The term Co bore in the drawing means counter bore. Check with your instructor for an example of a process plan. Assume the lot size here is 1200 parts/year made in lots of 120 every month.

Now assume that the designer provides you a design like CS 26b and calls for the flange to be made from cast iron. The casting will probably have a large hole in the center cored during the casting process. What casting process will you use? Prepare another process plan for the cast part. Will the sequence of operations be the same? What about the cost per unit? Which will be lower?

1. The part drawings failed to provide a critical specification in the design. What is it?
2. The drawing failed to show the final geometry (in the top view) correctly. Redraw the part to show these corrections.
3. As the process engineer, how would you advise the design engineer he screwed up twice?

CHAPTER 27

OTHER MACHINING PROCESSES

■ 27.1 INTRODUCTION

While milling, drilling, and turning make up the bulk of the machining processes, there are many other chipmaking (metal removal) processes. This chapter will cover shaping, planing, broaching, sawing, and filing.

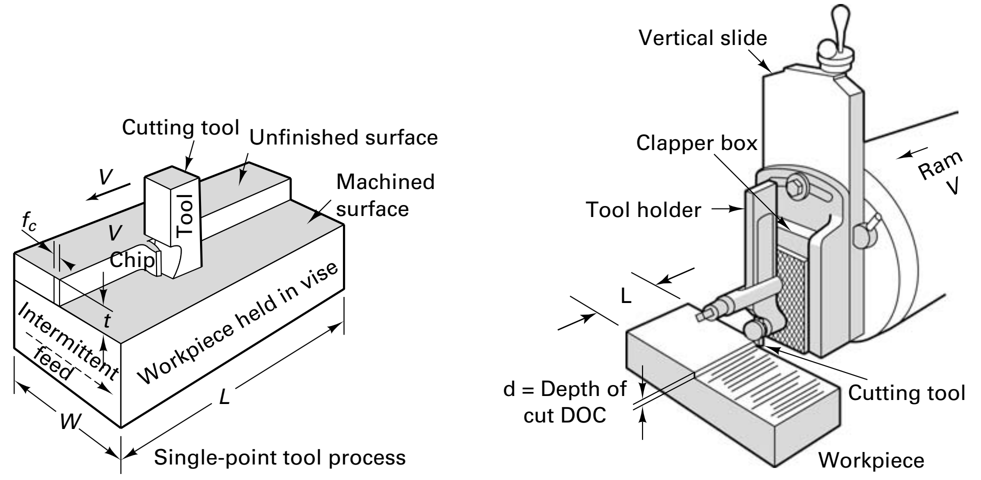
■ 27.2 INTRODUCTION TO SHAPING AND PLANING

The processes of *shaping* and *planing* are among the oldest single-point machining processes. Shaping has largely been replaced by milling and broaching as a production process, while planing still has applications in producing long flat cuts, like those in the ways of machine tools. From a consideration of the relative motions between the tool and the workpiece, shaping and planing both use a straight-line cutting motion with a single-point cutting tool to generate a flat surface.

In shaping, the workpiece is fed at right angles to the cutting motion between successive strokes of the tool, as shown in Figure 27-1, where f_c is the feed per stroke, V is the cutting speed, and d is the depth of cut (DOC). (In planing, discussed next, the workpiece is reciprocated and the tool is fed at right angles to the cutting motion.) For either shaping or planing, the tool is held in a clapper box, which prevents the cutting edge from being damaged on the return stroke of the tool. In addition to plain flat surfaces, the shapes most commonly produced on the shaper and planer are those illustrated in Figure 27-2. Relatively skilled workers are required to operate shapers and planers, and most of the shapes that can be produced on them can also be made by much more productive processes, such as milling, broaching, or grinding. Consequently, except for certain special types, planers that will do only planing have become obsolete. Today, shapers are used mainly in tool and die work, in very low volume production, or in the manufacture of gear teeth.

In shaping, the cutting tool is held in the tool post located in the ram, which reciprocates over the work with a forward stroke, cutting at velocity V and a quick return stroke at velocity V_R. The rpm of drive crank (N_s) drives the ram and determines the velocity of the operation (see Figure 27-1d). The stroke ratio is

$$R_s = \frac{\text{cutting stroke angle}}{360^\circ} = \frac{200^\circ}{360^\circ} = \frac{5}{9} \tag{27-1}$$



(a) Basic geometry for shaping and planing

(c) Shaper tool holder, clapper box and workpiece

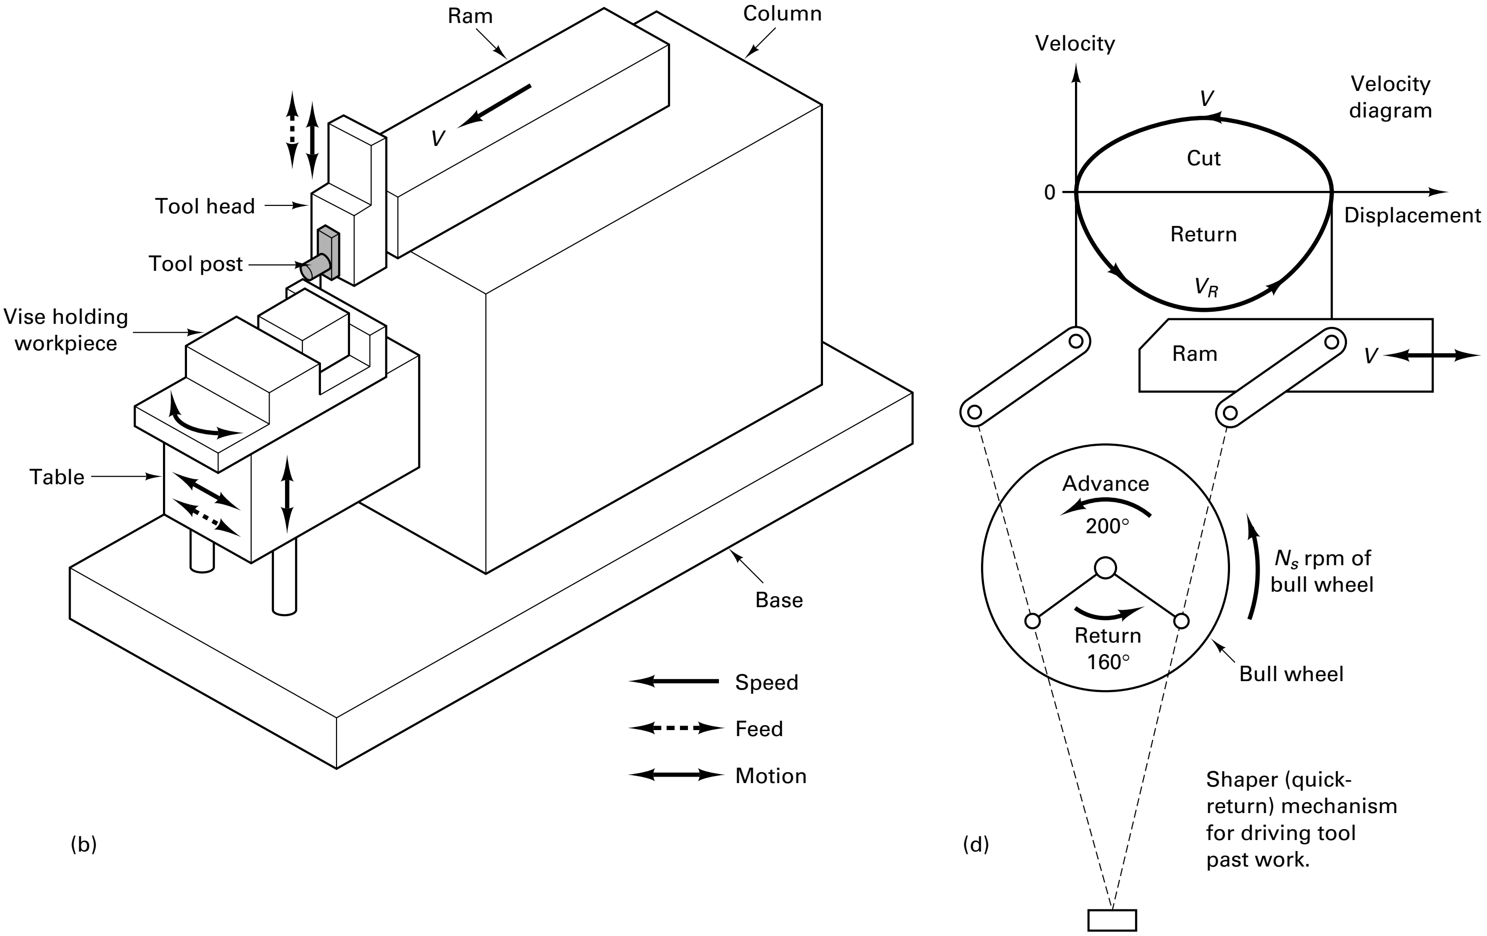


FIGURE 27-1 Basics of shaping and planing. (a) The cutting speed, V, and feed per stroke f_c. (b) Block diagram of the machine tool. (c) The cutting tool is held in a clapper box so the tool does not damage the workpiece on the return stroke. (d) The ram of the shaper carries the cutting tool at cutting velocity V and reciprocates at velocity V_R by the rotation of a bull wheel turning at rpm n_s.

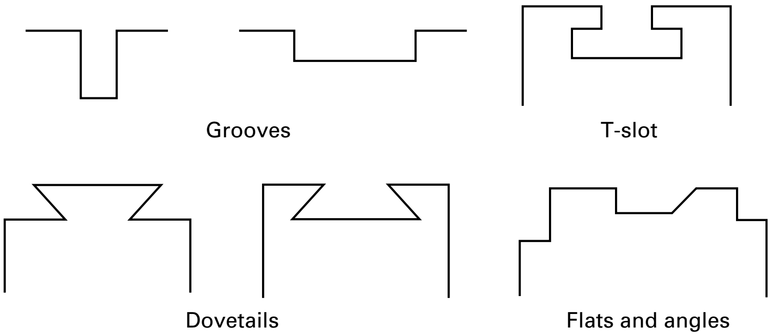

FIGURE 27-2 Types of surfaces commonly machined by shaping and planing.

The tool is advancing 55% of the time. The number of strokes per minute is determined by the rpm of the drive crank. Feed is in inches per stroke and is at right angles to the cutting direction. As in other machining processes, speed and feed are selected by the operator.

The length of stroke l must be greater than the length of the workpiece (or length of cut) L, since velocity is position variant. Let l = twice the length of the block being cut, or $2L$. The cutting velocity V is assumed to be twice the average forward velocity V of the ram. The general relationship between cutting speed and rpm is

$$V = \frac{\pi D N_s}{12 R_s} \text{ft/min} \tag{27-2}$$

where D is the diameter (of the rotating bull wheel) in inches. For shaping, the cutting speed is

$$V = \frac{2 I N_s}{12 R_s} \text{ft/min} \tag{27-3}$$

Once a cutting speed is selected, the rpm of the machine can be calculated. Tables for suggested feed values, f_c, are in inches per stroke (or cycle), and recommended depths of cut are also available. The maximum depth of cut is based on the horsepower available to form the chips. This calculation requires that the metal removal rate (MRR) be known. The MRR is the volume of metal removed per unit time

$$\text{MRR} = \frac{LWd}{T_m} \text{in.}^3/\text{min} \tag{27-4}$$

where W is the width of block being cut and L is the length of block being cut, so volume of cut = WLd, where d is the depth of cut and T_m is the time in minutes to cut that volume.

In general, T_m is the total length of the cut divided by the feed rate. For shaping, T_m is the width of the block divided by the feed rate f_c of the tool moving across the width. Thus, for shaping,

$$T_m = \frac{W}{N_s \times f_c} \tag{27-5}$$

Also,

$$T_m = \frac{S}{N_s} \tag{27-6}$$

where the number of strokes for the job is for a surface of width W.

MACHINE TOOLS FOR SHAPING

Shapers, as machine tools, are usually classified according to their general design features as follows:

1. Horizontal
   - **a.** Push-cut
   - **b.** Pull-cut or draw-cut shaper

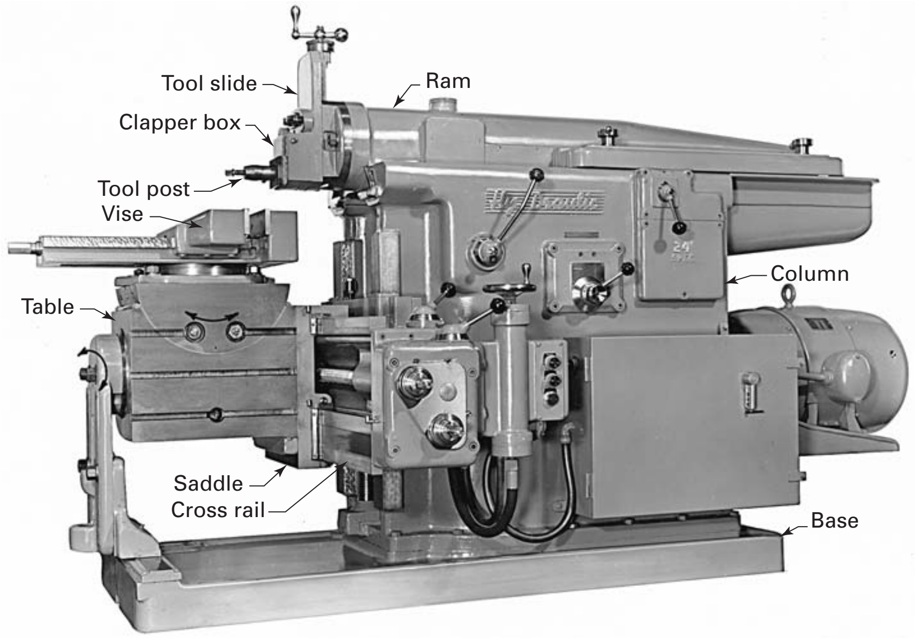

FIGURE 27-3 The most widely used shaper is the horizontal push-cut machine tool, shown here with no tool in the tool post.

2. Vertical
   a. Regular or slotters
   b. Keyseaters
3. Special

They are also classified as to the type of drive employed: *mechanical drive* or *hydraulic drive*. Most shapers are of the *horizontal push-cut* type (Figure 27-3), where cutting occurs as the ram *pushes* the tool across the work.

On horizontal push-cut shapers, the work is usually held in a heavy vise mounted on the top side of the table. Shaper vises have a very heavy movable jaw, because the vise must often be turned so that the cutting forces are directed against this jaw.

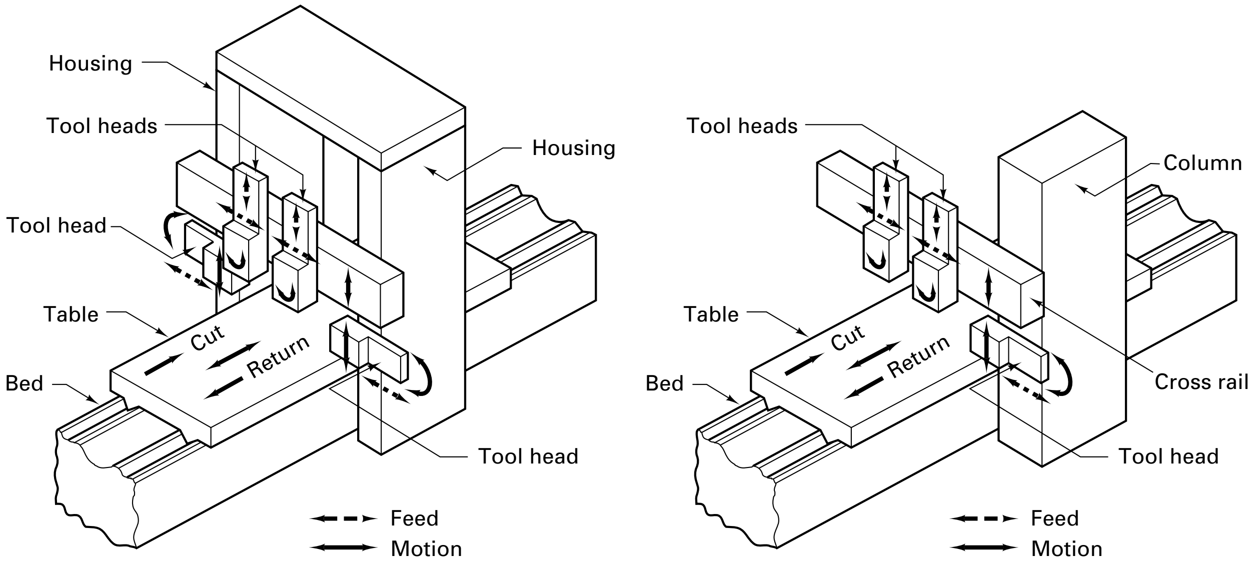
In clamping the workpiece in a shaper vise, care must be exercised to make sure that it rests solidly against the bottom of the vise (on parallel bars) so that it will not be deflected by the cutting force and so that it is held securely yet not distorted by the clamping pressure.

Most shaping is done with simple high-speed-steel or carbide-tipped cutting tool bits held in a heavy, forged tool holder. Although shapers are versatile tools, the precision of the work done on them is greatly dependent on the operator. Feed dials on shapers are nearly always graduated in 0.001-in. divisions, and work is seldom done to greater precision than this. A tolerance of 0.002 to 0.003 in. is desirable on parts that are to be machined on a shaper, because this gives some provision for variations due to clamping, possible looseness or deflection of the table, and deflection of the tool and ram during cutting.

PLANING MACHINES

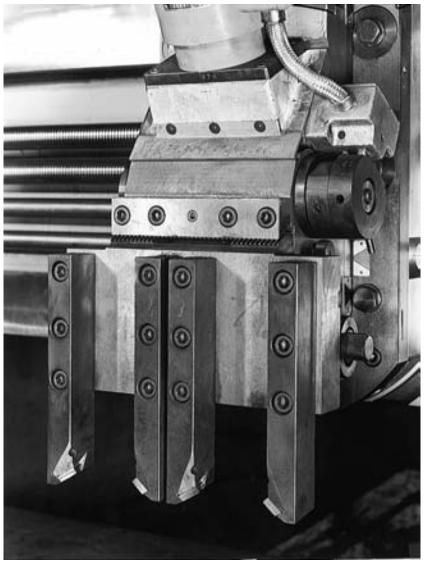
Planing can be used to produce horizontal, vertical, or inclined flat surfaces on large workpieces (too large for shapers). However, planing is much less efficient than other basic machining processes, such as milling, that will produce such surfaces. Consequently, planing and planers have largely been replaced by planer milling machines or machines that can do both milling and planing.

Figure 27-4 shows the basic components and motions of planers. In most planing, the action is opposite to that of shaping. The work is moved past one or more stationary single-point cutting tools. Because a large and heavy workpiece and table must be reciprocated at relatively low speeds, several tool heads are provided, often with multiple tools in each head. In addition, many planers are provided with tool heads arranged so that cuts occur on both directions of the table movement. However, because only single-point cutting tools are used and the cutting speeds are quite low, planers are low in productivity as compared with some other types of machine tools.



(a) Block diagram showing the basic components of a double-housing planer.

(b) Block diagram of an open-side planer.



(c) Four planer tools in tool holder

FIGURE 27-4 Schematic of planers. (a) Double-housing planer with multiple tool heads (4) and a large reciprocating table; (b) single-housing or open-sided planer; (c) interchangeable multiple tool holder for use in planers. *(Photograph courtesy Gebr Boehringer GmbH.)*

Figure 27-4 depicts the most common double-housing and single-housing types. The double-housing has a closed-housing structure, spanning the reciprocating worktable, with a cross rail supported at each end on a vertical column and carrying two tool heads. An additional tool head is usually mounted on each column, so that four tools (or four sets) can cut during each stroke of the table. Obviously, the closed-frame structure of this type of planer limits the size of the work that can be machined. Open-side planers have the cross rail supported on a single column. This design provides unrestricted access to one side of the table to permit wider workpieces to be accommodated. Some open-side planers are convertible, in that a second column can be attached to the bed when desired so as to provide added support for the cross rail.

WORKHOLDING AND SETUP ON PLANERS

Workpieces in planers are usually large and heavy. They must be securely clamped to resist large cutting forces and the high-inertia forces that result from the rapid velocity changes at the ends of the strokes. Special stops are provided at each end of the workpiece to prevent it from shifting.

Considerable time is usually required to set up the planer, thus reducing the time the machine is available for producing chips. Sometimes special setup plates are used for quick setup of the workpiece. Another procedure is to use two tables. Work is set up on one table while another workpiece is being machined on the other. The tables can be fastened together for machining long workpieces.

The large workpieces can usually support heavy cutting forces, so large depths of cut are recommended, which decrease the cutting time. Consequently, planer tools usually are quite massive and can sustain the large cutting forces. Usually, the main shank of the tools is made of plain-carbon steel, with tips made from high-speed steel or carbide. Chip breakers should be used to avoid long and dangerous chips in ductile materials.

Theoretically, planers have about the same precision as shapers. The feed and other dimension-controlling dials are usually graduated in 0.001-in. divisions. However, because larger and heavier workpieces are usually involved, and much longer beds and tables, the working tolerances for planer work are somewhat greater than for shaping.

■ 27.3 INTRODUCTION TO BROACHING

The process of *broaching* is one of the most productive of the basic machining processes. The machine tool is called a *broaching machine* or a *broach* and the cutting tool is also called the *broach*. Figure 27-5 shows the basic shape of a conventional pull broach. In this figure, P = pitch, n_s is the number of semiroughing teeth, and n_f is the number of finishing teeth where the rise per tooth gets smaller from rough to finish.

The feed per tooth in broaching is the change in height of successive teeth. This is called the rise per tooth (RPT or t_r; see Figure 27-6). Broaching looks similar to sawing except that the saw makes many passes through the cut, whereas the broach produces a finished part in one pass. The heart of this process lies in the broaching tool, in which roughing, semifinishing, and finishing teeth are combined into one tool, as shown in Figure 27-5. Broaching is unique in that it is the only one of the basic machining processes in which *feed*, which determines the chip thickness, is built into the cutting tool. The machined surface is always the inverse of the profile of the broach, and, in most cases,

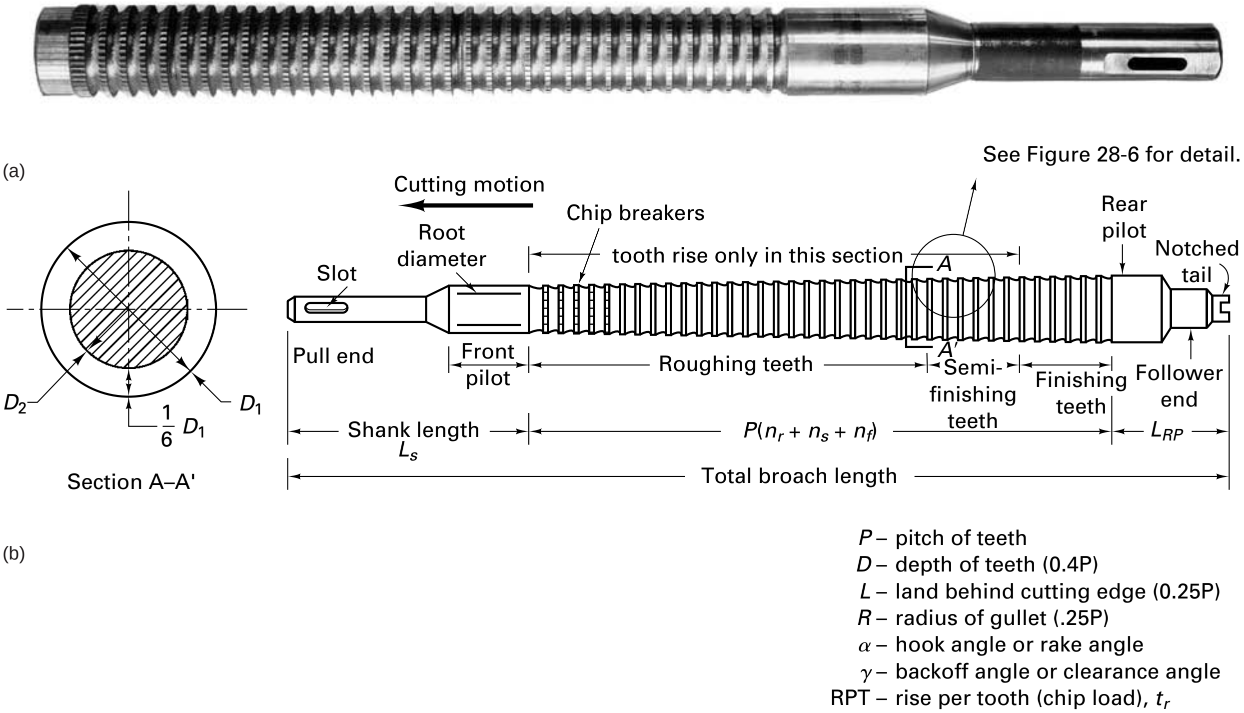


FIGURE 27-5 (a) Photo of pull broach. (b) Basic shape and nomenclature for a conventional pull (hole) broach. Section A–A′ shows the cross section of a tooth. P = pitch; n_r=number of roughing teeth; n_s = number of semifinishing teeth; n_f = number of finishing teeth.

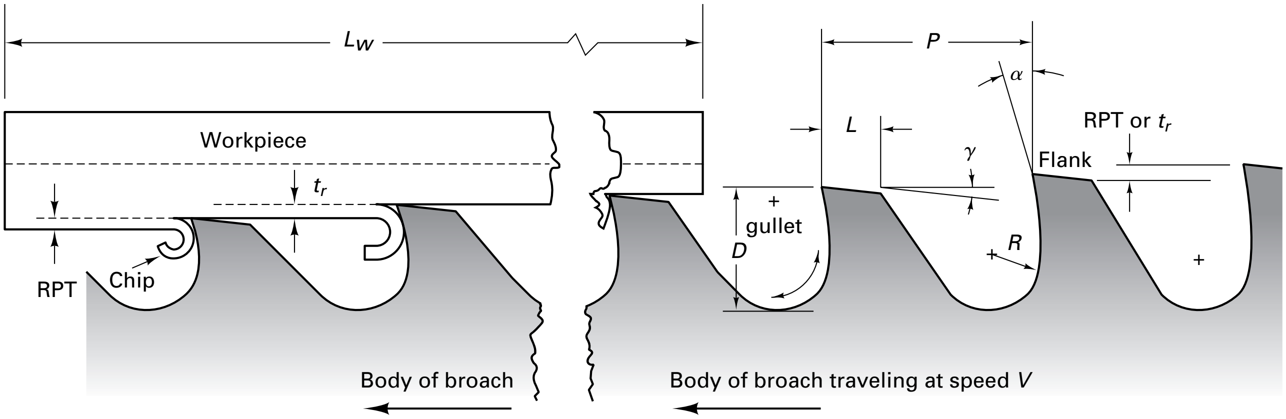

FIGURE 27-6 The feed in broaching depends on the rise per tooth t_r (RPT). The sum of the RPT gives the depth of cut, DOC. P = pitch of teeth; D = depth of teeth ($0.4P$); L = land behind cutting edge ($0.25P$); R = radius of gullet ($0.25P$); α = hook angle or rake angle; γ = backoff angle or clearance angle.

it is produced with a single linear stroke of the tool across the workpiece (or the workpiece across the broach).

Broaching competes economically with milling and boring and is capable of producing precision-machined surfaces. The broach finishes an entire surface in a single pass. Broaches are used in production to finish holes, splines, and flat surfaces. Typical workpieces include small to medium-sized castings, forgings, screw-machine parts, and stampings.

This rise per tooth (RPT), also known as *step* or the feed per tooth, determines the amount of material removed. No feeding of the broaching tool is required. The frontal contour of the teeth determines the shape of the resulting machined surface. As the result of these conditions being built into the tool, no complex motion of the tool relative to the workpiece is required and the need for highly skilled machine operators is minimized.

Figure 27-7 shows a *pull broach* in a vertical pull-down broaching machine. The pull end of the broach is passed through the part, and a key mates to the slot. The broach is pulled through the part. The broach is retracted (pulled up) out of the part. The part is transferred from the left fixture to the right fixture. One finished part is completed in every manufacturing cycle.

27.4 FUNDAMENTALS OF BROACHING

In broaching, the tool (or work) is translated past the work (or tool) with a single stroke of velocity V. The feed is provided by a gradual increase in height of successive teeth. The rise per tooth varies depending on whether the tooth is for roughing (t_r), semifinishing (t_s), or final sizing or finishing (t_f). In a typical broach there are three to five semifinishing and finishing teeth specified. The number of roughing teeth must be determined so that broach length, which is needed to estimate the cutting time, can be calculated. Other lengths needed for a typical pull broach are shown in Figure 27-6. The chip breakers in the first section of roughing teeth may be extended to more teeth if the cut is heavy or material difficult to machine. The distance between the teeth, called the pitch P, is important because it determines the tooth construction and strengths and the number of teeth actually cutting at a given instant. It is preferable that at least two teeth be in contact with the workpiece at any instant.

The pitch or distance between teeth is

$$P \cong 35\sqrt{L_w} \tag{27-7}$$

where length of cut usually equals L_w, as shown in Figure 27-5.

The number of roughing teeth is

$$n_r = \frac{\text{DOC} - n_s t_s - n_f t_f}{t_r} \tag{27-8}$$

where DOC is the total amount of metal to be removed and is the rise per tooth.

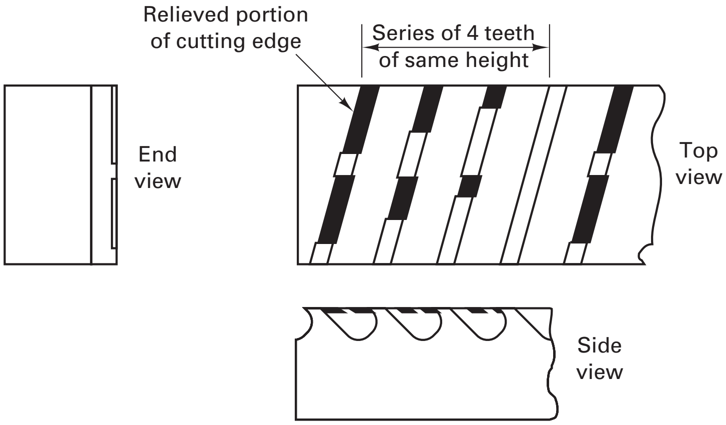
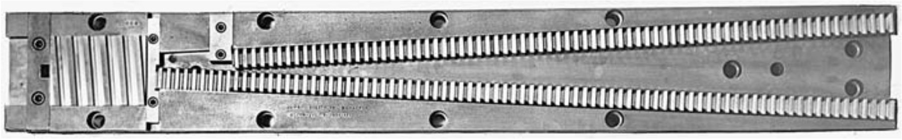
(b) Round, push-type broach with chip-breaking notches on alternate teeth except at the finishing end.



(c) Notched tooth, flat broach



(d) Progressive surface broach. *(Courtesy of Detroit Broach & Machine Company)*

FIGURE 27-7 Methods to decrease force or break up chip rings in broaches. (a) Rotor or jump tooth; (b) notched tooth, round; (c) notched tooth, flat design (overlapping teeth permit large RPTs without increasing chip load); (d) progressive tooth design for flat broach.

The overall length of the broach for a pull broach is

$$L_B = (n_r + n_s + n_f)\, P + L_s + L_{RP} \tag{27-9}$$

The length of stroke is $L = L_B - L_w$, in inches, if the broach moves past work or $L_w + L_B$ if the work moves past the broach. The cutting time is

$$T_m = \frac{L}{12V} \tag{27-10}$$

where V is the cutting speed, in surface feet per minute.

The metal removal rate depends upon the number of teeth (roughing) contacting the work.

$$\text{MRR (per tooth)} = 12t_r WV \text{ in.}^3\text{/min per roughing tooth} \tag{27-11}$$

where W is the width of broach tooth.

The number of roughing teeth in contact with part $n \cong L_w/P$ for a broach longer than the part.

$$\text{MRR (for process)} = 12t_rWV \text{ in.}^3/\text{min} \tag{27-12}$$

where n is usually rounded off to the next-largest whole number.

The pull broach must be strong enough so that it will not be pulled apart. The strength of a pull broach is determined by its minimum cross section, which occurs either at the root of the first tooth or at the pull end:

$$\text{allowable pull} = \frac{\text{area of minimum section} \times \text{Y.S. of broach material}}{\text{factor of safety}} \tag{27-13}$$

where Y.S. is yield strength.

The *push broach* must be strong enough so that it will not buckle. If the length-to-diameter ratio, L/D_r, is greater than 25, the broach must be considered a long column that can buckle if overloaded. Let L = length from push end to first tooth, D_r = root diameter at $0.5L$, and S = factor of safety:

$$\text{allowable load} = \frac{13.5 \times 10^6 \times D_r^4}{SL^2} \tag{27-14}$$

For L/D_r less than 25, the normal broach loads are not critical.

Calculation of the total push or pull load depends upon the number of teeth engaged, n estimated from L_w/P; the width of the cut, W; the RPT per tooth engaged, t_r; and the shear strength of the metal being machined.

The force necessary to operate a broach depends upon the material being broached, the conditions of the tool, and the nature of the process. An empirical constant is required in the force calculation to account for the large amount of rubbing (friction) between the tool, the chips captured in the tooth gullet, and the workpiece.

Let F_{CB} be the broach pull force in pounds:

$$F_{CB} \cong 5\tau_s n t_r W \tag{27-15}$$

where τ_s is flow stress.

τ_s found in Chapter 20, depends upon the hardness for the metal. This force estimate can be used to estimate the horsepower needed for the broaching machine.

THE ADVANTAGES AND LIMITATIONS OF BROACHING

Because of the features built into a broach, it is a simple and rapid method of machining. There is a close relationship among the contour of the surface to be produced, the amount of material that must be removed, and the design of the broach. For example, the total depth of the material to be removed cannot exceed the total step provided in the broach, and the step of each tooth must be sufficient to provide proper chip thickness for the type of material to be machined. Consequently, either a special broach must be made for each job or the workpiece must be designed so that a standard broach can be used. Broaching is widely used and particularly well suited for mass production because the volume can easily justify the cost of the broaching tool, which can be easily \$15,000 to \$30,000 per tool. It is also used for certain simple and standardized shapes, such as keyways, where inexpensive standard broaches can be used.

Broaching was originally developed for machining internal keyways. However, its obvious advantages quickly led to its development for mass-production machining of various surfaces, such as flat, interior or exterior, cylindrical or semicylindrical, and many irregular surfaces. Because there are few limitations as to the contour form that broach teeth may have, there is almost no limitation in the shape of surfaces that can be produced by broaching. The only physical limitations are that there must be no obstruction to interfere with the passage of the entire tool over the surface to be machined and that the workpiece must be strong enough to withstand the forces involved. In internal broaching, a hole must exist in the workpiece into which the broach may enter. Such a hole can be made by drilling, boring, or coring.

Broaching usually produces better accuracy and finish than can be obtained by drilling, boring, or reaming. Although the relative motion between the broaching tool and the work usually is a single linear one, a rotational motion can be added to permit the broaching of spiral splines or gun-barrel rifling.

BROACH DESIGN (THE CUTTING TOOL)

Broaches commonly are classified by the following design features:

Purpose	Motion	Construction	Function
Single	Push	Solid	Roughing
Combination	Pull	Built-up	Sizing
	Stationary		Burnishing

Figure 27-5 shows the principal components of a pull broach and the shape and arrangement of the teeth. Each tooth is essentially a single-edge cutting tool, arranged much like the teeth on a saw except for the step, which determines the depth cut by each tooth, as shown in Figure 27-6. The rise per tooth, which determines the chip load, varies from about 0.006 in. for roughing teeth in machining free-cutting steel to a minimum 0.001 in. for finishing teeth. Typically the RPT is 0.003 to 0.006 in. in surface broaching and 0.0012 to 0.0025 in. on the diameter for internal broaching. The exact amount depends on several factors. Too-large cuts impose undue stresses on the teeth and the work; too-small cuts result in rubbing rather than cutting action. The strength and ductility of the metal being cut are the primary factors.

Where it is desirable for each tooth to take a deep cut, as in broaching castings or forgings that have a hard, abrasive surface layer, *rotor-cut* or *jump-cut* tooth design may be used (Figure 27-7). In this design, two or three teeth in succession have the same diameter, or height, but each tooth of the group is notched or cut away so that it cuts only a portion of the circumference or width. This permits deeper but narrower cuts by each tooth without increasing the total load per tooth. This tooth design also reduces the forces and the power requirements. Chip-breaker notches are also used on round broaches to break up the chips (Figure 27-7b).

A similar idea can be used for flat surfaces. Tooth loads and cutting forces also can be reduced by using the *double-cut* construction, shown in Figure 27-7c. Four consecutive teeth get progressively wider. The teeth remove metal over only a portion of their width until the fourth tooth completes the cut.

Another technique for reducing tooth loads utilizes the principle illustrated in Figure 27-7d. Employed primarily for broaching wide, flat surfaces, the first few teeth in *progressive* broaches completely machine the center, while succeeding teeth are offset in two groups to complete the remainder of the surface. Rotor, double-cut, and progressive designs require the broach to be made longer than if normal teeth were used, and they therefore can be used only on a machine having adequate stroke length.

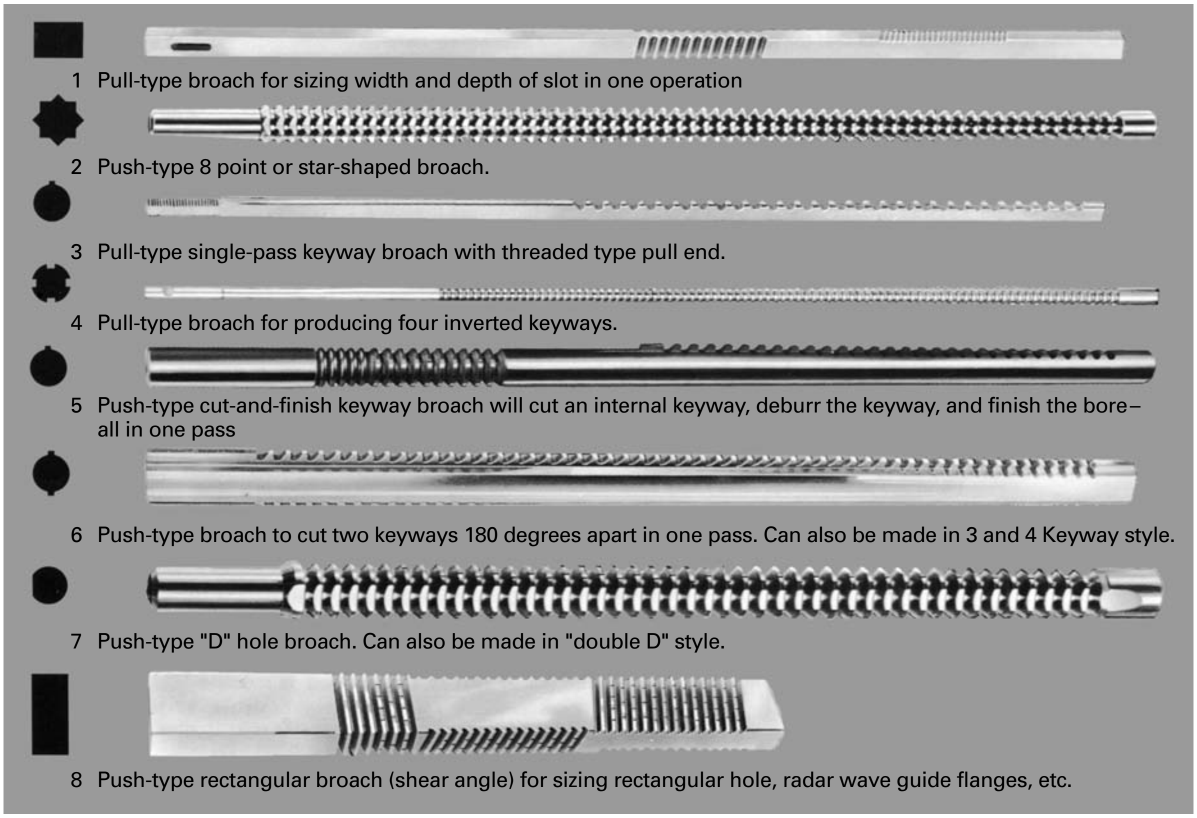
The cutting edges of the teeth on surface broaches may be either normal to the direction of motion or at an angle of from 5° to 20°. The latter, *shear-cut* broaches, provide smoother cutting action with less tendency to vibrate. Other shapes that can be broached are shown in Figure 27-8 along with push- or pull-type broaches used for the job.

The pitch of the teeth and the gullet between them must be sufficient to provide ample room for the chips. All chips produced by a given tooth during its passage over the full length of the workpiece must be contained in the space between successive teeth.

At the same time, it is desirable to have the pitch sufficiently small so that at least two or three teeth are cutting at all times.

The *hook* determines the primary rake angle and is a function of the material being cut. It is 15° to 20° for steel and 6° to 8° for cast iron. *Back-off* or end clearance angles are from 1° to 3° to prevent rubbing.

Most of the metal removal is done by the *roughing teeth*. *Semifinishing teeth* provide surface smoothness, whereas *finishing teeth* produce exact size. On a new broach all the finishing teeth are usually the same size. As the first finishing teeth become worn, those behind continue the sizing function. On some round broaches, *burnishing teeth* are provided for finishing. These teeth have no cutting edges but are rounded disks of



1 Pull-type broach for sizing width and depth of slot in one operation

2 Push-type 8 point or star-shaped broach.

3 Pull-type single-pass keyway broach with threaded type pull end.

4 Pull-type broach for producing four inverted keyways.

5 Push-type cut-and-finish keyway broach will cut an internal keyway, deburr the keyway, and finish the bore–all in one pass

6 Push-type broach to cut two keyways 180 degrees apart in one pass. Can also be made in 3 and 4 Keyway style.

7 Push-type "D" hole broach. Can also be made in "double D" style.

8 Push-type rectangular broach (shear angle) for sizing rectangular hole, radar wave guide flanges, etc.

FIGURE 27-8 Examples of push- or pull-type broaches. *(Courtesy of DuMont Corporation.)*

hard steel or carbide that are from 0.001 to 0.003 in. larger than the size of the hole. The resulting rubbing action smooths and sizes the hole. They are used primarily on cast iron and nonferrous metals.

The *pull end* of a broach provides a means of quickly attaching the broach to the pulling mechanism. The *front pilot* aligns the broach in the hole before it begins to cut, and the *rear pilot* keeps the tool square with the finished hole as it leaves the workpiece. *Shank length* must be sufficient to permit the broach to pass through the workpiece and be attached to the puller before the first roughing tooth engages the work. If a broach is to be used on a vertical machine that has a tool-handling mechanism, a *tail* is necessary.

A broach should not be used to remove a greater depth of metal than that for which it is designed—the sum of the steps of all the teeth. In designing workpieces, a minimum of 0.020 in. should be provided on surfaces that are to be broached, and about 0.025 in. is the practical maximum.

BROACHING SPEEDS, ACCURACY, FINISH

Depending on the metal being cut, cutting speeds for broaching range from low (25 to 20 sfpm) to high while completing the surface in a single stroke, so the productivity is high. A complete cycle usually requires only from 5 to 30 seconds, with most of that time being taken up by the return stroke, broach handling, and workpiece loading and unloading. Such cutting conditions facilitate cooling and lubrication and result in very low tool wear rates, which reduce the necessity for frequent resharpening and prolong the life of the expensive broaching tool.

For a given cutting speed and material, the force required to pull or push a broach is a function of the tooth width, the step, and the number of teeth cutting. Consequently, it is necessary to design or specify a broach within the stroke length and power limitations of the machine on which it is to be used. The average machining precision is typically ±0.001-in. (±0.02-mm) tolerance with surface finish 120 to 60 RMS or better. Burrs are minimal on the exit side of cuts.

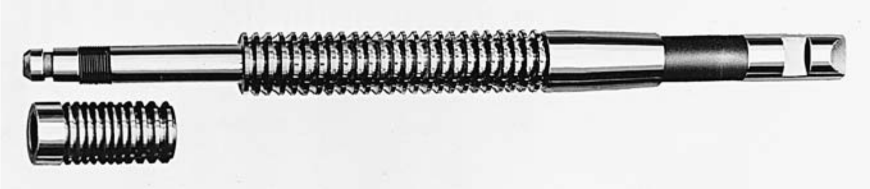


FIGURE 27-9 Shell construction for a pull broach.

BROACHING MATERIALS AND CONSTRUCTION

Because of the low cutting speeds employed, most broaches are made of alloy or high-speed tool steel. Carbide-tipped broaches are seldom used for machining steel parts or forgings, as the cutting edges tend to chip on the first stroke, probably due to a lack of rigidity in the combination of machine tool and cutting tool. TiN coating of high-speed-steel (HSS) broaches is becoming more common, greatly prolonging the life of broaches. When they are used in continuous mass-production machines, particularly in surface broaching of cast iron, tungsten carbide teeth may be used, permitting the broach to be used for long periods of time without resharpening.

Internal broaches are usually solid but may be made of *shells* mounted on an arbor (Figure 27-9). When the broach (or a section of it) is subject to rapid wear, a single shell can be replaced. This will be much cheaper than replacing an entire solid broach. Shell construction, however, is initially more expensive than a solid broach of comparable size.

Small-surface broaches may be of solid construction, but larger ones usually use modular construction (Figure 27-10). Building in sections makes the broach easier and cheaper to construct and sharpen. It also often provides some degree of interchangeability of the sections for different parts, bringing down the tool cost significantly.

SHARPENING BROACHES

Most broaches are resharpened by grinding the hook faces of the teeth. The lands of internal broaches must not be reground because this would change the size of the broach. Lands of flat-surface broaches are sometimes ground, in which case all of them must be ground to maintain their proper relationship.

■ 27.5 BROACHING MACHINES

Because all the factors that determine the shape of the machined surface and that determine all cutting conditions except speed are built into the broaching tool, broaching machines are relatively simple. Their primary functions are to impart plain reciprocating motion to the broach and to provide a means for handling the broach automatically.

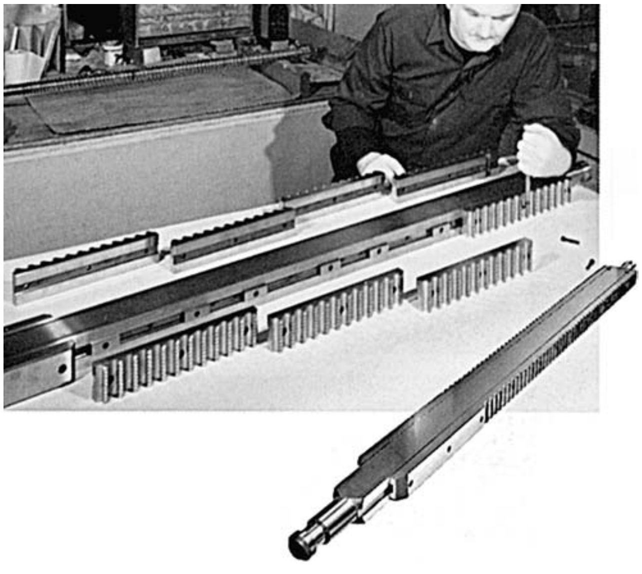

FIGURE 27-10 A modularly constructed broach is cheaper to build and can be sharpened in sections.

TABLE 27-1 Broaching Machines

Vertical	
Push-broaching	Arbor press with guided ram 5- to 50-ton capacity Internal broaching
Pull-down	Double-ram design most common Long changeover times
Pull-up	Ram above table pulling broach up Machines with multiple rams common
Surface	No handling of broach Multiple slides
Horizontal	**Short Cycle Times**
Pull	Longer strokes and broaches Basically vertical machines laid on side
Surface	Broaches stationary, work moves on conveyor Work held in fixtures
Continuous	Conveyor chain holds fixtures
Rotary	Rotary broach stationary, work translates beneath tool Work held in fixtures

Most broaching machines are driven hydraulically, although mechanical drive is used in a few special types. The major classification relates to whether the motion of the broach is vertical or horizontal, as given in Table 27-1.

The choice between vertical and horizontal machines is determined primarily by the length of the stroke required and the available floor space. Vertical machines seldom have strokes greater than 60 in. because of height limitations. Horizontal machines can have almost any length of stroke, but they require greater floor space. The most common machine is the vertical pull-down machine shown in Figure 27-11. The worktable, usually having a spherical-seated workholder, sits below the broach elevator, with a pulling mechanism below the table. When the elevator raises the broach above the table, the work can be placed into position. The elevator then lowers the pilot end of the broach through the hole in the workpiece, where it is engaged by the puller. The elevator then releases the upper end of the broach, and it is pulled through the workpiece. The workpieces are removed from the table, and the broach is raised upward to be engaged by the elevator mechanism. In some machines with two rams, one broach is being pulled down while the work is being unloaded and the broach raised at the other station. In Figure 27-11, the part is being broached in two passes, first on the left, then on the right.

■ 27.6 INTRODUCTION TO SAWING

Sawing is a basic machining process in which chips are produced by a succession of small cutting edges, or *teeth*, arranged in a narrow line on a saw "blade." As shown in Figure 27-12, each tooth forms a chip progressively as it passes through the workpiece. The chips are contained within the spaces between successive teeth until the teeth pass from the work. Because sections of considerable size can be severed from the workpiece with the removal of only a small amount of the material in the form of chips, sawing is probably the most economical of the basic machining processes with respect to the waste of material and power consumption, and in many cases with respect to labor.

In recent years vast improvements have been made in saw blades (design and materials) and sawing machines, resulting in improved accuracy and precision of the process. Most sawing is done to sever bar stock and shapes into desired lengths for use in other operations. There are many cases in which sawing is used to produce desired shapes. Frequently, and especially for producing only a few parts, contour sawing may be more economical than any other machining process.

SAW BLADES

Saw blades are made in three basic configurations. The first type, commonly called a *hacksaw* blade, is straight, relatively rigid, and of limited length, with teeth on one edge.

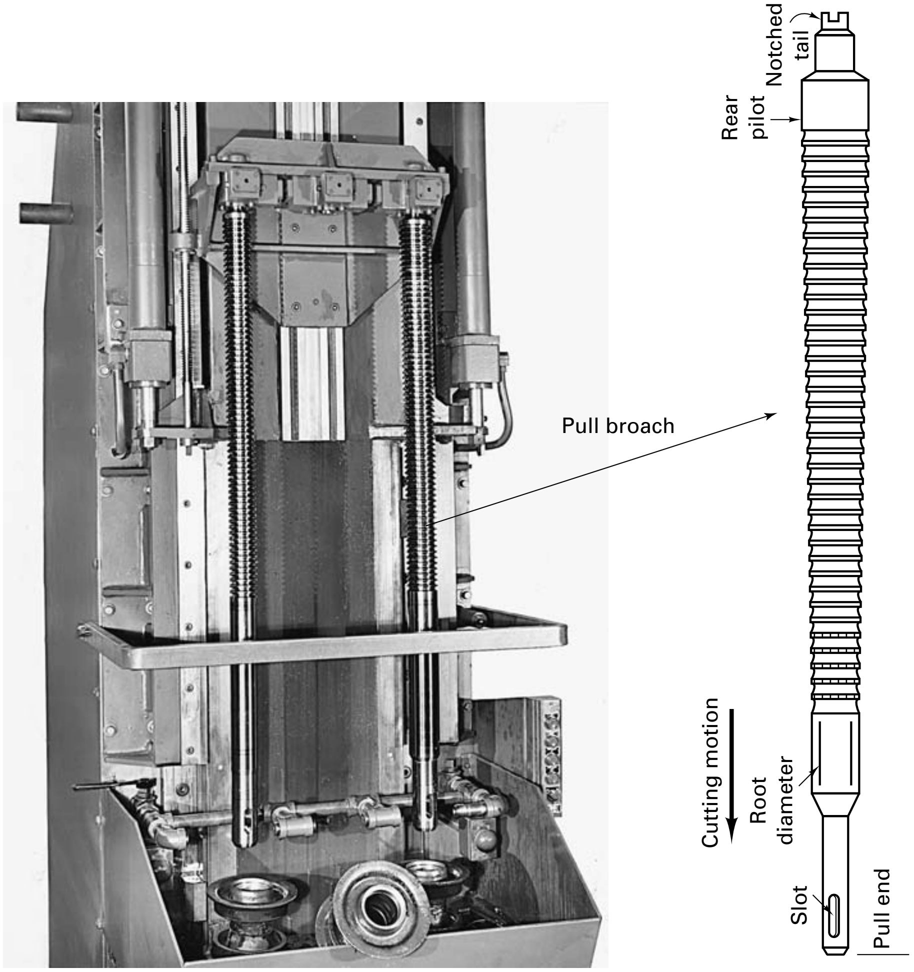

FIGURE 27-11 Vertical pull-down broaching machine shown with parts in position ready for the two broaches to be inserted. An extra part is shown lying at the front of the machine.

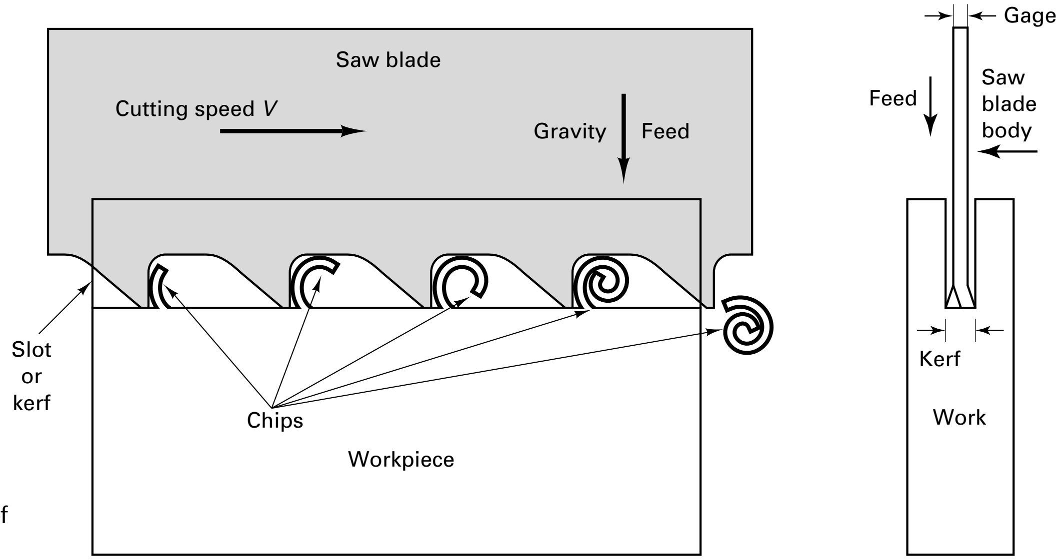

FIGURE 27-12 Formation of chips in sawing.

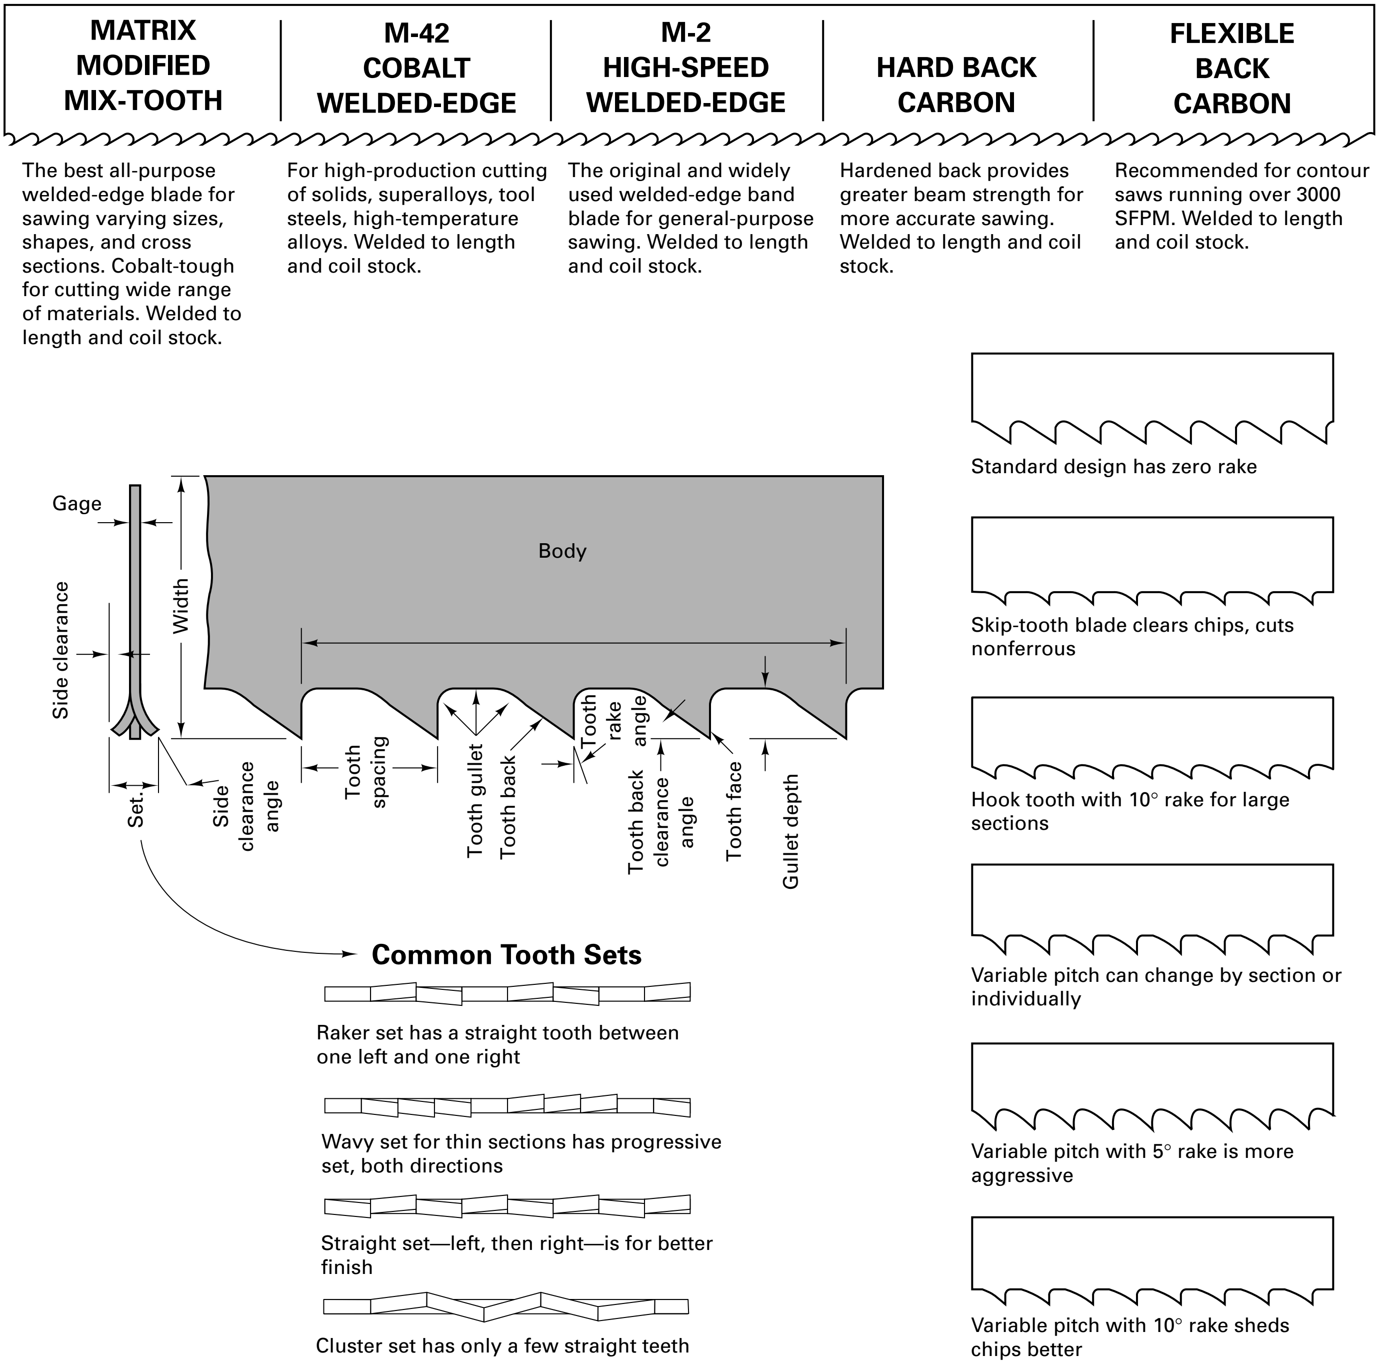
The second type, called a *bandsaw*, is sufficiently flexible that a long length can be formed into a continuous band with teeth on one edge. The third form is a rigid disk having teeth on the periphery; these are called *circular saws* or *cold saws*. Figure 27-13 gives the standard nomenclature for a saw blade.



The best all-purpose welded-edge blade for sawing varying sizes, shapes, and cross sections. Cobalt-tough for cutting wide range of materials. Welded to length and coil stock.

For high-production cutting of solids, superalloys, tool steels, high-temperature alloys. Welded to length and coil stock.

The original and widely used welded-edge band blade for general-purpose sawing. Welded to length and coil stock.

Hardened back provides greater beam strength for more accurate sawing. Welded to length and coil stock.

Recommended for contour saws running over 3000 SFPM. Welded to length and coil stock.

Raker set has a straight tooth between one left and one right

Wavy set for thin sections has progressive set, both directions

Straight set—left, then right—is for better finish

Cluster set has only a few straight teeth

Standard design has zero rake

Skip-tooth blade clears chips, cuts nonferrous

Hook tooth with 10° rake for large sections

Variable pitch can change by section or individually

Variable pitch with 5° rake is more aggressive

Variable pitch with 10° rake sheds chips better

FIGURE 27-13 Bandsaw blade designs and nomenclature (above). Tooth set patterns (left) and tooth designs (right).

All saw blades have certain common and basic features: (1) material, (2) tooth form, (3) tooth spacing, (4) tooth set, and (5) blade thickness or gage. Small hacksaw blades are usually made entirely of tungsten or molybdenum high-speed steel. Blades for power-operated hacksaws are often made with teeth cut from a strip of high-speed steel that has been electron-beam-welded to the heavy main portion of the blade, which is made from a tougher and cheaper alloy steel (see Figure 27-13). Bandsaw blades are frequently made with this same type of construction but with the main portion of the blade made of relatively thin, high-tensile-strength alloy steel to provide the required flexibility. Bandsaw blades are also available with tungsten carbide teeth and TiN coatings. The three most common *tooth forms* are regular, skip tooth, and hook. *Tooth spacing* is very important in all sawing because it determines three factors. First, it controls the size of the teeth. From the viewpoint of strength, large teeth are desirable. Second, tooth spacing determines the space (*gullet*) available to contain the chip that is formed. The chip cannot drop from this space until it emerges from the slot cut in the workpiece, called the *kerf*. *Tooth set* refers to the manner in which the teeth are offset from the centerline in order to make the kerf wider than the gage (the thickness of the back) of the blade. This allows the saw to move more freely in the kerf, reducing rubbing, friction, and heating. The kerf–gullet space must be such that there is no crowding of the chip. Chips should not become wedged between the teeth and not drop out of the gullet when the saw emerges from the cut.

Third, tooth spacing determines how many teeth will bear against the work. This is very important in cutting thin material, such as tubing. At least two teeth should be in contact with the work at all times. If the teeth are too coarse, only one tooth rests on the work at a given time, permitting the saw to rock, and the teeth may be stripped from the saw.

Hand hacksaw blades have 14 to 32 teeth per inch. In order to make it easier to start a cut, some hand hacksaw blades are made with a short section at the forward end having teeth of a special form with negative rake angles. Tooth spacing for power hacksaw blades ranges from 4 to 18 teeth per inch.

Raker-tooth saws are used in cutting most steel and iron. *Straight-set teeth* are used for sawing brass, copper, and plastics. Saws with *wave-set teeth* are used primarily for cutting thin sheets and thin-walled tubing.

The gage or *blade thickness* of nearly all hand hacksaw blades is 0.025 in. Saw blades for power hacksaws vary in thickness from 0.050 to 0.100 in. Hand hacksaw blades come in two standard lengths, 10 and 12 in. All are $^1/_2$ in. wide. Blades for power hacksaws vary in length from 12 to 24 in. and in width from 1 to 2 in. Wider and thicker blades are desirable for heavy-duty work. As a general rule, in hacksawing the blade should be at least twice as long as the maximum length of cut that is to be made.

Bandsaw blades are available in straight, raker, wave, or combination sets. In order to reduce the noise from high-speed bandsawing, it is becoming increasingly common to use blades that have more than one pitch, size of teeth, and type of set. Blade width is very important in bandsawing because it determines the minimum radius that can be cut. The most common widths are from $^1/_{16}$ in. to $^1/_2$ in., although wider blades can be obtained. Because wider blades are stronger, select the widest blade possible. However, cutting small radii requires a narrower and weaker blade. Bandsaw blades come in tooth spacings from 2 to 32 teeth per inch.

Circular saws for cutting metal are often called *cold saws* to distinguish them from friction-type disk saws. Friction saws do not make chips but rather heat the metal to the melting temperature at the point of metal removal. Cold saws cut rapidly and produce chips like a milling cutter while producing surfaces that are comparable in smoothness and accuracy with surfaces made by slitting saws in a milling machine or by a cutoff tool in a lathe.

Disk or *circular saws* necessarily differ somewhat from straight-blade forms. The sizes up to about 18 in. in diameter have an integral-tooth design with teeth cut directly into the disk (Figure 27-14). Larger saws use either *segmented* or *inserted* teeth. The teeth are made of high-speed steel or tungsten carbide. The remainder of the disk is made of ordinary, less expensive, and tougher steel. *Segmental* blades are composed of segments mounted around the periphery of the disk, usually fitted with a tongue and groove and fastened by means of screws or rivets. Each segment contains several teeth. If a single tooth is broken, only one segment needs be replaced to restore the saw to an operating condition.

As shown in Figure 27-14, circular saw teeth are usually *beveled*. A common tooth form has every other tooth beveled on both sides; that is, the first tooth is beveled on the left side, the second tooth on both sides, the third tooth on the right side, the fourth tooth on the left side, and so forth. Another method is to bevel the opposite sides of successive teeth. Beveling is done to produce a smoother cut. Precision circular saws made from carbide, which are becoming available, are very thin (0.03 in.) and have high cutting-off accuracy, around ±0.00008 in., with negligible burrs.

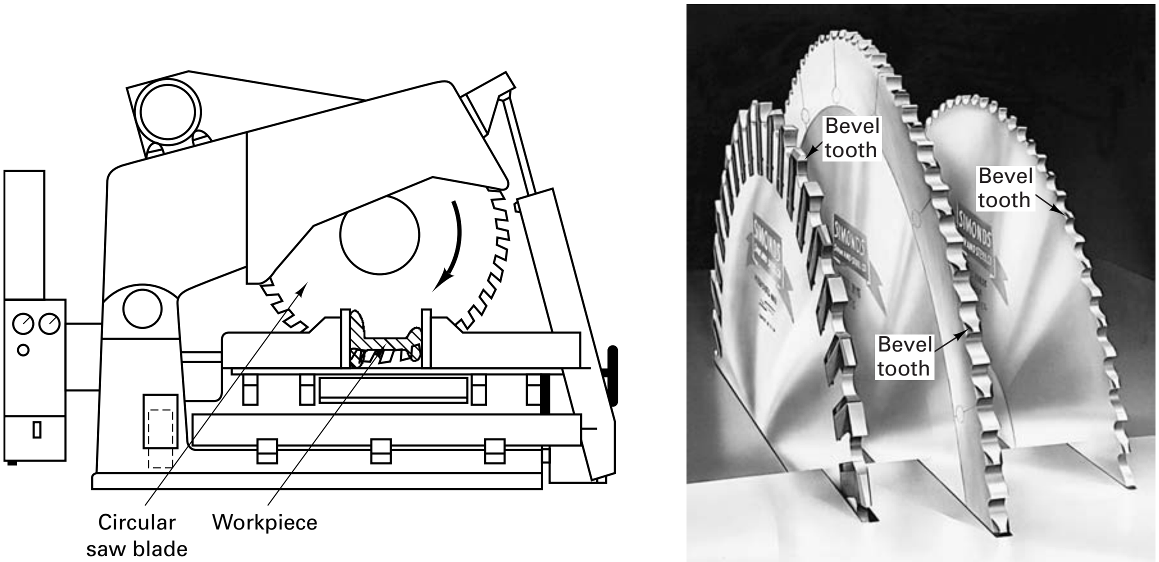


FIGURE 27-14 Circular sawing a structural shape, using (*left* to *right*) an insert tooth, a segmental tooth, and an integral-tooth circular saw blade.

TYPES OF SAWING MACHINES

Metal-sawing machines may be classified as follows:

1. Reciprocating saw
   - **a.** Manual hacksaw
   - **b.** Power hacksaw (Figure 27-15)
   - **c.** Abrasive disc
2. Bandsaw
   - **a.** Vertical cutoff (Figure 27-16)
   - **b.** Horizontal cutoff (Figure 27-17)
   - **c.** Combination cutoff and contour (Figure 27-18)
   - **d.** Friction
3. Circular saw (Figure 27-14)
   - **a.** Cold saw
   - **b.** Steel friction disk

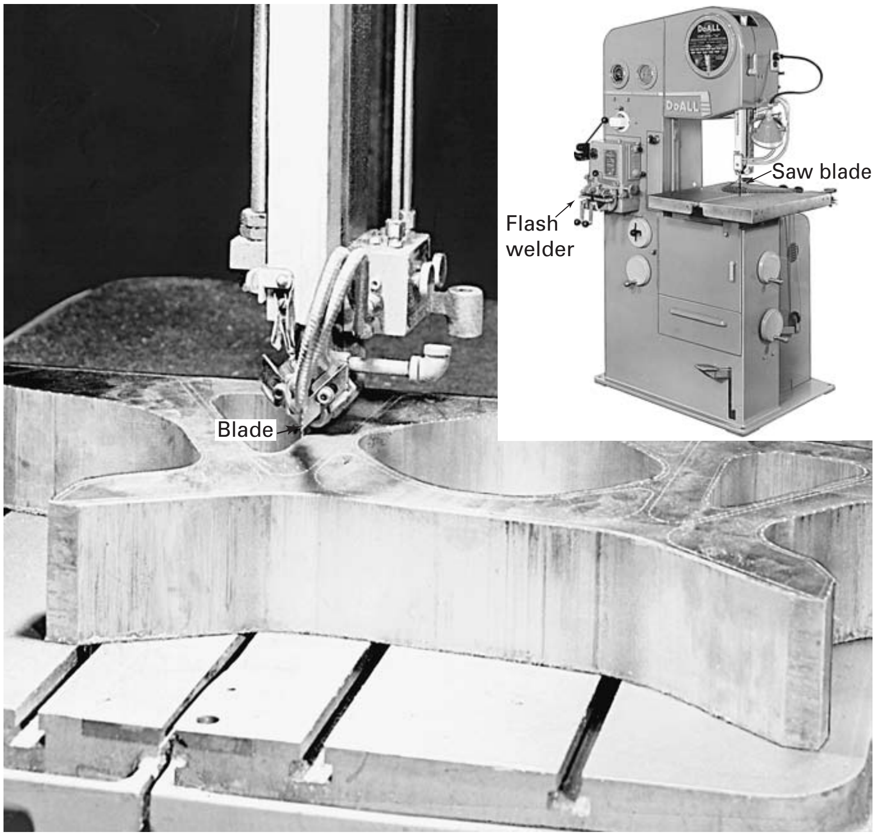

FIGURE 27-18 Contour bandsawing on vertical bandsawing machine, shown in inset.

POWER HACKSAWS

As the name implies, power hacksaws are machines that mechanically reciprocate a large hacksaw blade (Figure 27-15). These machines consist of a bed, a workholding frame, a power mechanism for *reciprocating* the saw frame, and some type of feeding mechanism. Because of the inherent inefficiency of cutting in only one stroke direction, they have often been replaced by more efficient, horizontal bandsawing machines.

BANDSAWING MACHINES

The earliest metalcutting bandsawing machines were direct adaptations from woodcutting bandsaws. Modern machines of this type are much more sophisticated and versatile and have been developed specifically for metal cutting. To a large degree they were made possible by the development of vastly better and more flexible bandsaw blades and simple flash-welding equipment, which can weld the two ends of a strip of bandsaw blade together to form a band of any desired length. Three basic types of bandsawing machines are in common use.

Horizontal metalcutting bandsawing machines were developed to combine the flexibility of reciprocating power hacksaws and the continuous cutting action of vertical bandsaws. These heavy-duty automatic bandsaws feed the saw vertically by a hydraulic mechanism and have automatic stock feed that can be set to feed the stock laterally any desired distance after a cut is completed and automatically clamp it for the next cut. Such machines can be arranged to hold, clamp, and cut several bars of material simultaneously. Computer numerical control (CNC) bandsaws are available with automatic storage and retrieval systems for the bar stock. Smaller and less expensive types have swing-frame construction, with the bandsaw head mounted in a pivot on the rear of the machine. Feed is accomplished by gravity through rotation of the head about the pivot point. Because of their continuous cutting action, horizontal bandsawing machines are very efficient (Figure 27-16).

Upright, *cutoff*, *bandsawing machines* (Figure 27-17) are designed primarily for cutoff work on single stationary workpieces that can be held on a table. On many machines the blade mechanism can be tilted to about 45°, as shown, to permit cutting at an angle. They usually have automatic power feed of the blade into the work, automatic stops, and provision for supplying coolant.

Combination cutoff and contour bandsawing machines (Figure 27-18) can be used not only for cutoff work but also for contour sawing. They are widely used for cutting irregular shapes in connection with making dies and the production of small numbers of parts and are often equipped with rotary tables. Additional features on these machines include a table that pivots so that it can be tilted to any angle up to 45°. Usually these machines have a small flash butt welder on the vertical column, so that a straight length of bandsaw blade can be welded quickly into a continuous band. A small grinding wheel is located beneath the welder so that the flash can be ground from the weld to provide a smooth joint that will pass through the saw guides. This welding and grinding unit makes it possible to cut internal openings in a part by first drilling a hole, inserting one end of the saw blade through the hole, and then butt welding the two ends together. When the cut is finished, the band is again cut apart and removed from the opening. The cutting speed of the saw blade can be varied continuously over a wide range to provide correct operating conditions for any material. A method of power feeding the work is provided, sometimes gravity-actuated.

Contour-sawing machines are made in a wide range of sizes, the principal size dimension being the throat depth. Sizes from 12 to 72 in. are available. The speeds available on most machines range from about 50 to 2000 ft/min. Modern horizontal bandsaws are accurate to ±0.002 in. per vertical inch of cut but have feeding accuracy of only ±0.005 in., subject to the size of the stock and the feed rate. Repeatability from one feed to the next may be ±0.010 to ±0.020 in.

CNC-controlled sawing centers with microprocessor controls have opened up new automation aspects for sawing. Such control systems can improve accuracy to within ±0.005 in. over entire cuts by controlling saw speed, blade feed pressure, and feed rate.

Special bandsawing machines are available with very high speed ranges, up to 14,000 ft/min. These are known as *friction bandsawing machines*. Material is not cut by chip formation. Instead, the friction between the rapidly moving saw blade and the work is sufficient to raise the temperature of the material at the end of the kerf to or just below the melting point, where its strength is very low. The saw blade then pulls the molten, or weakened, material out of the kerf. Consequently, the blades do not need to be sharp; they frequently have no teeth—only occasional notches in the blade to aid in removing the metal.

Almost any material, including ceramics, can be cut by friction sawing. Because only a small portion of the blade is in contact with the work for an instant and then is cooled by its passage through the air, it remains cool. Usually, the major portion of the work, away from contact with the saw blade, also remains quite cool. The metal adjacent to the kerf is heat affected, recast, and sometimes harder than the bulk metal. It is also a very rapid method for trimming the flash from sheet metal parts, castings, and forgings.

CUTTING FLUIDS

Cutting fluids should be used for all bandsawing, with the exception that cast iron is always cut dry. Commercially available oils or light cutting oils will give good results in cutting ferrous materials. Beeswax or paraffin are common lubricants for cutting aluminum and aluminum alloys.

FEEDS AND SPEEDS

Because of the many different types of feed involved in bandsawing, it is not practical to provide tabular feed or pressure data. Under general conditions, however, an even pressure, without forcing the work, gives best results. A nicely curled chip usually indicates an ideal feed pressure. Burned or discolored chips indicate excessive pressure, which can cause tooth breakage and premature wear.

Most bandsaws provide recommended cutting speed information right on the machine, depending upon the material being sawed. In general, HSS blades are run at 200 to 300 ft/min when cutting 1-in.-thick, low- and medium-carbon steels. For high-carbon steels, alloy steels, and tool and die steels, the range is from 150 to 225 ft/min, and most stainless steels are cut at 100 to 125 ft/min.

CIRCULAR-BLADE SAWING MACHINES

Machines employing rotating circular or cold saw blades are used exclusively for cutoff work. These range from small, simple types, in which the saw is fed manually, to very large saws having power feed and built-in coolant systems, commonly used for cutting off hot-rolled shapes as they come from a rolling mill. In some cases friction saws are used for this purpose, having disks up to 6 ft in diameter and operating at surface speeds up to 25,000 ft/min. Steel sections up to 24 in. can be cut in less than 1 minute by this technique.

Although technically not a sawing operation, cutoff work up to about 6 in. is often done utilizing thin *abrasive* disks. The equipment used is the same as for sawing. It has the advantage that very hard materials that would be very difficult to saw can be cut readily. A thin rubber- or resinoid-bonded abrasive wheel is used. Usually a somewhat smoother surface is produced.

27.7 INTRODUCTION TO FILING

Basically, the metal-removing action in filing is the same as in sawing, in that chips are removed by cutting teeth that are arranged in succession along the same plane on the surface of a tool, called a *file*. There are two differences: (1) the chips are very small, and therefore the cutting action is slow and easily controlled, and (2) the cutting teeth are much wider. Consequently, fine and accurate work can be done.

Files are classified according to the following:

1. The type, or *cut*, of the teeth
2. The degree of coarseness of the teeth
3. Construction
   a. Single solid units for hand use or in die-filing machines
   b. Band segments, for use in band-filing machines
   c. Disks, for use in disk-filing machines

Four types of *cuts* are available. *Single-cut files* have rows of parallel teeth that extend across the entire width of the file at the angle of from 65° to 85°. *Double-cut files* have two series of parallel teeth that extend across the width of the file. One series is cut at an angle of 40° to 45°. The other series is coarser and is cut at an opposite angle that varies from about 10° to 80°. A *vixen-cut file* has a series of parallel curved teeth, each extending across the file face. On a *rasp-cut* file, each tooth is short and is raised out of the surface by means of a punch. These four types of cuts are shown in Figure 27-19.

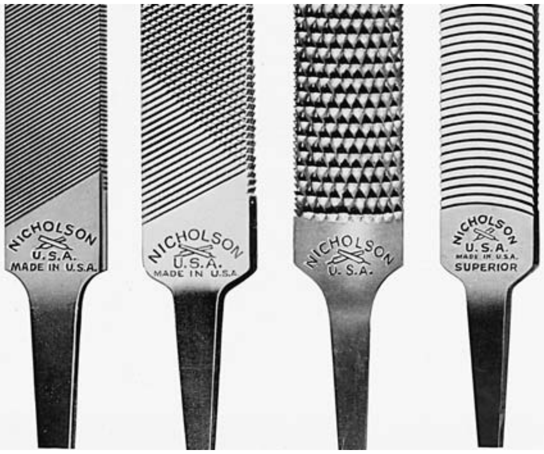

FIGURE 27-19 Four types of teeth (cuts) used in files. Left to right: Single, double, rasp, and curved (vixen). *(Courtesy of Nicholson File Company.)*

The coarseness of files is designated by the following terms, arranged in order of increasing coarseness: *dead smooth*, *smooth*, *second cut*, *bastard*, *coarse*, and *rough*. There is also a series of finer Swiss pattern files, designated by numbers from 00 to 8.

Files are available in a number of cross-sectional shapes: *flat*, *round*, *square*, *triangular*, and *half-round*. Flat files can be obtained with no teeth on one or both narrow edges, known as *safe edges*. Safe edges prevent material from being removed from a surface that is normal to the one being filed. Most files for hand filing are from 10 to 14 in. in length and have a pointed *tang* at one end on which a wood or metal handle can be fitted for easy grasping.

FILING MACHINES

An experienced operator can do very accurate work by hand filing, but it can be a difficult task. Therefore, three types of filing machines have been developed that permit quite accurate results to be obtained rapidly and with much less effort. *Die-filing machines* hold and reciprocate a file that extends upward through the worktable. The file rides against a roller guide at its upper end, and cutting occurs on the downward stroke; therefore, the cutting force tends to hold the work against the table. The table can be tilted to any desired angle. Such machines operate at from 300 to 500 strokes per minute, and the resulting surface tends to be at a uniform angle with respect to the table. Quite accurate work can be done. Because of the reciprocating action, approximately 50% of the operating time is nonproductive.

Band-filing machines provide continuous cutting action. Most band filing is done on contour bandsawing machines by means of a special band file that is substituted for the usual bandsaw blade. The principle of a band file is shown in Figure 27-20. Rigid, straight file segments, about 3 in. long, are riveted to a flexible steel band near their leading ends. One end of the steel band contains a slot that can be hooked over a pin in the other end to form a continuous band. As the band passes over the drive and idler wheels of the machine, it flexes so that the ends of adjacent file segments move apart. When the band becomes straight, the ends of adjacent segments move together and interlock to form a continuous straight file. Where the file passes through the worktable, it is guided and supported by a grooved guide, which provides the necessary support to

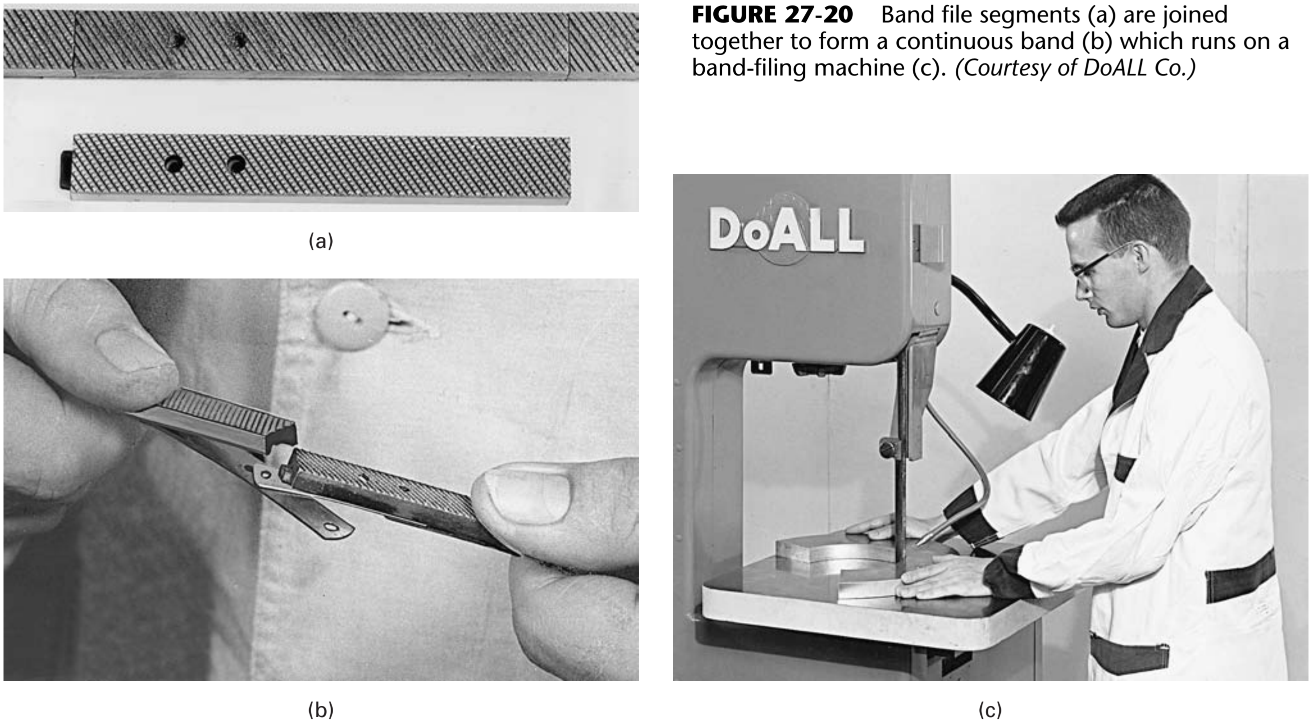

FIGURE 27-20 Band file segments (a) are joined together to form a continuous band (b) which runs on a band-filing machine (c). *(Courtesy of DoALL Co.)*

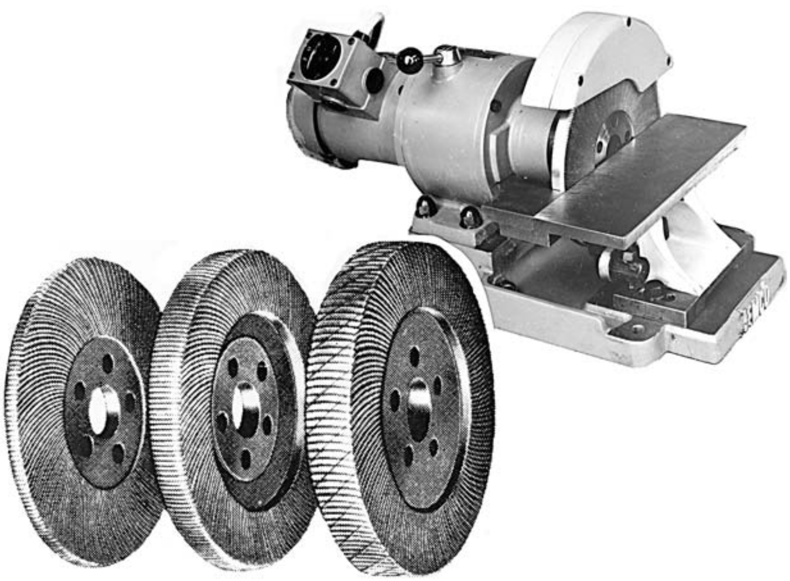

FIGURE 27-21 Disk-type filing machine and some of the available types of disk files. *(Courtesy of Jersey Manufacturing Company.)*

resist the pressure of the work against the file. Band files are available in most of the standard cuts and in several widths and shapes. Operating speeds range from about 50 to 250 ft/min.

Although band filing is considerably more rapid than can be done on a die-filing machine, it usually is not quite as accurate. Frequently, band filing may be followed by some finish filing on a die-filing machine.

Some *disk-filing machines* have files in the form of disks (Figure 27-21). These are even simpler than die-filing machines and provide continuous cutting action. However, it is difficult to obtain accurate results by their use.

■ Review Questions

1. What is unique about the broaching process compared to the other basic machining processes?
2. Can a thick saw blade be used as a broach? Why or why not?
3. Broaching machines are simpler in a basic design than most other machine tools. Why is this?
4. Why is broaching particularly well suited for mass production?
5. In designing a broach, what would be the first thing you have to calculate?
6. Why is it necessary to relate the design of a broach to the specific workpiece that is to be machined?
7. What two methods can be utilized to reduce the force and power requirements for a particular broaching cut?
8. For a given job, how would a broach having rotor-tooth design compare in length with one having regular, full-width teeth?
9. Why are the pitch and radius of the gullet between teeth on a broach of importance?
10. Why are broaching speeds usually relatively low, as compared with other machining operations?
11. What are the advantages of shell-type broach construction?
12. Why are most broaches made from alloy or high-speed steel rather than from tungsten carbide?
13. What are the advantages of TiN-coated broaching tools?
14. For mass-production operations, which process is preferred, pull-up broaching or pull-down broaching?
15. What is the difference between the roughing teeth and the finishing teeth in a typical pull broach?
16. The sides of a square, blind hole must be machined all the way to the bottom (who designed this part?). The hole is first drilled to full depth, then the bottom is milled flat. Is it possible to machine the hole square by broaching? Why or why not?

17. The interior, flat surfaces of socket wrenches, which have one "closed" end, often are finished to size by broaching. By examining one of these, determine what design modification was incorporated to make broaching possible.
18. Why is sawing one of the most efficient of the chip-forming processes?
19. Explain why tooth spacing (pitch) is important in sawing.
20. What is the tooth gullet used for on a saw blade?
21. Explain what is meant by the "set" of the teeth on a saw blade.
22. How is tooth set related to saw kerf?
23. Why can a bandsaw blade not be hardened throughout the entire width of the band?
24. What are the advantages of using circular saws?
25. Why have bandsawing machines largely replaced reciprocating saws?
26. Explain how the hole in Figure 27-18 is made on a contour bandsawing machine.
27. How would you calculate or estimate T_m for a horizontal bandsaw cutting a 3-in. round of 1040 steel?
28. What is the disadvantage of using gravity to feed a saw in cutting round bar stock?
29. To what extent is filing different from sawing?
30. What is a safe edge on a file?
31. Why is an end-filing machine more efficient than a die-filing machine?
32. How does a rasp-cut file differ from other types of files?
33. How does the process of shaping differ from planing?
34. How is feed per stroke in shaping related to feed per tooth in milling?
35. What are some ways to improve the efficiency of a planer? Do any of these apply to the shaper?

Problems

1. A surface 12 in. long is to be machined with a flat, solid broach that has a rise per tooth of 0.0047 in. What is the minimum cross-sectional area that must be provided in the chip gullet between adjacent teeth?
2. The pitch of the teeth on a simple surface broach can be determined by equation 27-1. If a broach is to remove 0.25 in. of material from a gray iron casting that is 3 in. wide and 17.75 in. long, and if each tooth has a rise per tooth of .004 in., what will be the length of the roughing section of the broach?
3. Estimate the (approximate maximum) horsepower needed to accomplish the operation described in Problem 2 at a cutting speed of 10 m/min. (*Hint:* First find the HP used per tooth and determine the maximum number of teeth engaged at any time. What are those units?)
4. Estimate the approximate force acting in the forward direction during cutting for the conditions stated in Problems 2 and 3.
5. In cutting a 6-in.-long slot in a piece of AISI 1020 cold-rolled steel that is 1 in. thick, the material is fed to a bandsaw blade with teeth having a pitch of 1.27 mm (20 pitch) at the rate of 0.0001 in. per tooth. Estimate the cutting time for the cut.
6. The strength of a pull broach is determined by its minimum cross section, which usually occurs either at the root of the first tooth or at the pull end. Suppose the minimum root diameter is D_r, the pull end diameter is D_p and the width of the pull slot is W. Write an equation for the allowable pull, in psi, using 200,000 as the yield strength for the broach material.
7. Suppose you want to shape a block of metal 7 in. wide and 4 in. long ($L = 4$ in.) using a shaper as set up in Figure 27-1. You have determined for this metal that the cutting speed should be 25 sfpm, the depth of cut needed here for roughing is 0.25 in., and the feed will be 0.1 in. per stroke. Determine the approximate crank rpm and then estimate the cutting time and the MRR.
8. Could you have saved any time in Problem 7 by cutting the block in the 7-in. direction? Redo with $L = 7$ and $W = 4$ in.
9. Derive the equation for shaping cutting speed, equation 27-6.
10. How many strokes per minute would be required to obtain a cutting speed of 36.6 m (120 ft) per minute on a typical mechanical drive shaper if a 254-mm (10-in.) stroke is used?
11. How much time would be required to shape a flat surface 254 mm (1 in.) wide and 203 mm (8 in.) long on a hydraulic drive shaper, using a cutting speed of 45.7 m (150 ft) per minute, a feed of 0.51 mm (0.020 in.) per stroke, and an overrun of 12.7 mm $^{1}/_{2}$ in.) at each end of the cut?
12. What is the metal removal rate in Problem 11 if the depth of cut is 6.35 mm ($^{1}/_{4}$ in.)?
13. Suppose you decide to mill the flat surface described in Problems 11 and 12. The work will be done on a vertical milling machine using a 1.25-in.-diameter end mill (four teeth) (HSS) cutting at 150 sfpm with a feed per tooth of 0.005 in. per tooth cutting at $d = 0.25$ in. Compare the milling time and MRR to that of shaping.
14. A planer has a 10-hp motor, and 75% of the motor output is available at the cutting tool. The specific power for cutting cast iron metal is 0.03 W/mm^3, or 0.67 hp/in.^{3}/ min. What is the maximum depth of cut that can be taken in shaping a surface in this material if the surface is 305 × 305 mm (12 × 12), the feed is 0.25 in. per stroke, and the cutting speed is 54.9 mm (180 ft) per minute?
15. Calculate the T_m for planing the block of cast iron in Problem 14 and then estimate T_m for milling the same surface. You will have to determine which milling process to use and select speeds and feeds for an HSS cutter.

Chapter 27 CASE STUDY

Cost Estimating—Planing vs. Milling

KC Kendoric works in the BRC factory as a manufacturing engineer. There are two machine tools available for a job the company is bidding on. One is a 48 × 48 X 10 double housing planer that originally costs $80,000, is depreciated over a 20-year period, and is operated about 6,000 hr/yr. The charge for the use of the machine is $2.50/hr. and labor and overhead in addition are charged at $20.00/hr. The other machine is a large vertical spindle CNC milling machine that costs $165,000 new, depreciated over a 20-year time period also. The charge for the use of the CNC milling machine is $6.00/hr., and labor and overhead in addition are charged at $32.00/hr. To machine the workpiece under consideration takes 10 hours on the planer and 5 hours on the CNC milling machine. The cutting tools consumed cost $5.00/piece for the planer and $31.00/piece for the mill.

Purchasing has not issued an order (quantity not yet decided) so KC needs to determine the BEQ so she knows which machine to use when the order is placed.

CHAPTER 28

ABRASIVE MACHINING PROCESSES

28.1 INTRODUCTION

Abrasive machining is a material removal process that involves the interaction of abrasive grits with the workpiece at high cutting speeds and shallow penetration depths. The chips that are formed resemble those formed by other machining processes. Unquestionably, abrasive machining is the oldest of the basic machining processes. Museums abound with examples of utensils, tools, and weapons that ancient peoples produced by rubbing hard stones against softer materials to abrade away unwanted portions, leaving desired shapes. For centuries, only natural abrasives were available for grinding, while other more modern basic machining processes were developed using superior cutting materials. However, the development of manufactured abrasives and a better fundamental understanding of the abrasive machining process have resulted in placing abrasive machining and its variations among the most important of all the basic machining processes.

The results that can be obtained by abrasive machining range from the finest and smoothest surfaces produced by any machining process, in which very little material is removed, to rough, coarse surfaces that accompany high material removal rates. The abrasive particles may be (1) free; (2) mounted in resin on a belt (called *coated product*); or, most commonly (3) close packed into wheels or stones, with abrasive grits held together by bonding material (called *bonded product* or a grinding wheel). Figure 28-1 shows a surface grinding process using a grinding wheel. The depth of cut *d* is determined by the infeed and is usually very small, 0.002 to 0.005 in., so the arc of contact (and the chips) is small. The table reciprocates back and forth beneath the rotating wheel. The work feeds into the wheel in the cross-feed direction. After the work is clear of the wheel, the wheel is lowered and another pass is made, again removing a couple of thousandths of inches of metal. The metal removal process is basically the same in all abrasive machining processes but with important differences due to spacing of active grains (grains in contact with work) and the rigidity and degree of fixation of the grains. Table 28-1 summarizes the primary abrasive processes. The term *abrasive machining* applied to one particular form of the grinding process is unfortunate, because all these process are machining with abrasives.

Compared to machining, abrasive machining processes have three unique characteristics. First, each cutting edge is very small, and many of these edges can cut simultaneously. When suitable machine tools are employed, very fine cuts are possible, and fine surfaces and close dimensional control can be obtained. Second, because extremely

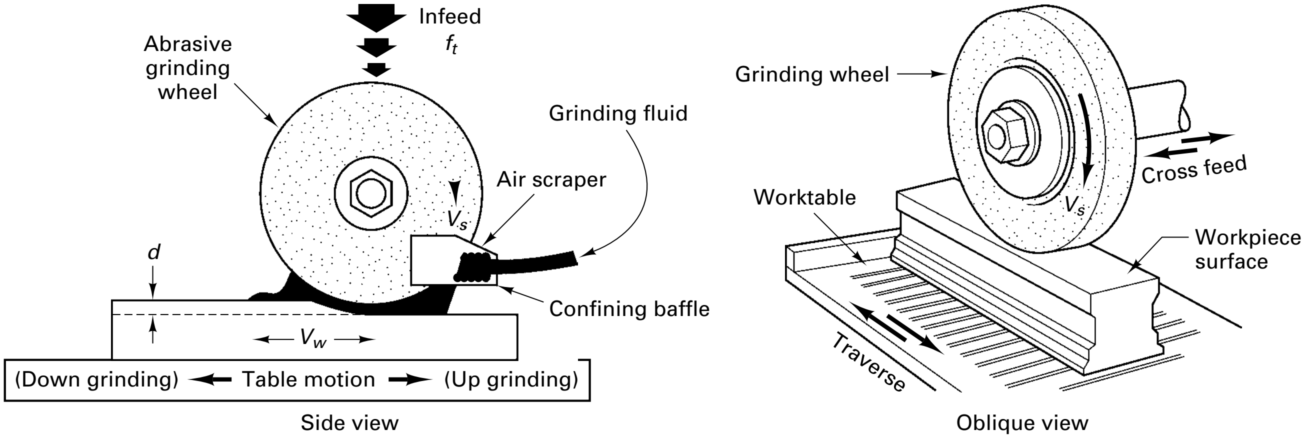

FIGURE 28-1 Schematic of surface grinding, showing infeed and cross feed motions along with cutting speeds V_S, and workpiece velocity V_W.

hard abrasive grits, including diamonds, are employed as cutting tool materials, very hard materials, such as hardened steel, glass, carbides, and ceramics, can readily be machined. As a result, the abrasive machining processes are not only important as manufacturing processes, they are indeed essential. Many of our modern products, such as modern machine tools, automobiles, space vehicles, and aircraft, could not be manufactured without these processes. Third, in grinding, you have no control over the actual tool geometry (rake angles, cutting edge radius) or all the cutting parameters (depth of cut). As a result of these parameters and variables, grinding is a complex process.

To get a handle on the complexity, Table 28-2 presents the primary grinding parameters, grouped by their independence or dependence. Independent variables are those that are controllable (by the machine operator) while the dependent variables are the resultant effects of those inputs. Not listed in the table is workpiece hardness, which has a significant effect on all the resulting effects. Workpiece hardness will be an input factor but it is not usually controllable.

28.2 ABRASIVES

An *abrasive* is a hard material that can cut or abrade other substances. Natural abrasives have existed from the earliest times. For example, sandstone was used by ancient peoples to sharpen tools and weapons. Early grinding wheels were cut from slabs of sandstone, but because they were not uniform in structure throughout, they wore unevenly and did not produce consistent results. *Emery*, a mixture of alumina (Al_2O_3) and magnetite (Fe_3O_4), is another natural abrasive still in use today and is used on coated paper and cloth (emery paper). *Corundum* (natural Al_2O_3) and diamonds are other naturally occurring abrasive materials. Today, the only natural abrasives that have commercial

TABLE 28-1 Abrasive Machining Processes

Process	Particle Mounting	Features
Grinding	Bonded	Uses wheels, accurate sizing, finishing, low MRR; can be done at high speeds (over 12,000 sfpm)
Creep feed grinding	Bonded open, soft	Uses wheels with long cutting arc, very slow feed rate, and large depth of cut
Abrasive machining	Bonded	High MRR, to obtain desired shapes and approximate sizes
Snagging	Bonded belted	High MRR, rough rapid technique to clean up and deburr castings, forgings
Honing	Bonded	"Stones" containing fine abrasives; primarily a hole-finishing process
Lapping	Free	Fine particles embedded in soft metal or cloth; primarily a surface-finishing process
Abrasive waterjet	Free in jet	Water jets with velocities up to 3000 sfpm carry abrasive particles (silica and garnet).
Ultrasonic	Free in liquid	Vibrating tool impacts abrasives at high velocity
Abrasive flow	Free in gel	Abrasives in gel flow over surface-edge finishing
Abrasive jet	Free in	A focused jet of abrasives in an inert gas at high velocity

Method of application	

importance are quartz, sand, garnets, and diamonds. For example, *quartz* is used primarily in coated abrasives and in air blasting, but artificial abrasives are also making inroads in these applications. The development of artificial abrasives having known uniform properties has permitted abrasive processes to become precision manufacturing processes.

Hardness, the ability to resist penetration, is the key property for an abrasive. Table 28-3 lists the primary abrasives and their approximate Knoop hardness (kg/mm^2). The particles must be able to decompose at elevated temperatures. Two other properties are significant in abrasive grits—attrition and friability. *Attrition* refers to the abrasive wear action of the grits resulting in dulled edges, grit flattening, and wheel glazing. *Friability* refers to the fracture of the grits and is the opposite of toughness. In grinding, it is important that grits be able to fracture to expose new, sharp edges.

Artificial abrasives date from 1891, when E. G. Acheson, while attempting to produce precious gems, discovered how to make *silicon carbide* (SiC). Silicon carbide is made by charging an electric furnace with silica sand, petroleum coke, salt, and sawdust. By passing large amounts of current through the charge, a temperature of over 4000°F is maintained for several hours, and a solid mass of silicon carbide crystals results. After the furnace has cooled, the mass of crystals is removed, crushed, and graded (sorted) into

TABLE 28-3 Knoop Hardness Values for Common Abrasives

Abrasive Material	Year of Discovery	Hardness (Knoop)	Temperature of Decomposition in Oxygen (°C)	Comments and Uses
Quartz	?	320		Sand blasting
Aluminum oxide	1893	1600–2100	1700–2400	Softer and tougher than silicon carbide; used on steel, iron, brass, silicon
Carbide	1891	2200–2800	1500–2000	Used for brass, bronze, aluminum, and stainless and cast iron
Borazon [cubic boron nitride stainless (CBN)]	1957	4200–5400	1200–1400	For grinding hard, tough tool steels, stainless steel, cobalt and nickel based, superalloys, and hard coatings
Diamond (synthetic)	1955	6000–9000	700–800	Used to grind nonferrous materials, tungsten carbide, and ceramics

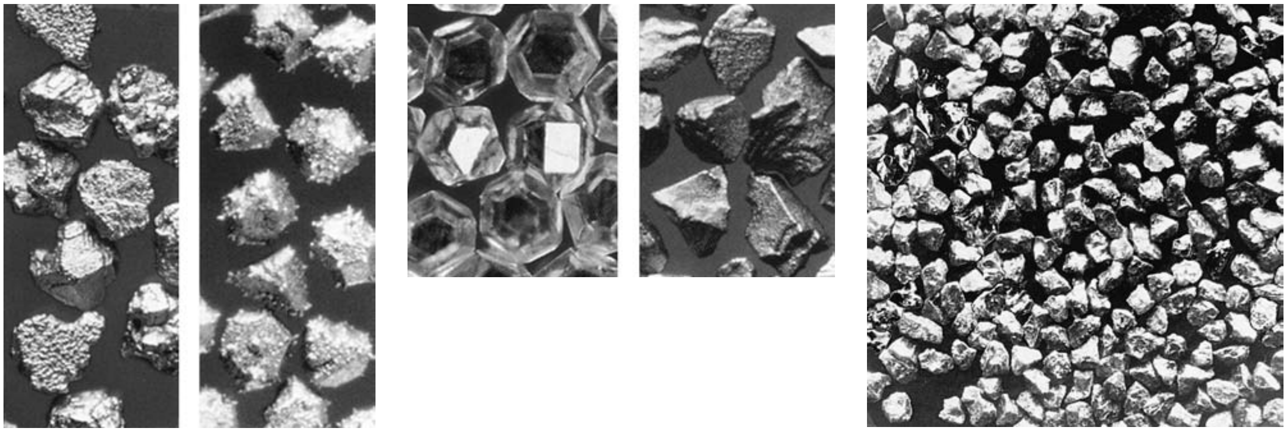

FIGURE 28-2 Loose abrasive grains at high magnification, showing their irregular, sharp cutting edges. *(Courtesy of Norton Company.)*

various desired sizes. As can be seen in Figure 28-2, the resulting grits, or grains, are irregular in shape, with cutting edges having every possible rake angle. Silicon carbide crystals are very hard (Knoop 2480), friable, and rather brittle. This limits their use. Silicon carbide is sold under the trade names Carborundum and Crystolon.

Aluminum oxide (Al_2O_3) is the most widely used artificial abrasive. Also produced in an arc furnace from bauxite, iron filings, and small amounts of coke, it contains aluminum hydroxide, ferric oxide, silica, and other impurities. The mass of aluminum oxide that is formed is crushed, and the particles are graded to size. Common trade names for aluminum oxide abrasives are Alundum and Aloxite. Although aluminum oxide is softer (Knoop 2100) than silicon carbide, it is considerably tougher. Consequently, it is a better general-purpose abrasive.

Diamonds are the hardest of all materials. Those that are used for abrasives are either natural, off-color stones (called *garnets*) that are not suitable for gems, or small, synthetic stones that are produced specifically for abrasive purposes. Manufactured stones appear to be somewhat more friable and thus tend to cut faster and cooler. They do not perform as satisfactorily in metal-bonded wheels. Diamond abrasive wheels are used extensively for sharpening carbide and ceramic cutting tools. Diamonds also are used for truing and dressing other types of abrasive wheels. Diamonds are usually used only when cheaper abrasives will not produce the desired results. Garnets are used primarily in the form of very finely crushed and graded powders for fine polishing.

Cubic boron nitride (CBN) is not found in nature. It is produced by a combination of intensive heat and pressure in the presence of a catalyst. CBN is extremely hard, registering at 4700 on the Knoop scale. It is the second-hardest substance created by nature or manufactured and is often referred to, along with diamonds, as a superabrasive. Hardness, however, is not everything.

CBN far surpasses diamond in the important characteristic of thermal resistance. At temperatures of 650°C, at which diamond may begin to revert to plain carbon dioxide, CBN continues to maintain its hardness and chemical integrity. When the temperature of 1400°C is reached, CBN changes from its cubic form to a hexagonal form and loses hardness. CBN can be used successfully in grinding iron, steel, alloys of iron, Ni-based alloys, and other materials. CBN works very effectively (long wheel life, high *G* ratio, good surface quality, no burn or chatter, low scrap rate, and overall increase in parts/shift) on hardened materials (R_c 50 or higher). It can also be used for soft steel in selected situations. CBN does well at conventional grinding speeds (6000 to 12,000 ft/min), resulting in lower total grinding in conventional equipment. CBN can also perform well at high grinding speeds (12,000 ft/min and higher) and will enhance the benefits from future machine tools. CBN can solve difficult-to-grind jobs, but it also generates cost benefits in many production grinding operations despite its higher cost. CBN is manufactured by the General Electric Company under the trade name of Borazon.

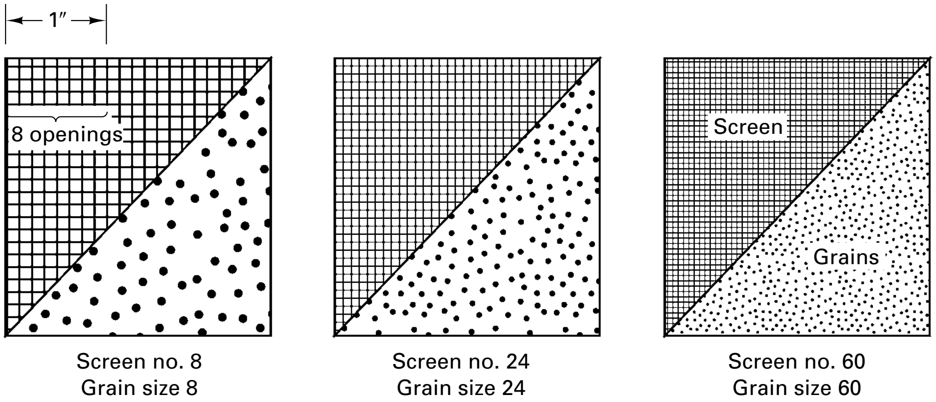

FIGURE 28-3 Typical screens for sifting abrasives into sizes. The larger the screen number (of opening per linear inch), the smaller the grain size. *(Courtesy of Carborundum Company.)*

ABRASIVE GRAIN SIZE AND GEOMETRY

To enhance the process capability of grinding, abrasive grains are sorted into sizes by mechanical sieving machines. The number of openings per linear inch in a sieve (or screen) through which most of the particles of a particular size can pass determines the grain size (Figure 28-3).

A no. 24 grit would pass through a standard screen having 24 openings per inch but would not pass through one having 30 openings per inch. These numbers have since been specified in terms of millimeters and micrometers (see ANSI B74.12 for details). Commercial practice commonly designates grain sizes from 4 to 24, inclusive, as *coarse*; 30 to 60, inclusive, as *medium*; and 70 to 600, inclusive, as *fine*. Grains smaller than 220 are usually termed *powders*. Silicon carbide is obtainable in grit sizes ranging from 2 to 240 and aluminum oxide in sizes from 4 to 240. Superabrasive grit sizes normally range from 120 grit for CBN to 400 grit for diamond. Sizes from 240 to 600 are designated as *flour* sizes. These are used primarily for lapping, or in fine-honing stones for fine finishing tasks.

The grain size is closely related to the surface finish and metal removal rate. In grinding wheels and belts, coarse grains cut faster while fine grains provide better finish, as shown in Figure 28-4.

The grain diameter can be estimated from the screen number (S), which corresponds to the number of openings per inch. The mean diameter of the grain (g) is related to the screen number by $g \cong 0.7/S$.

Regardless of the size of the grain, only a small percentage (2 to 5%) of the surface of the grain is operative at any one time. That is, the depth of cut for an individual grain (the actual feed per grit) with respect to the grain diameter is very small. Thus the

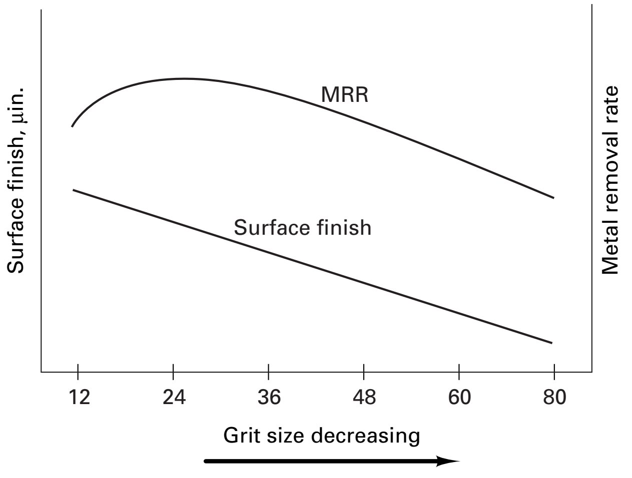

FIGURE 28-4 MRR and surface finish versus grit size.

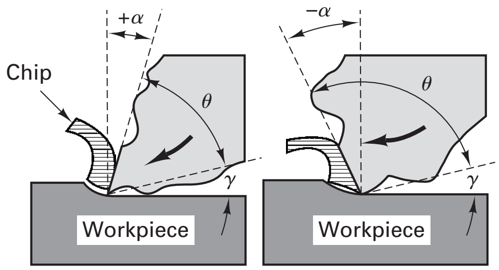

FIGURE 28-5 The rake angle of abrasive particles can be positive, zero, or negative.

chips are small. As the grain diameter decreases, the number of active grains per unit area increases and the cuts become finer because grain size is the controlling factor for surface finish (roughness). Of course, the MRR also decreases.

The grain shape is also important, because it determines the tool geometry—that is, the back rake angle and the clearance angle at the cutting edge of the grit (Figure 28-5). In the figure, γ is the clearance angle, θ is the wedge angle, and α is the rake angle. The cavities between the grits provide space for the chips, as shown in Figure 28-6. The volume of the cavities must be greater than the volume of the chips generated during the cut.

Obviously, there is no specific rake angle but rather a distribution of angles. Thus a grinding wheel can present to the surface rake angles in the range of +45° to −60° or greater. Grits with large negative rake angles or rounded cutting edges do not form chips but will rub or *plow* a groove in the surface (Figure 28-7). Thus abrasive machining is a

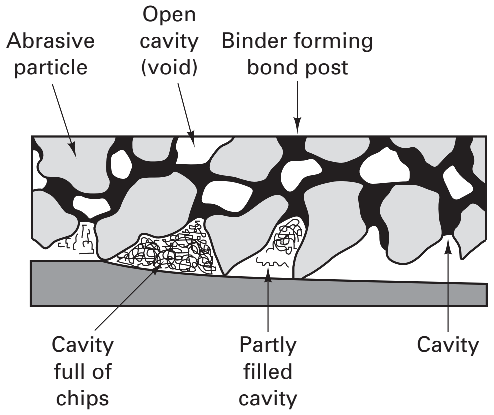

FIGURE 28-6 The cavities or voids between the grains must be large enough to hold all the chips during the cut.

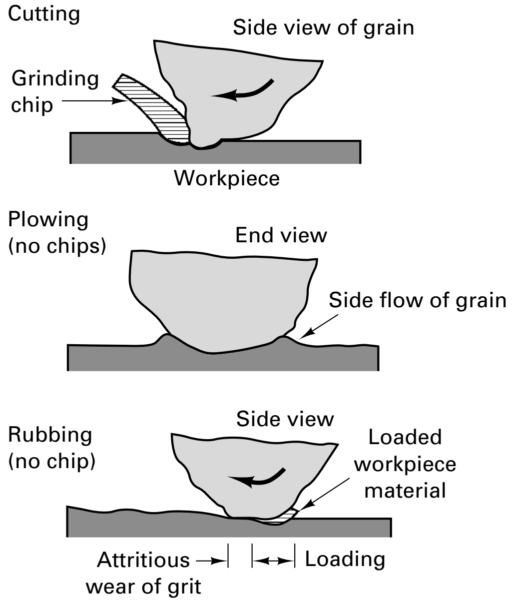

FIGURE 28-7 The grits interact with the surface in three ways: cutting, plowing, and rubbing.

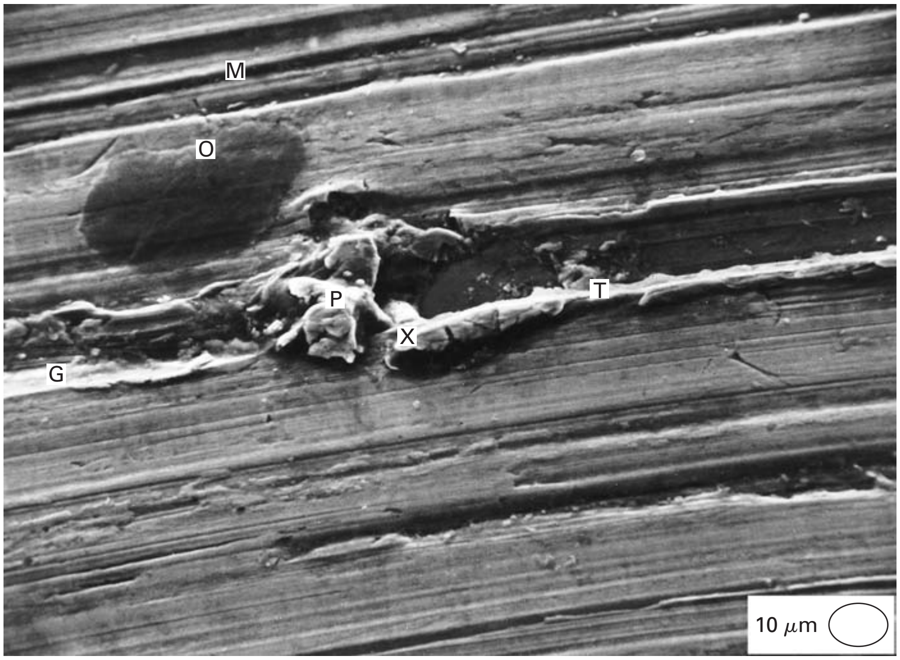

FIGURE 28-8 SEM micrograph of a ground steel surface showing a plowed track (T) in the middle and a machined track (M) above. The grit fractured, leaving a portion of the grit in the surface (X), a prow formation (P), and a groove (G) where the fractured portion was pushed farther across the surface. The area marked (O) is an oil deposit.

mixture of *cutting, plowing, and rubbing*, with the percentage of each being highly dependent on the geometry of the grit. As the grits are continuously abraded, fractured, or dislodged from the bond, new grits are exposed and the mixture of cutting, plowing, and rubbing is changing continuously. A high percentage of the energy used for rubbing and plowing goes into the workpiece, but when chips are found, 95 to 98% of the energy (the heat) goes into the chip. Figure 28-8 shows a scanning electron microscope (SEM) micrograph of a ground surface with a plowing track.

In grinding, the chips are small but are formed by the same basic mechanism of compression and shear as discussed in Chapter 20 for regular metalcutting. Figure 28-9 shows steel chips from a grinding process at high magnification. They show the same structure as chips from other machining processes. Chips flying in the air from a grinding process often have sufficient heat energy to burn or melt in the atmosphere. Sparks observed during grinding steel with no cutting fluid are really burning chips, as shown in Figure 28-8.

The feeds and depths of cut in grinding are small while the cutting speeds are high, resulting in high specific horsepower numbers. Because cutting is obviously more efficient than plowing or rubbing, grain fracture and grain pullout are natural phenomena

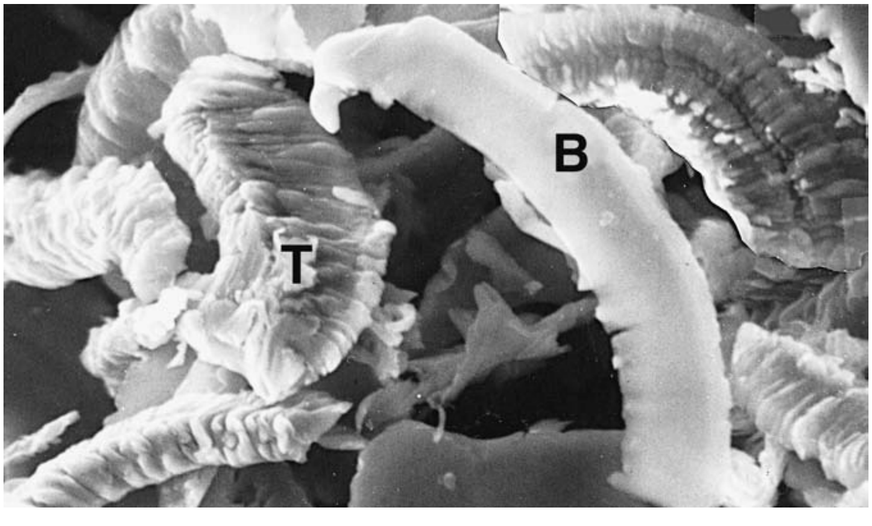

FIGURE 28-9 SEM micrograph of stainless steel chips from a grinding process. The tops (T) of the chips have the typical shear-front-lamella structure while the bottoms (B) are smooth where they slide over the grit 4800×.

used to keep the grains sharp. As the grains become dull, cutting forces increase, and there is an increased tendency for the grains to fracture or break free from the bonding material.

28.3 GRINDING WHEEL STRUCTURE AND GRADE

Grinding, wherein the abrasives are bonded together into a wheel, is the most common abrasive machining process. The performance of grinding wheels is greatly affected by the bonding material and the spatial arrangement of the particles' grits.

The spacing of the abrasive particles with respect to each other is called *structure*. Close-packed grains have dense structure; open structure means widely spaced grains. Open-structure wheels have larger chip cavities but fewer cutting edges per unit area (Figure 28-10a).

The fracturing of the grits is controlled by the bond strength, which is known as the *grade*. Thus, grade is a measure of how strongly the grains are held in the wheel. It is really dependent on two factors: the strength of the bonding materials and the amount of the bonding agent connecting the grains. The latter factor is illustrated in Figure 28-10b. Abrasive wheels are really porous. The grains are held together with "posts" of bonding material. If these posts are large in cross section, the force required to break a grain free from the wheel is greater than when the posts are small. If a high dislodging force is required, the bond is said to be *hard*. If only a small force is required, the bond is said to be *soft*. Wheels are commonly referred to as hard or soft, referring to the net strength of the bond, resulting from both the strength of the bonding material and its disposition between the grains.

G RATIO

The loss of grains from the wheel means that the wheel is changing size. The grinding ratio, or *G* ratio, is defined as the cubic inches of stock removed divided by the cubic inches of wheel lost. In conventional grinding, the *G* ratio is in the range 20:1 to 80:1. The *G* ratio is a measure of grinding production and reflects the amount of work a wheel can do during its useful life. As the wheel loses material, it must be reset or repositioned to maintain workpiece size.

A typical vitrified grinding wheel will consist of 50 vol% abrasive particles, 10 vol% bond, and 40 vol% cavities; that is, the wheels have porosity. The manner in which the wheel performs is influenced by the following factors:

1. The mean force required to dislodge a grain from the surface (the grade of the wheel)
2. The cavity size and distribution of the porosity (the structure)

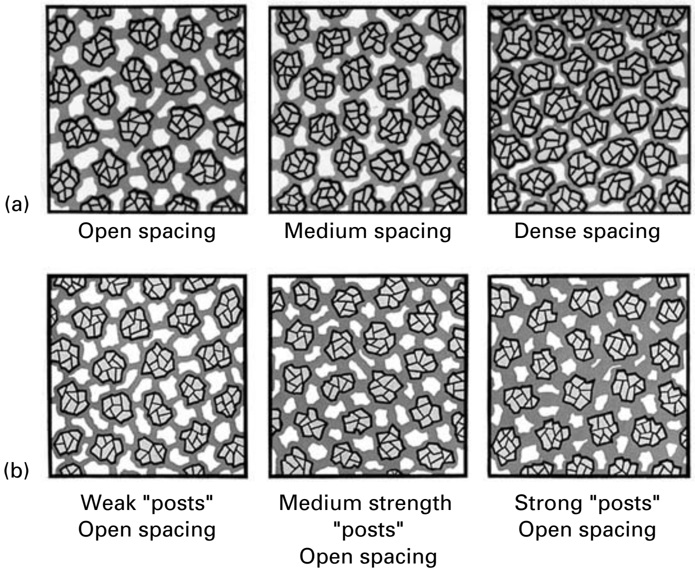

FIGURE 28-10 Meaning of terms *structure* and *grade* for grinding wheels. (a) The structure of a grinding wheel depends on the spacing of the grits. (b) The grade of a grinding wheel depends on the amount of bonding agent (posts) holding abrasive grains in the wheel.

3. The mean spacing of active grains in the wheel surface (grain size and structure)
4. The properties of the grain (hardness, attrition, and friability)
5. The geometry of the cutting edges of the grains (rake angles and cutting-edge radius compared to depth of cut)
6. The process parameters (speeds, feeds, cutting fluids) and type of grinding (surface, or cylindrical)

It is easy to see why grinding is a complex process, difficult to control.

BONDING MATERIALS FOR GRINDING WHEELS

Bonding material is a very important factor to be considered in selecting a grinding wheel. It determines the strength of the wheel, thus establishing the maximum operating speed. It determines the elastic behavior or deflection of the grits in the wheel during grinding. The wheel can be hard or rigid, or it can be flexible. Finally, the bond determines the force required to dislodge an abrasive particle from the wheel and thus plays a major role in the cutting action. Bond materials are formulated so that the ratio of bond wear matches the rate of wear of the abrasive grits. Bonding materials in common use are the following:

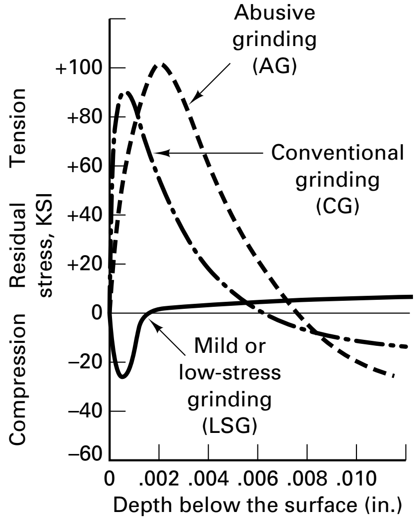
1. *Vitrified bonds* are composed of clays and other ceramic substances. The abrasive particles are mixed with the wet clays so that each grain is coated. Wheels are formed from the mix, usually by pressing, and then dried. They are then fired in a kiln, which results in the bonding material's becoming hard and strong, having properties similar to glass. Vitrified wheels are porous, strong, rigid, and unaffected by oils, water, or temperature over the ranges usually encountered in metal cutting. The operating speed range in most cases is 5500 to 6500 ft/min, but some wheels now operate at surface speeds up to 16,000 ft/min.
2. *Resinoid*, or phenolic resins, can be used. Because plastics can be compounded to have a wide range of properties, such wheels can be obtained to cover a variety of work conditions. They have, to a considerable extent, replaced shellac and rubber wheels. Composite materials are being used in rubber-bonded or resinoid-bonded wheels that are to have some degree of flexibility or are to receive considerable abuse and side loading. Various natural and synthetic fabrics and fibers, glass fibers, and nonferrous wire mesh are used for this purpose.
3. *Silicate* wheels use silicate of soda (waterglass) as the bond material. The wheels are formed and then baked at about 500°F for a day or more. Because they are more brittle and not so strong as vitrified wheels, the abrasive grains are released more readily. Consequently, they machine at lower surface temperatures than vitrified wheels and are useful in grinding tools when heat must be kept to a minimum.
4. *Shellac-bonded* wheels are made by mixing the abrasive grains with shellac in a heated mixture, pressing or rolling into the desired shapes, and baking for several hours at about 300°F. This type of bond is used primarily for strong, thin wheels having some elasticity. They tend to produce a high polish and thus have been used in grinding such parts as camshafts and mill rolls.
5. *Rubber* bonding is used to produce wheels that can operate at high speeds but must have a considerable degree of flexibility so as to resist side thrust. Rubber, sulfur, and other vulcanizing agents are mixed with the abrasive grains. The mixture is then rolled out into sheets of the desired thickness, and the wheels are cut from these sheets and vulcanized. Rubber-bonded wheels can be operated at speeds up to 16,000 ft/min. They are commonly used for snagging work in foundries and for thin cutoff wheels.
6. *Superabrasive* wheels are either electroplated (single layer of superabrasive plated to outside diameter of a steel blank) or a thin segmented drum of vitrified CBN surrounds a steel core. The steel core provides dimensional accuracy, and the replaceable segments provide durability, homogeneity, and repeatability while increasing wheel life. The latter type of wheels can use resin, metal, or vitrified bonding. Selection of bond grade and structure (also called abrasive concentration) is critical.

For the electroplated wheels, nickel is used to attach a single layer of CBN (or diamond) to the OD of an accurately ground or turned steel blank. For the vitrified wheel, superabrasives are mixed with bonding media and molded (or preformed and sintered) into segments or a ring. The ring is mounted on a split steel body. Porosity is varied (to alter structure) by varying preform pressure or by using "pore-forming" additives to the bond material that are vaporized during the sintering cycle. The steel-cored segmented design can rotate at 40,000 sfpm (200 m/s) whereas a plain vitrified wheel may burst at 20,000 fpm.

ABRASIVE MACHINING VERSUS CONVENTIONAL GRINDING VERSUS LOW-STRESS GRINDING

The condition wherein very rapid metal removal can be achieved by grinding is the one to which some have applied the term *abrasive machining*. The metal removal rates are compared with, or exceed, those obtainable by milling or turning or broaching, and the size tolerances are comparable. It is obviously just a special type of grinding, using abrasive grains as cutting tools, as do all other types of abrasive machining. Abrasive grinding done in an aggressive way can produce sufficient localized plastic deformation and heat in the surface so as to develop tensile residual stresses, layers of overtempered martensite (in steels), and even microcracks, because this process is quite abusive. See Figure 28-11 for a discussion of residual stresses produced by varius surface grinding processes.

Conventional grinding can be replaced by procedures that develop lower surface stresses when service failures due to fatigue or stress corrosion are possible. This is accomplished by employing softer grades of grinding wheels, reducing the grinding speeds and infeed rates, using chemically active cutting fluids (e.g., highly sulfurized oil or KNO_2 in water), as outlined in the table of grinding conditions in Figure 28-11. These procedures may require the addition of a variable-speed drive to the grinding machine. Generally, only about 0.005 to 0.010 in. of surface stock needs to be finish ground in this way, as the depth of the surface damage due to conventional grinding or abusive grinding is 0.005 to 0.007 in. High-strength steels, high-temperature nickel, and cobalt-based alloys and titanium alloys are particularly sensitive to surface deformation and cracking problems from grinding. Other postprocessing processes, such as polishing, honing, and chemical milling plus peening, can be used to remove the deformed layers in critically stressed parts. It is strongly recommended, however, that testing programs be used along with service experience on critical parts before these procedures are employed in production.



Grinding conditions

	Abusive AG	Conventional CG	Low-stress LSG
Wheel	A46MV	A46KV	A46HV or A60IV
Wheel speed ft/min	6,000–18,000	4,500–6,500	2500–3000
Down feed in./pass	.002–.004	.001–.003	.0002–.005
Cross feed in./pass	.040–.060	.040–.060	.040–.060
Table speed ft/min	40–100	40–100	40–100
Fluid	Dry	Sol oil (1:20)	Sulfurized oil

FIGURE 28-11 Typical residual stress distributions produced by surface grinding with different grinding conditions for abusive, conventional, and low-stress grinding. Material is 4340 steel. *(From M. Field and W. P. Kosher, "Surface Integrity in Grinding," in* New Developments in Grinding, *Carnegie-Mellon University Press, Pittsburgh, 1972, p. 666.)*

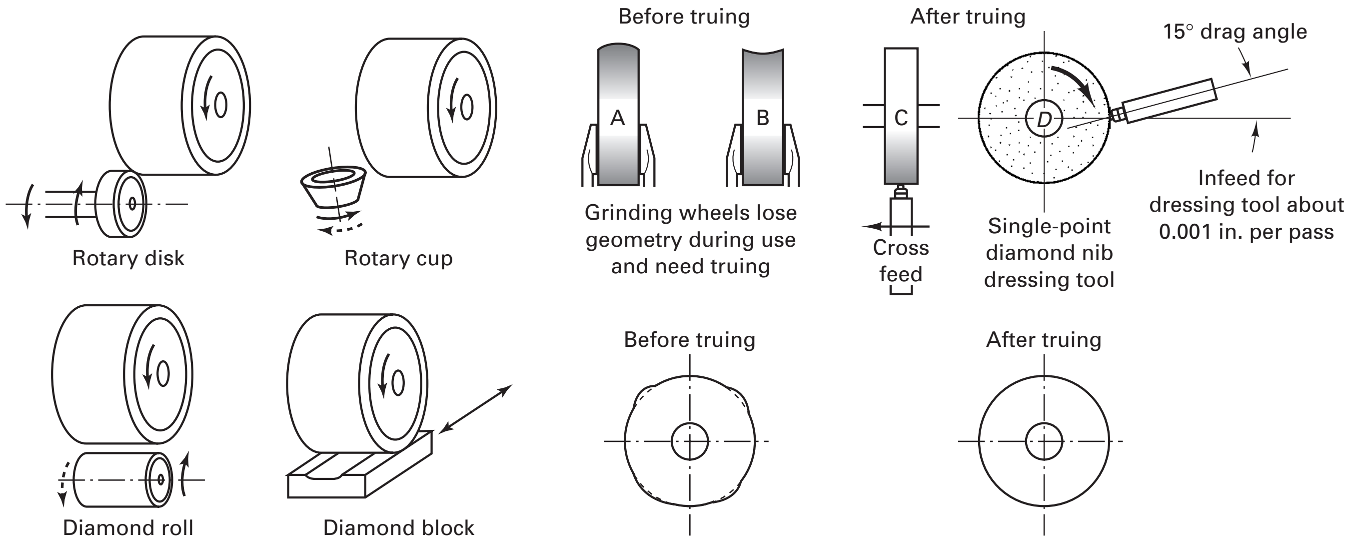


FIGURE 28-12 Truing methods for restoring grinding geometry include nibs, rolls, disks, cups, and blocks.

In the casting and forging industries, the term often used for abrasive maching is *snagging*. *Snagging* is a type of rough manual grinding that is done to remove fins, gates, risers, and rough spots from castings or flash from forgings, preparatory to further machining. The primary objective is to remove substantial amounts of metal rapidly without much regard for accuracy, so this is a form of abrasive machining except that pedestal-type or *swing grinders* ordinarily are used. Portable electric or hand air grinders are also used for this purpose and for miscellaneous grinding in connection with welding.

Grinding wheels lose their geometry during use. *Truing* restores the original shape. A single-point diamond tool can be used to *true* the wheel while fracturing abrasive grains to expose new grains and new cutting edges on worn, glazed grains (Figure 28-12). Truing can also be accomplished by grinding the grinding wheel with a controlled-path or powered rotary device using conventional abrasive wheels. The precision in generating a trued wheel surface by these methods is poorer than by the method described earlier.

As the wheel is used, there is a tendency for the wheel to become *loaded* (metal chips become lodged in the cavities between the grains). Also, the grains dull or glaze (grits wear, flatten, and polish). Unless the wheel is cleaned and sharpened (or dressed), the wheel will not cut as well and will tend to plow and rub more. Figure 28-13 shows an arrangement for stick *dressing* a grinding wheel. The dulled grains cause the cutting forces on the grains to increase, ideally resulting in the grains' fracturing or being pulled out of the bond, thus providing a continuous exposure of sharp cutting edges. Such a continuous action ordinarily will not occur for light feeds and depths of cut. For heavier cuts, grinding wheels do become somewhat self-dressing, but the workpiece may become overheated and turn a bluish temper color (this is called *burn*) before the wheel reaches a

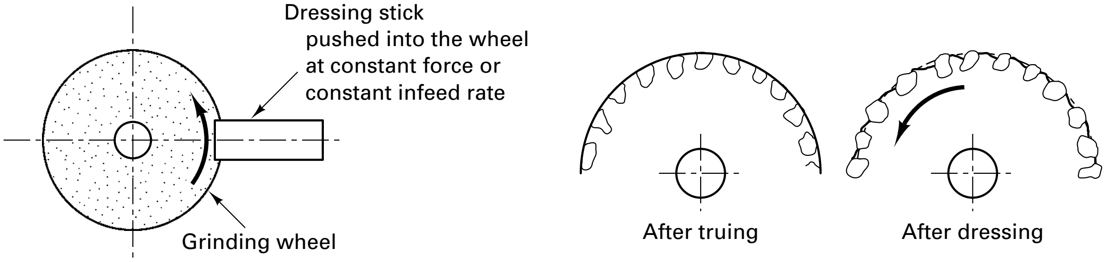

FIGURE 28-13 Schematic arrangement of stick dressing versus truing.

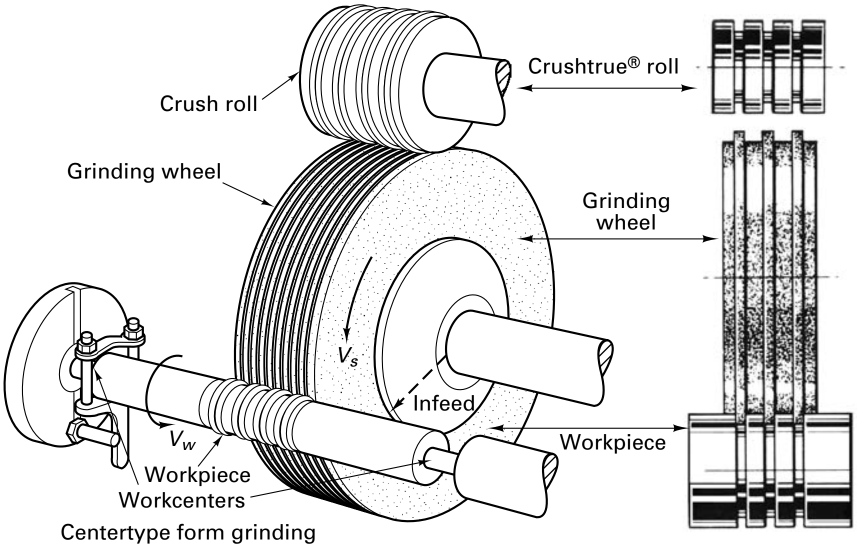

FIGURE 28-14 Continuous crush roll dressing and truing of a grinding wheel (form—truing and dressing throughout the process rather than between cycles) doing plunge cut grinding on a cylinder held between centers.

fully dressed condition. A burned surface, the consequence of an oxide layer formation, results in the scrapping of several workpieces before parts of good quality are ground.

Resin-bonded wheels can be trued by grinding with hard ceramics such as tungsten carbide. The procedure for truing and dressing a CBN wheel in a surface grinder might be as follows: Use 0.0002-in. downfeed per pass and cross feed slightly more than half the wheel thickness at moderate table speeds. The wheel speed is the same as the grinding speed. The grinding power will gradually increase, as the wheel is getting dull, while being trued. When the power exceeds normal power drawn during workpiece grinding, stop the truing operation. Dress the wheel face open using a J-grade stick, with abrasive one grit size smaller than CBN. Continue the truing. Repeat this cycle until the wheel is completely trued.

Modern grinding machines are equipped so that the wheel can be dressed and/or trued continuously or intermittently while grinding continues. A common way to do this is by *crush dressing* (Figure 28-14). Crush dressing consists of forcing a hard roll (tungsten carbide or high speed steel) having the same contour as the part to be ground against the grinding wheel while it is revolving—usually quite slowly. A water-based coolant is used to flood the dressing zone at 5 to 10 gal/min. The crushing action fractures and dislodges some of the abrasive grains, exposing fresh sharp edges, allowing free cutting for faster infeed rates. This procedure is usually employed to produce and maintain a special contour to the abrasive wheel. This is also called wheel profiling. Crush dressing is a very rapid method of dressing grinding wheels, and because it fractures abrasive grains, it results in free cutting and somewhat cooler grinding. The resulting surfaces may be slightly rougher than when diamond dressing is used.

■ 28.4 GRINDING WHEEL IDENTIFICATION

Most grinding wheels are identified by a standard marking system that has been established by the American National Standards Institute. This system is illustrated and explained in Figure 28-15. The first and last symbols in the marking are left to the discretion of the manufacturer.

GRINDING WHEEL GEOMETRY

The shape and size of the wheel are critical selection factors. Obviously, the shape must permit proper contact between the wheel and all of the surface that must be ground. Grinding wheel shapes have been standardized, and eight of the most commonly used types are shown in Figure 28-16. Types 1, 2, and 5 are used primarily for grinding external or internal cylindrical surfaces and for plain surface grinding. Type 2 can be mounted for grinding on either the periphery or the side of the wheel. Type 4 is used with tapered safety flanges so that if the wheel breaks during rough grinding, such as snagging, these

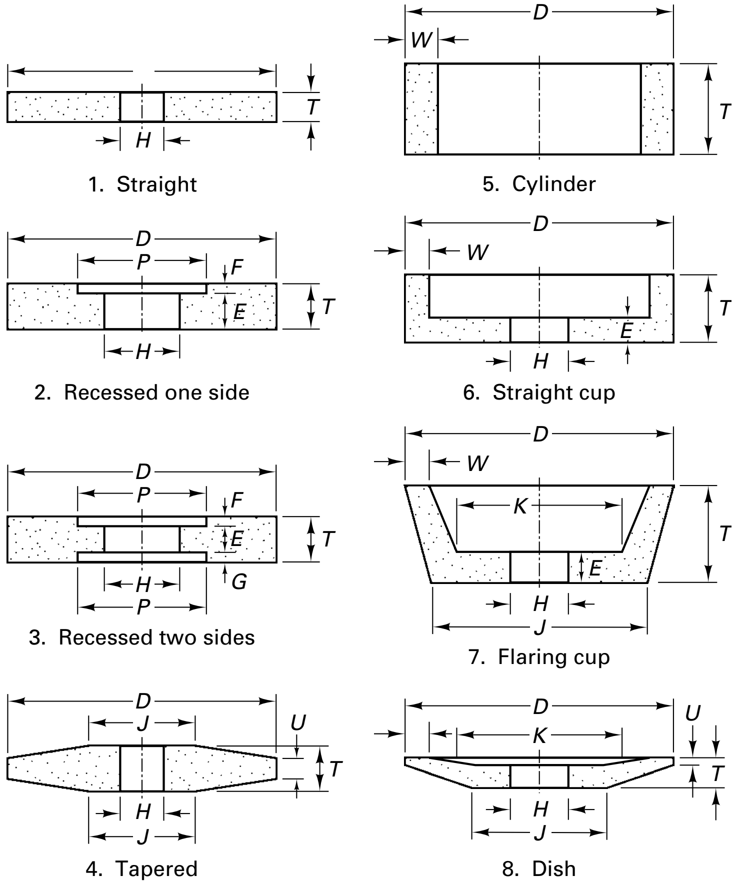

FIGURE 28-16 Standard grinding wheel shapes commonly used. *(Courtesy of Carborundum Company.)*

flanges will prevent the pieces of the wheel from flying and causing damage. Type 6, the straight cup, is used primarily for surface grinding but can also be used for certain types of offhand grinding. The flaring-cup type of wheel is used for tool grinding. Dish-type wheels are used for grinding tools and saws.

Type 1, the straight grinding wheels, can be obtained with a variety of standard faces. Some of these are shown in Figure 28-17.

The size of the wheel to be used is determined primarily by the spindle rpm values available on the grinding machine and the proper cutting speed for the wheel, as dictated by the type of bond. For most grinding operations the cutting speed is about 2500 to 6500 ft/min. Different types and grades of bond often justify considerable deviation from these speeds. For certain types of work using special wheels and machines, as in thread grinding and "abrasive machining," much higher speeds are used.

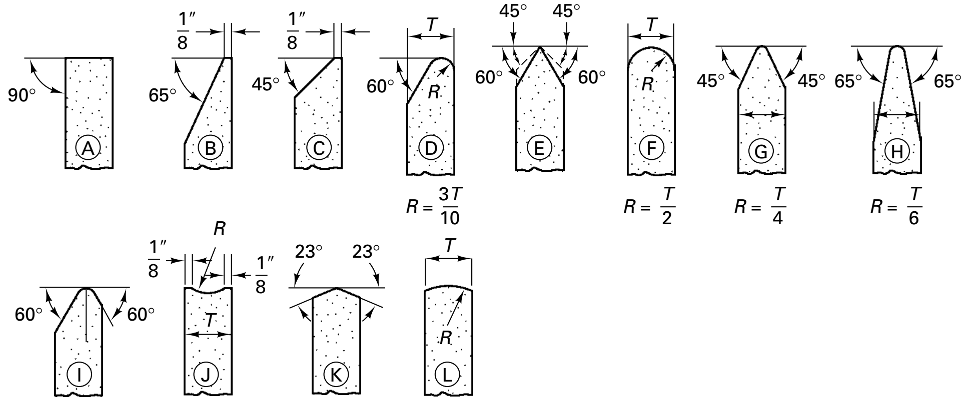

FIGURE 28-17 Standard face contours for straight grinding wheels. *(Courtesy of Carborundum Company.)*

The operation for which the abrasive wheel is intended will also influence the wheel shape and size. The major use categories are the following:

1. *Cutting off*: for slicing and slotting parts; use thin wheel, organic bond
2. *Cylindrical between centers*: grinding outside diameters of cylindrical workpieces
3. *Cylindrical, centerless*: grinding outside diameters with work rotated by regulating wheel
4. *Internal cylindrical*: grinding bores and large holes
5. *Snagging*: removing large amounts of metal without regard to surface finish or tolerances
6. *Surface grinding*: grinding flat workpieces
7. *Tool grinding*: for grinding cutting edges on tools such as drills, milling cutters, taps, reamers, and single-point high-speed-steel tools
8. *Offhand grinding*: work or the grinding tool is handheld

In many cases, the classification of processes coincides with the classification of machines that do the process. Other factors that will influence the choice of wheel to be selected include the workpiece material, the amount of stock to be removed, the shape of the workpiece, and the accuracy and surface finish desired. Workpiece material has a great impact on choice of the wheel. Hard, high-strength metals (tool steels, alloy steels) are generally ground with aluminum oxide wheels or cubic boron nitride wheels. Silicon carbide and CBN are employed in grinding brittle materials (cast iron and ceramics) as well as softer, low-strength metals such as aluminum, brass, copper, and bronze. Diamonds have taken over the cutting of tungsten carbides, and CBN is used for precision grinding of tool and die steel, alloy steels, stainless steel, and other very hard materials. There are so many factors that affect the cutting action that there are no hard-and-fast rules with regard to abrasive selection.

Selection of grain size is determined by whether coarse or fine cutting and finish are desired. Coarse grains take larger depths of cut and cut more rapidly. Hard wheels with fine grains leave smaller tracks and therefore are usually selected for finishing cuts. If there is a tendency for the work material to load the wheel, larger grains with a more open structure may be used for finishing.

BALANCING GRINDING WHEELS

Because of the high rotation speeds involved, grinding wheels must never be used unless they are in good balance. A slight imbalance will produce vibrations that will cause waviness in the work surface. It may cause a wheel to break, with the probability of serious damage and injury. The wheel should be mounted with proper bushings so that it fits snugly on the spindle of the machine. Rings of blotting paper should be placed between the wheel and the flanges to ensure that the clamping pressure is evenly distributed. Most grinding wheels will run in good balance if they are mounted properly and trued. Most machines have provision for compensating for a small amount of wheel imbalance by attaching weights to one mounting flange. Some have provision for semiautomatic balancing with weights that are permanently attached to the machine spindle.

SAFETY IN GRINDING

Because the rotational speeds are quite high, and the strength of grinding wheels is usually much less than that of the materials being ground, serious accidents occur much too frequently in connection with the use of grinding wheels. Virtually all such accidents could be avoided and are due to one or a combination of four causes. First, grinding wheels are occasionally operated at unsafe and improper speeds. All grinding wheels are clearly marked with the maximum rpm value at which they should be rotated. They are all tested to considerably above the designated rpm and are safe at the specified speed *unless abused*. *They should never*, *under any condition*, *be operated above the rated speed*. Second, a very common form of abuse, frequently accidental, is dropping the wheel or striking it against a hard object. This can cause a crack (which may not be readily visible), resulting in subsequent failure of the wheel while rotating at high speed under load. If a wheel is dropped or struck against a hard object, it should be discarded and never used unless tested at above the rated speed in a properly designed test stand. A third common cause of grinding wheel failure is

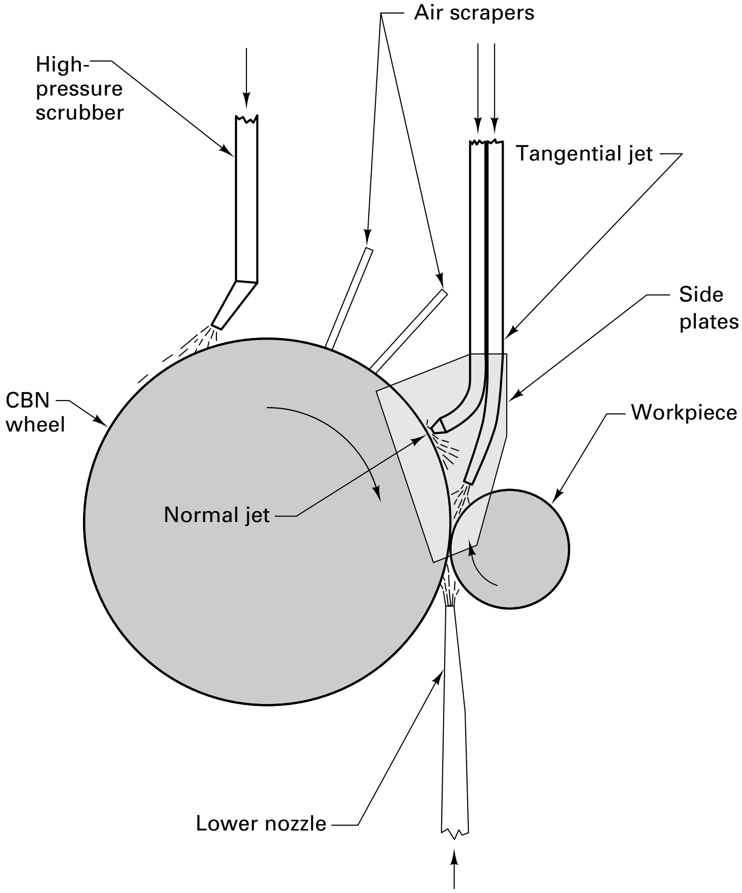

FIGURE 28-18 Coolant delivery system for optimum CBN grinding. (*Source: "Production Grinding with CBN," M. P. Hitchiner, CBN Grinding Systems Manager, Universal Beck, Romulus, MI,* Machining Technology, *Vol. 2, No. 2, 1991.)*

improper use, such as grinding against the side of a wheel that was designed for grinding only on its periphery. The fourth and most common cause of injury from grinding is the absence of a proper safety guard over the wheel and/or over the eyes or face of the operator. The frequency with which operators will remove safety guards from grinding equipment or fail to use safety goggles or face shields is amazing and inexcusable.

USE OF CUTTING FLUIDS IN GRINDING

Because grinding involves cutting, the selection and use of a cutting fluid is governed by the basic principles discussed in Chapter 21. If a fluid is used, it should be applied in sufficient quantities and in a manner that will ensure that the chips are washed away, not trapped between the wheel and the work. This is of particular importance in grinding horizontal surfaces. In hardened steel, the use of a fluid can help to prevent fine microcracks that result from highly localized heating. The air scraper shown in Figure 28-18 permits the cutting fluid (lubricant) to get onto the face of the wheel. Metal air scrapers disrupt the airflow. Upper and lower nozzles cool the grinding zone, while a high-pressure scrubber helps deter loading of the wheel.

Much snagging and off-hand grinding is done dry. On some types of material, dry grinding produces a better finish than can be obtained by wet grinding.

Grinding fluids strongly influence the performance of CBN wheels. Straight, sulfurized, or sulfochlorinated oils can enhance performance considerably when used with straight oils.

28.5 GRINDING MACHINES

Grinding machines commonly are classified according to the type of surface they produce. Table 28-4 presents such a classification, with further subdivision to indicate characteristic features of different types of machines within each classification. Grinding on all machines is done in three ways. In the first, the depth of cut (d_t) is obtained by *infeed*—moving the

TABLE 28-4 Grinding Machines

Type of Machine	Type of Surface	Specific Types or Features
Cylindrical external	External surface on rotating, usually cylindrical parts	Work rotated between centers Centerless Centerless Chucking Tool post Crankshaft, cam, etc.
Cylindrical internal	Internal diameters of holes	Chucking Planetary (work stationary) Centerless
Surface conventional	Flat surfaces	Reciprocating table or rotating table Horizontal or vertical spindle
Creep feed	Deep slots, profiles in hard steels, carbides, and ceramics using CBN and diamond	Rigid, chatter-free, creep feed rate Continuous dressing Heavy coolant flows NC or CNC control Variable speed wheel
Tool grinders	Tool angles and geometries	Universal Special
Other	Special or any of the above	Disk, contour, thread, flexible shaft, swing frame, snag, pedestal, bench

wheel down into the work or the work up into the wheel (Figure 28-19). The desired surface is then produced by traversing the wheel across (cross feed) the workpiece, or vice versa (Figure 28-19). In the second method, known as *plunge-cut* grinding, the basic movement is of the wheel being fed radially into the work while the latter revolves on centers. It is similar to form cutting on a lathe; usually a formed grinding wheel is used (Figure 28-14). In the third method, the work is fed very slowly past the wheel and the

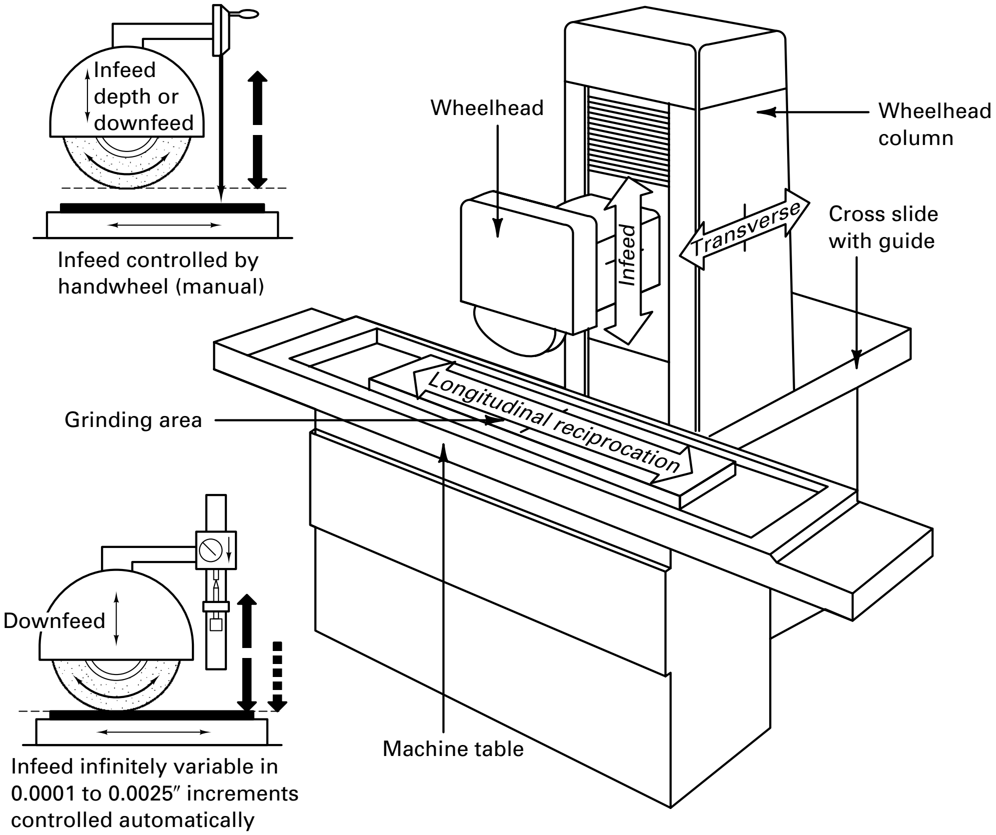

FIGURE 28-19 Horizontal-spindle surface grinder, with insets showing movements of wheelhead.

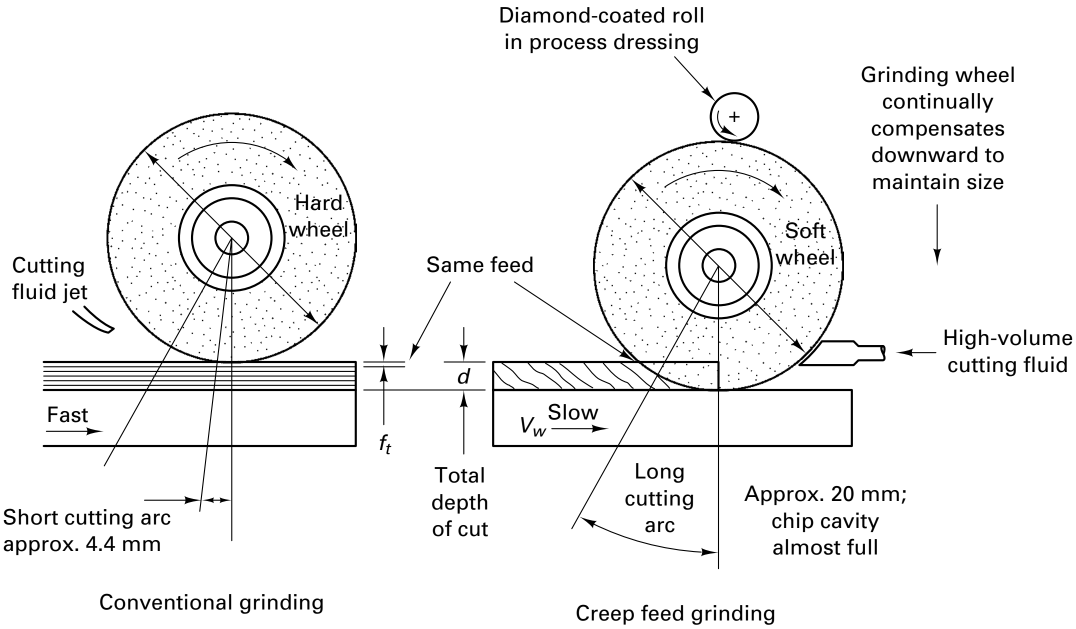

FIGURE 28-20 Conventional grinding contrasted to creep feed grinding. Note that crush roll dressing is used here; see Figure 28-14.

total downfeed or depth (d) is accomplished in a single pass (Figure 28-20). This is called *creep feed grinding* (CFG). (Table 28-5 compares CFG to conventional and high-speed grinding for CBN applications.)

The CFG method, often done in the surface grinding mode, is markedly different from conventional surface grinding. The depth of cut is increased 1000 to 10,000 times, and the work feed ratio is decreased in the same proportion; hence the name *creep feed grinding*. The long arc of contact between the wheel and the work increases the cutting forces and the power required. Therefore, the machine tools to perform this type of grinding must be specially designed with high static and dynamic stability, stick-slip-free ways, adequate damping, increased horsepower, infinitely variable spindle speed, variable but extremely consistent table feed (especially in the low ranges), high-pressure cooling systems, integrated devices for dressing the grinding wheels, and specially designed (soft with open structure) grinding wheels. The process is mainly being applied to grinding deep slots with straight parallel sides or to grinding complex profiles in difficult-to-grind materials. The process is capable of producing extreme precision at relatively high metal removal rates. Because the process can operate at relatively low surface temperatures, the surface integrity of the metals being ground is good.

However, in CFG, the grinding wheels must maintain their initial profile much longer, so continuous dressing is used that is form-truing and dressing the grinding wheel throughout the process rather than between cycles. Continuous crush dressing results in higher MRRs, improved dimensional accuracy and form tolerance, reduced grinding

TABLE 28-5 Starting Conditions for CBN Grinding

Grinding Variable	Conventional Grinding	Creep Feed Grinding	High-speed Grinding
Wheel speed (fpm)	5500–9500 versus 4500–6500 vitrified	5000–9000 versus 3000–5000	12000–25000
Table speed (fpm)	80–150	0.5–5	5–20
Feed (f_t) in./pass	0.0005–0.0015	0.100–0.250	250–.500
Grinding fluids	10% heavy-duty soluble oil or 3–5% light-duty soluble for light feeds	Sulfurized or sulfochlorinated straight grinding oil applied at 80 to 100 gal/min at 100 psi or more	

forces (and power), and reduced thermal effects while sacrificing wheel wear. Creep feed grinding eliminates preparatory operations such as milling or broaching, since profiles are ground into the solid workpiece. This can result in significant savings in unit part costs.

Grinding machines that are used for precision work have certain important characteristics that permit them to produce parts having close dimensional tolerances. They are constructed very accurately, with heavy, rigid frames to ensure permanency of alignment. Rotating parts are accurately balanced to avoid vibration. Spindles are mounted in very accurate bearings, usually of the preloaded ball-bearing type. Controls are provided so that all movements that determine dimensions of the workpiece can be made with accuracy—usually to 0.001 or 0.00001 in.

The abrasive dust that results from grinding must be prevented from entering between moving parts. All ways and bearings must be fully covered or protected by seals. If this is not done, the abrasive dust between moving parts becomes embedded in the softer of the two, causing it to act as lap and abrade the harder of the two surfaces, resulting in permanent loss of accuracy.

These special characteristics add considerably to the cost of these machines and require that they be operated by trained personnel. Production-type grinders are more fully automated and have higher metal removal rates and excellent dimensional accuracy. Fine surface finish can be obtained very economically.

CYLINDRICAL GRINDING

Center-type cylindrical grinding is commonly used for producing external cylindrical surfaces. Figures 28-14 and Figure 28-21 show the basic principles and motions of this process. The grinding wheel revolves at an ordinary cutting speed, and the workpiece rotates on centers at a much slower speed, usually from 75 to 125 ft/min. The grinding wheel and the workpiece move in opposite directions at their point of contact. The depth of cut is determined by infeed of the wheel or workpiece. Because this motion also determines the finished diameter of the workpiece, accurate control of this movement is required. Provision is made to traverse the workpiece with the wheel, or the work can be reciprocated past the wheel. In very large grinders, the wheel is reciprocated because of the massiveness of the work. For form or plunge grinding, the detail of the wheel is maintained by periodic crush roll dressing.

A *plain center-type cylindrical grinder* is shown in Figure 28-21. On this type the work is mounted between headstock and tailstock centers. Solid dead centers are always used in the tailstock, and provision is usually made so that the headstock center can be operated either dead or alive. High-precision work is usually ground with a dead headstock center, because this eliminates any possibility that the workpiece will run out of round due to any eccentricity in the headstock.

The table assembly can be reciprocated, in most cases, by using a hydraulic drive. The speed can be varied, and the length of the movement can be controlled by means of adjustable trip dogs.

Infeed is provided by movement of the wheelhead at right angles to the longitudinal axis of the table. The spindle is driven by an electric motor that is also mounted on the wheelhead. If the infeed movement is controlled manually by some type of vernier drive to provide control to 0.001 in. or less, the machine is usually equipped with digital readout equipment to show the exact size being produced. Most production-type grinders have automatic infeed with retraction when the desired size has been obtained. Such machines are usually equipped with an automatic diamond wheel-truing device that dresses the wheel and resets the measuring element before grinding is started on each piece.

The longitudinal traverse should be about one-fourth to three-fourths of the wheel width for each revolution of the work. For light machines and fine finishes, it should be held to the smaller end of this range. The depth of cut (infeed) varies with the purpose of the grinding operation and the finish desired. When grinding is done to obtain accurate size, infeeds of 0.002 to 0.004 in. are commonly used for roughing cuts. For finishing, the infeed is reduced to 0.00025 to 0.0005 in. The design allowance for grinding should be from 0.005 to 0.010 in. on short parts and on parts that are not to be hardened. On long or large parts and on work that is to be hardened, a grinding allowance of from

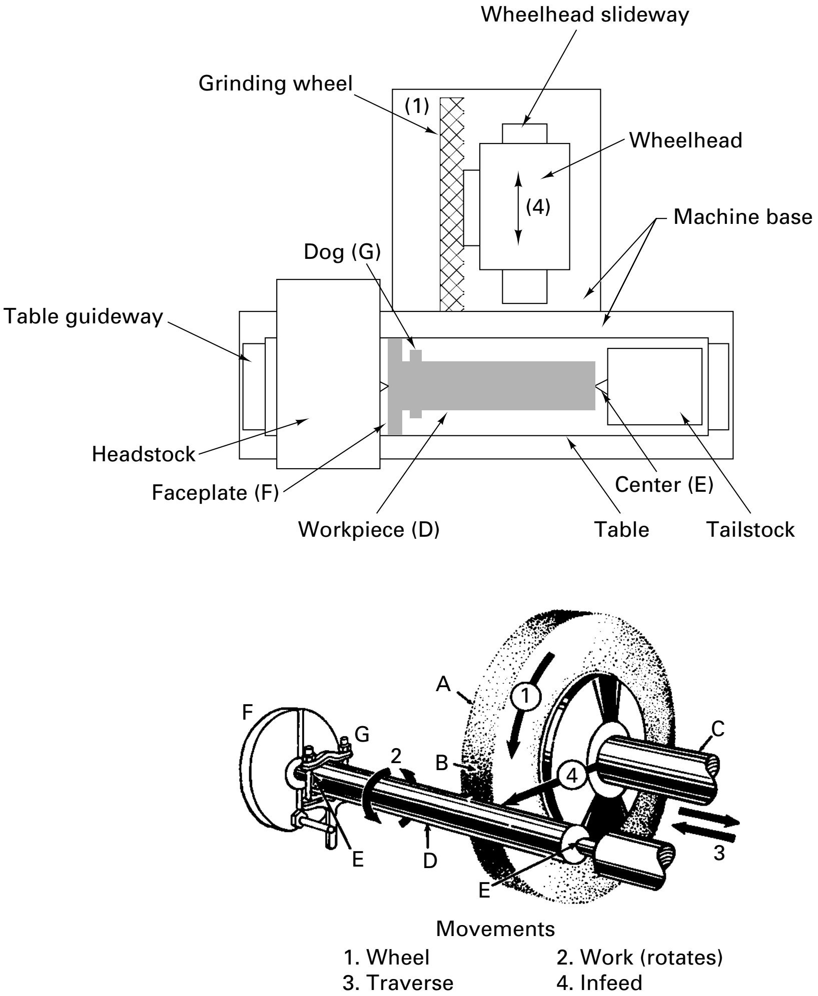

FIGURE 28-21 Cylindrical grinding between centers.

0.015 to 0.030 in. is desirable. When grinding is used primarily for metal removal (called abrasive machining), infeeds are much higher, 0.020 to 0.040 in. being common. Continuous downfeed is often used, with rates up to 0.100 in./min being common.

Grinding machines are available in which the workpiece is held in a chuck for grinding both external and internal cylindrical surfaces. *Chucking-type external grinders* are production-type machines for use in rapid grinding of relatively short parts, such as ball-bearing races. Both chucks and collets are used for holding the work, the means dictated by the shape of the workpiece and rapid loading and removal.

In chucking-type internal grinding machines, the chuck-held workpiece revolves, and a relatively small, high-speed grinding wheel is rotated on a spindle arranged so that it can be reciprocated in and out of the workpiece. Infeed movement of the wheelhead is normal to the axis of rotation of the work (Figure 28-21).

CENTERLESS GRINDING

Centerless grinding makes it possible to grind both external and internal cylindrical surfaces without requiring the workpiece to be mounted between centers or in a chuck. This eliminates the requirement of center holes in some workpieces and the necessity for mounting the workpiece, thereby reducing the cycle time.

The principle of *centerless external grinding* is illustrated in Figure 28-22. Two wheels are used. The larger one operates at regular grinding speeds and does the actual grinding. The smaller wheel is the *regulating* wheel. It is mounted at an angle to the plane of the grinding wheel. Revolving at a much slower surface speed—usually 50 to 200 ft/min—the regulating wheel controls the rotation and longitudinal motion of the workpiece and is a usually a plastic- or rubber-bonded wheel with a fairly wide face.

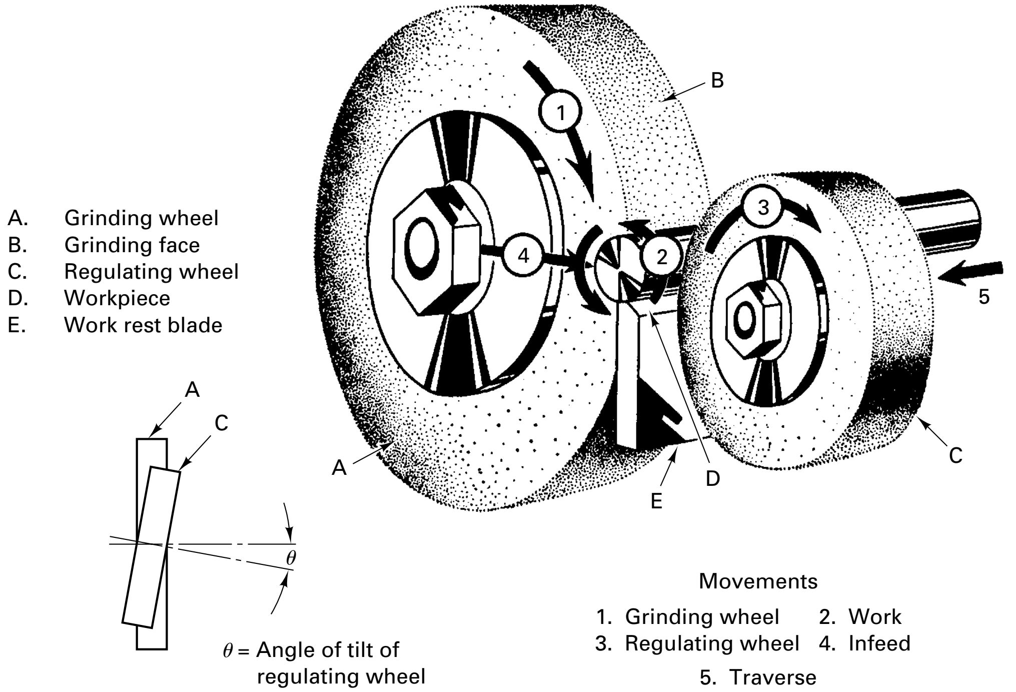

FIGURE 28-22 Centerless grinding showing the relationship among the grinding wheel, the regulating wheel, and the workpiece in centerless method. *(Courtesy of Carborundum Company.)*

The workpiece is held against the work-rest blade by the cutting forces exerted by the grinding wheel and rotates at approximately the same surface speed as that of the regulating wheel. This axial feed is calculated approximately by the equation

$$F = ND \sin \phi \tag{28-1}$$

where

F = feed (mm/min or in./min)

D = diameter of the regulating wheel (mm or in.)

N = revolutions per minute of the regulating wheel

ϕ = angle of inclination of the regulating wheel

Centerless grinding has several important advantages:

1. It is very rapid; infeed centerless grinding is almost continuous.
2. Very little skill is required of the operator.
3. It can often be made automatic (single-cycle automatic).
4. Where the cutting occurs, the work is fully supported by the work rest and the regulating wheel. This permits heavy cuts to be made.
5. Because there is no distortion of the workpiece, accurate size control is easily achieved.
6. Large grinding wheels can be used, thereby minimizing wheel wear.

Thus centerless grinding is ideally suited to certain types of mass-production operations. The major disadvantages are as follows:

1. Special machines are required that can do no other type of work.
2. The work must be round—no flats, such as keyways, can be present.
3. Its use on work having more than one diameter or on curved parts is limited.
4. In grinding tubes, there is no guarantee that the OD and Internal Diameter (ID) are concentric.

Special centerless grinding machines are available for grinding balls and tapered workpieces. The centerless grinding principle can also be applied to internal grinding, but the external surface of the cylinder must be finished accurately before the internal operation is started. However, it assures that the internal and external surfaces will be concentric. The operation is easily mechanized for many applications.

SURFACE GRINDING MACHINES

Surface grinding machines are used primarily to grind flat surfaces. However formed, irregular surfaces can be produced on some types of surface grinders by use of a formed wheel. There are four basic types of surface grinding machines, differing in the movement of their tables and the orientation of the grinding wheel spindles (Figure 28-23):

1. Horizontal spindle and reciprocating table
2. Vertical spindle and reciprocating table
3. Horizontal spindle and rotary table
4. Vertical spindle and rotary table

The most common type of surface grinding machine has a reciprocating table and horizontal spindle (Figures 28-19). The table can be reciprocated longitudinally either by handwheel or by hydraulic power. The wheelhead is given transverse (cross-feed) motion at the end of each table motion, again either by handwheel or by hydraulic power feed. Both the longitudinal and transverse motions can be controlled by limit switches. Infeed or downfeed on such grinders is controlled by handwheels or automatically. The size of such machines is determined by the size of the surface that can be ground.

In using such machines, the wheel should overtravel the work at both ends of the table reciprocation, so as to prevent the wheel from grinding in one spot while the table is being reversed. The transverse or cross-feed motion should be one-fourth to three-fourths of the wheel width between each stroke.

FIGURE 28-23 Surface grinding: (a) horizontal surface grinding and reciprocating table; (b) vertical spindle with reciprocating table; (c) and (d) both horizontal- and vertical-spindle machines can have rotary tables. *(Courtesy of Carborundum Company.)*

Vertical-spindle reciprocating-table surface grinders differ basically from those with horizontal spindles only in that their spindles are vertical and that the wheel diameter must exceed the width of the surface to be ground. Usually, no transverse motion of either the table or the wheelhead is provided. Such machines can produce very flat surfaces.

Rotary-table surface grinders can have either vertical or horizontal spindles, but those with horizontal spindles are limited in the type of work they will accommodate and therefore are not used to a great extent. *Vertical-spindle rotary-table surface grinders* are primarily production-type machines. They frequently have two or more grinding heads, and therefore both rough grinding and finish grinding are accomplished in one rotation of the workpiece. The work can be held either on a magnetic chuck or in special fixtures attached to the table.

By using special rotary feeding mechanisms, machines of this type often are made automatic. Parts are dumped on the rotary feeding table and fed automatically onto work-holding devices and moved past the grinding wheels. After they pass the last grinding head, they are automatically unloaded.

DISK-GRINDING MACHINES

Disk grinders have relatively large side-mounted abrasive disks. The work is held against one side of the disk for grinding. Both single- and double-disk grinders are used; in the latter type the work is passed between the two disks and is ground on both sides simultaneously. On these machines, the work is always held and fed automatically. On small, single-disk grinders the work can be held and fed by hand while resting on a supporting table. Although manual disk grinding is not very precise, flat surfaces can be obtained quite rapidly with little or no tooling cost. On specialized, production-type machines, excellent accuracy can be obtained very economically.

TOOL AND CUTTER GRINDERS

Simple, single-point tools are often sharpened by hand on bench or pedestal grinders (*off-hand grinding*). More complex tools, such as milling cutters, reamers, hobs, and single-point tools for production-type operations require more sophisticated grinding machines, commonly called *universal tool and cutter grinders*. These machines are similar to small universal cylindrical center-type grinders, but they differ in four important respects:

1. The headstock is not motorized.
2. The headstock can be swiveled about a horizontal as well as a vertical axis.
3. The wheelhead can be raised and lowered and can be swiveled through at 360° rotation about a vertical axis.
4. All table motions are manual. No power feeds being provided.

Specific rake and clearance angles must be created, often repeatedly, on a given tool or on duplicate tools. Tool and cutter grinders have a high degree of flexibility built into them so that the required relationships between the tool and the grinding wheel can be established for almost any type of tool. Although setting up such a grinder is quite complicated and requires a highly skilled worker, after the setup is made for a particular job, the actual grinding is accomplished rather easily. Figure 28-24 shows several typical setups on a tool and cutter grinder.

Hand-ground cutting tools are not accurate enough for automated machining processes. Many numerically controlled (NC) machine tools have been sold on the premise that they can position work to very close tolerances—within ± 0.0001 to 0.0002 in.—only to have the initial workpieces produced by those machines out of tolerance by as much as 0.015 to 0.020 in. In most instances, the culprit was a poorly ground tool. For example, a twist drill with a point ground 0.005 in. off-center can “walk” as much as 0.015 in., thus causing poor hole location. Many companies are turning to computer numeric control (CNC) grinders to handle the regrinding of their cutting tools. A six-axis CNC grinder is capable of restoring the proper tool angles (rake and clearance), concentricity, cutting edges, and dimensional size.

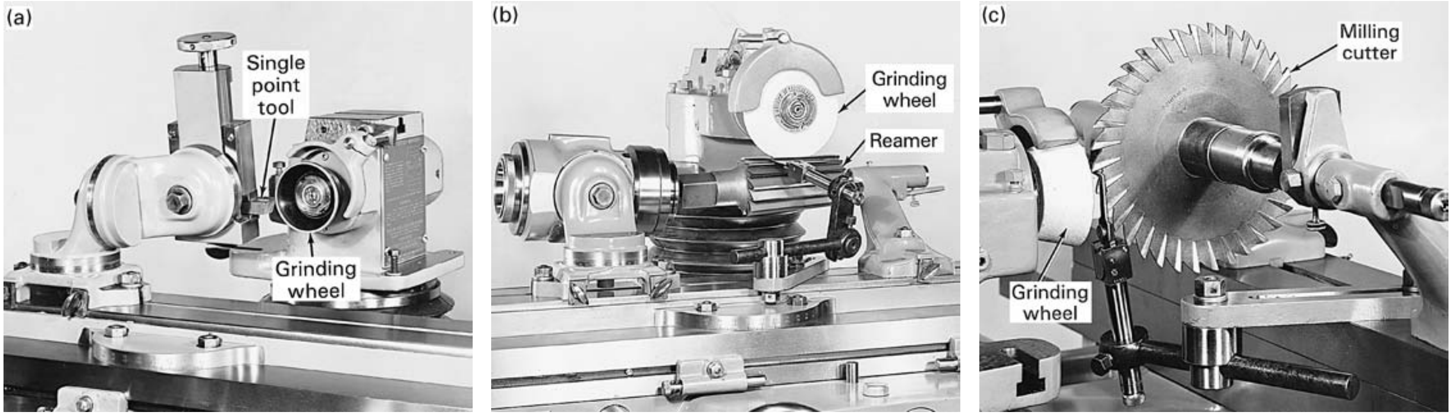

FIGURE 28-24 Three typical setups for grinding single- and multiple-edge tools on a universal tool and cutter grinder. (a) Single-point tool is held in a device that permits all possible angles to be ground. (b) Edges of a large hand reamer are being ground. (c) Milling cutter is sharpened with a cupped grinding wheel.

MOUNTED WHEELS AND POINTS

Mounted wheels and points are small grinding wheels of various shapes that are permanently attached to metal shanks that can be inserted in the chucks of portable, high-speed electric or air motors. They are operated at speeds up to 100,000 rpm, depending on their diameters, and are used primarily for deburring and finishing in mold and die work. Several types are shown in Figure 28-25.

COATED ABRASIVES

Coated abrasives are being used increasingly in finishing both metal and nonmetal products. These are made by gluing abrasive grains onto a cloth or paper backing (Figure 28-26). Synthetic abrasives—aluminum oxide, silicon carbide, aluminum, zirconia, CBN, and diamond—are used most commonly, but some natural abrasives—sand, flint, garnet, and emery—also are employed. Various types of glues are utilized to attach the abrasive grains to the backing, usually compounded to allow the finished product to have some flexibility.

Coated abrasives are available in sheets, rolls, endless belts, and disks of various sizes. Some of the available forms are shown in Figure 28-26. Although the cutting action of coated abrasives basically is the same as with grinding wheels, there is one major difference: they have little tendency to be self-sharpened when dull grains are pulled from the backing. Consequently, when the abrasive particles become dull or the belt loaded, the belt must be replaced. Finer grades result in finer first cuts but slower material removal rates (MRR). This versatile process is now widely used for rapid stock removal as well as fine surface finishing.

■ 28.6 HONING

Honing is a stock-removal process that uses fine abrasive stones to remove very small amounts of metal. Cutting speed is much lower than that of grinding. The process is used to size and finish bored holes, remove common errors left by boring (taper, waviness, and tool marks), or remove the tool marks left by grinding. The amount of metal removed is typically about 0.005 in. or less. Although honing is occasionally done by hand, as in finishing the face of a cutting tool, it usually is done with special equipment. Most honing is done on internal cylindrical surfaces, such as automobile cylinder walls. The honing stones are usually held in a honing head, with the stones being held against the work with controlled light pressure. The honing head is not guided externally but, instead, *floats* in the hole, being guided by the work surface (Figure 28-27).

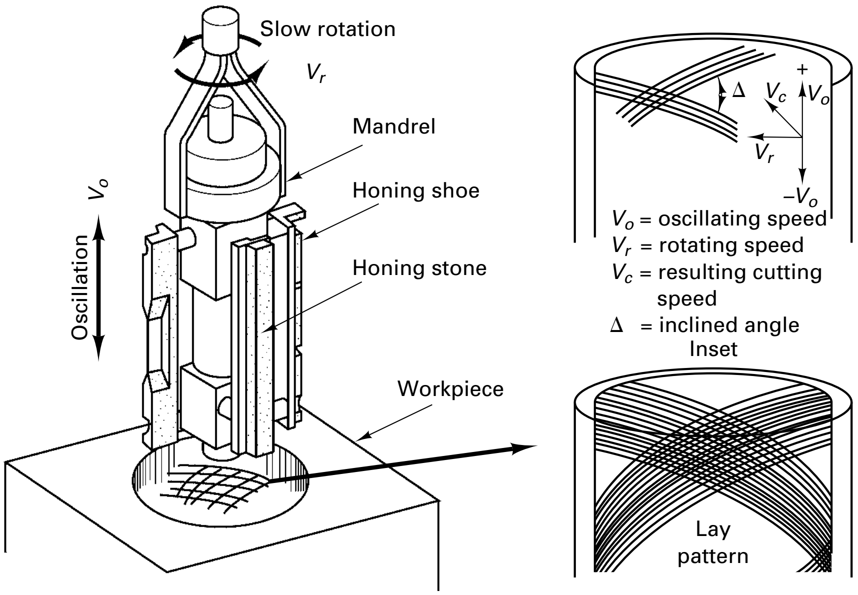

FIGURE 28-27 Schematic of honing head showing the manner in which the stones are held. The rotary and oscillatory motions combine to produce a crosshatched lay pattern. Typical values for V_c and P_s are given below.

For:	Honing Parameters	Conventional Abrasives	Diamonds	CBN
High MRR	V_c (m/min)	20-30	40-70	35-90
	P_s (N/mm^2)	1-2	2-8	2-4
Best-quality service	V_c (m/min)	5-30	40-70	20-60
	P_s (N/mm^2)	0.5-1.5	1.0-3.0	1.0-2.0

The stones are given a complex motion so as to prevent a single grit from repeating its path over the work surface. Rotation is combined with an oscillatory axial motion. For external and flat surfaces, varying oscillatory motions are used. The length of the motions should be such that the stones extend beyond the work surface at the end. A cutting fluid is used in virtually all honing operations. The critical process parameters are rotational speed, V_r, oscillation speed, V_o, the length and position of stroke, and the honing stick pressure. V_c and the inclination angle are both products of V_o and V_r

Virtually all honing is done with stones made by bonding together various fine artificial abrasives. *Honing stones* differ from grinding wheels in that additional materials, such as sulfur, resin, or wax, are often added to the bonding agent to modify the cutting action. The abrasive grains range in size from 80 to 600 grit. The stones are equally spaced about the periphery of the tool. Reference values for V_c and honing stick pressure, P_s, for various abrasives are shown in Figure 28-27.

Single- and multiple-spindle honing machines are available in both horizontal and vertical types. Some are equipped with special sensitive measuring devices that collapse the honing head when the desired size has been reached.

For honing single, small, internal cylindrical surfaces, a procedure is often used wherein the workpiece is manually held and reciprocated over a rotating hone. If the volume of work is sufficient, honing is a fairly inexpensive process. A complete honing cycle, including loading and unloading the work, is often less than one minute. Size control within 0.0003 in. is achieved routinely.

■ 28.7 SUPERFINISHING

Superfinishing is a variation of honing that is typically used on flat surfaces. The process is:

1. Very light, controlled pressure, 10 to 40 psi
2. Rapid (over 400 cycles per minute), short strokes—less than $^1/_4$ in.
3. Stroke paths controlled so that a single grit never traverses the same path twice
4. Copious amounts of low-viscosity lubricant-coolant flooded over the work surface

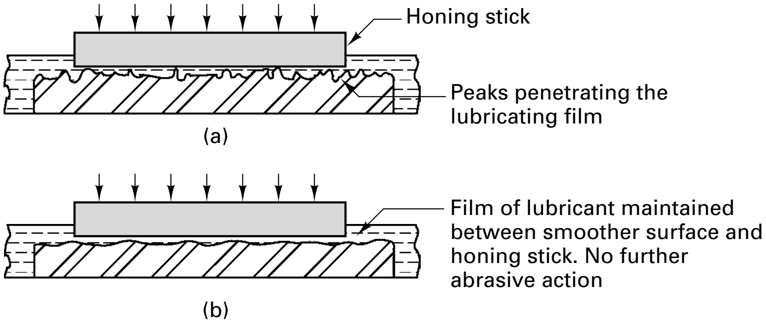

FIGURE 28-28 In superfinishing and honing, a film of lubricant is established between the work and the abrasive stone as the work becomes smoother.

This procedure, illustrated in Figure 28-28, results in surfaces of very uniform, repeatable smoothness.

Superfinishing is based on the phenomenon that a lubricant of a given viscosity will establish and maintain a separating, lubricating film between two mating surfaces if their roughness does not exceed a certain value and if a certain critical pressure, holding them apart, is not exceeded. Consequently, as the minute peaks on a surface are cut away by the honing stone, applied with a controlled pressure, a certain degree of smoothness is achieved. The lubricant establishes a continuous film between the stone and the workpiece and separates them so that no further cutting action occurs. Thus, with a given pressure, lubricant, and honing stone, each workpiece is honed to the same degree of smoothness.

Superfinishing is applied to both cylindrical and plane surfaces. The amount of metal removed usually is less than 0.002 in., most of it being the peaks of the surface roughness. Copious amounts of lubricant-coolant maintain the work at a uniform temperature and wash away all abraded metal particles to prevent scratching.

LAPPING

Lapping is an abrasive surface finishing process wherein fine abrasive particles are *charged* (caused to become embedded) into a soft material, called a *lap*. The material of the lap may range from cloth to cast iron or copper, but it is always softer than the material to be finished, being only a holder for the hard abrasive particles. Lapping is applied to both metals and nonmetals.

As the charged lap is rubbed against a surface, the abrasive particles in the surface of the lap remove small amounts of material from the surface to be machined. Thus the abrasive does the cutting, and the soft lap is not worn away because the abrasive particles become embedded in its surface instead of moving across it. This action always occurs when two materials rub together in the presence of a fine abrasive: the softer one forms a lap, and the harder one is abraded away.

In lapping, the abrasive is usually carried between the lap and the work surface in some sort of a vehicle, such as grease, oil, or water. The abrasive particles are from 120 grit up to the finest powder sizes. As a result, only very small amounts of metal are removed, usually considerably less than 0.001 in. Because it is such a slow metal removing process, lapping is used only to remove scratch marks left by grinding or honing, or to obtain very flat or smooth surfaces, such as are required on gage blocks or for liquid tight seals where high pressures are involved.

Materials of almost any hardness can be lapped. However, it is difficult to lap soft materials because the abrasive tends to become embedded. The most common lap material is fine-grained cast iron. Copper is used quite often and is the common material for lapping diamonds. For lapping hardened metals for metallographic examination, cloth laps are used.

Lapping can be done either by hand or by special machines. In hand lapping, the lap is flat, similar to a surface plate. Grooves are usually cut across the surface of a lap to collect the excess abrasive and chips. The work is moved across the surface of the lap, using an irregular, rotary motion, and is turned frequently to obtain a uniform cutting action.

In lapping machines for obtaining flat surfaces, workpieces are placed loosely in holders and are held against the rotating lap by means of floating heads. The holders, rotating slowly, move the workpieces in an irregular path. When two parallel surfaces are to be produced, two laps may be employed, one rotating below and the other above the workpieces.

Various types of lapping machines are available for lapping round surfaces. A special type of centerless lapping machine is used for lapping small cylindrical parts, such as piston pins and ball-bearing races.

Because the demand for surfaces having only a few micrometers of roughness on hardened materials has become quite common, the use of lapping has increased greatly. However, it is a very slow method of removing metal, obviously costly compared with other methods, and should not be specified unless such a surface is absolutely necessary.

■ 28.8 FREE ABRASIVES

ULTRASONIC MACHINING

Ultrasonic machining (USM), sometimes called *ultrasonic impact grinding*, employs an ultrasonically vibrating tool to impel the abrasives in a slurry at high velocity against the workpiece. The tool is fed into the part as it vibrates along an axis parallel to the tool feed at an amplitude on the order of several thousandths of an inch and a frequency of 20 kHz. As the tool is fed into the workpiece, a negative of the tool is machined into the workpiece. The cutting action is performed by the abrasives in the slurry, which is continuously flooded under the tool. The slurry is loaded up to 60% by weight with abrasive particles. Lighter abrasive loadings are used to facilitate the flow of the slurry for deep drilling (up to 2 in. deep). Boron carbide, aluminum oxide, and silicon carbide are the most commonly used abrasives in grit sizes ranging from 400 to 2000. The amplitude of the vibration should be set approximately to the size of the grit. The process can use shaped tools to cut virtually any material but is most effective on materials with hardnesses greater than R_C 40, including brittle and nonconductive materials such as glass. Figure 28-29 shows a simple schematic of this process.

USM uses piezoelectric or magnetostrictive transducers to impart high-frequency vibrations to the tool holder and tool. Abrasive particles in the slurry are accelerated to great speed by the vibrating tool. The tool materials are usually brass, carbide, mild

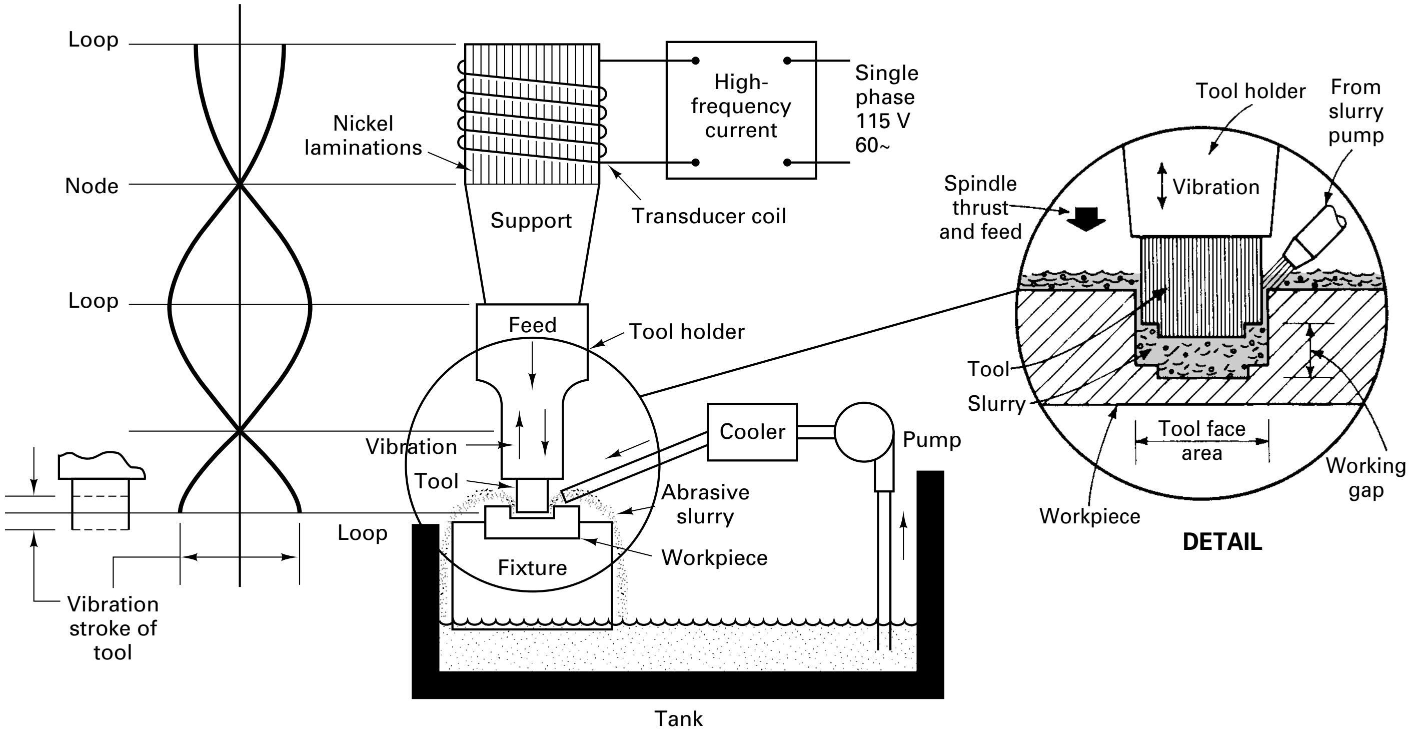

FIGURE 28-29 Sinking a hole in a workpiece with an ultrasonically vibrating tool driving an abrasive slurry.

steel, or tool steel and will vary in tool wear depending on their hardness. Wear ratios (workpiece material removed versus tool material lost) from 1:1 (for tool steel) to 100:1 (for glass) are possible. Because of the high number of cyclic loads, the tool must be strong enough to resist fatigue failure.

The cut will be oversize by about twice the size of the abrasive particles being used, and holes will be tapered, usually limiting the hole depth-to-diameter ratio to about 3:1. Surface roughness is controlled by the size of the abrasive particles (finer finish with smaller particles). Holes, slots, or shaped cavities can be readily eroded in any hard material—conductive or nonconductive, metallic, ceramic, or composite. Advantages of the process include that it is one of the few machining methods capable of machining glass. Also, it is the safest machining method. Skin is impervious to the process because of its ductility. High-pitched noise can be a problem due to secondary vibrations. In addition to machining, ultrasonic energy has also been employed for coining, lapping, deburring, and broaching. Plastics can be welded using ultrasonic energy.

WATERJET CUTTING AND ABRASIVE WATERJET MACHINING

Waterjet cutting (WJC), also known as *waterjet machining* or *hydrodynamic machining*, uses a high-velocity fluid jet impinging on the workpiece to perform a slitting operation (Figure 28-30). Water is ejected from a nozzle orifice at high pressure (up to 60,000 psi). The jet is typically 0.003 to 0.020 in. in diameter and exits the orifice at velocities up to 3000 ft/sec. Key process parameters include water pressure, orifice diameter, water flow rate, and working distance (distance between the workpiece and the nozzle).

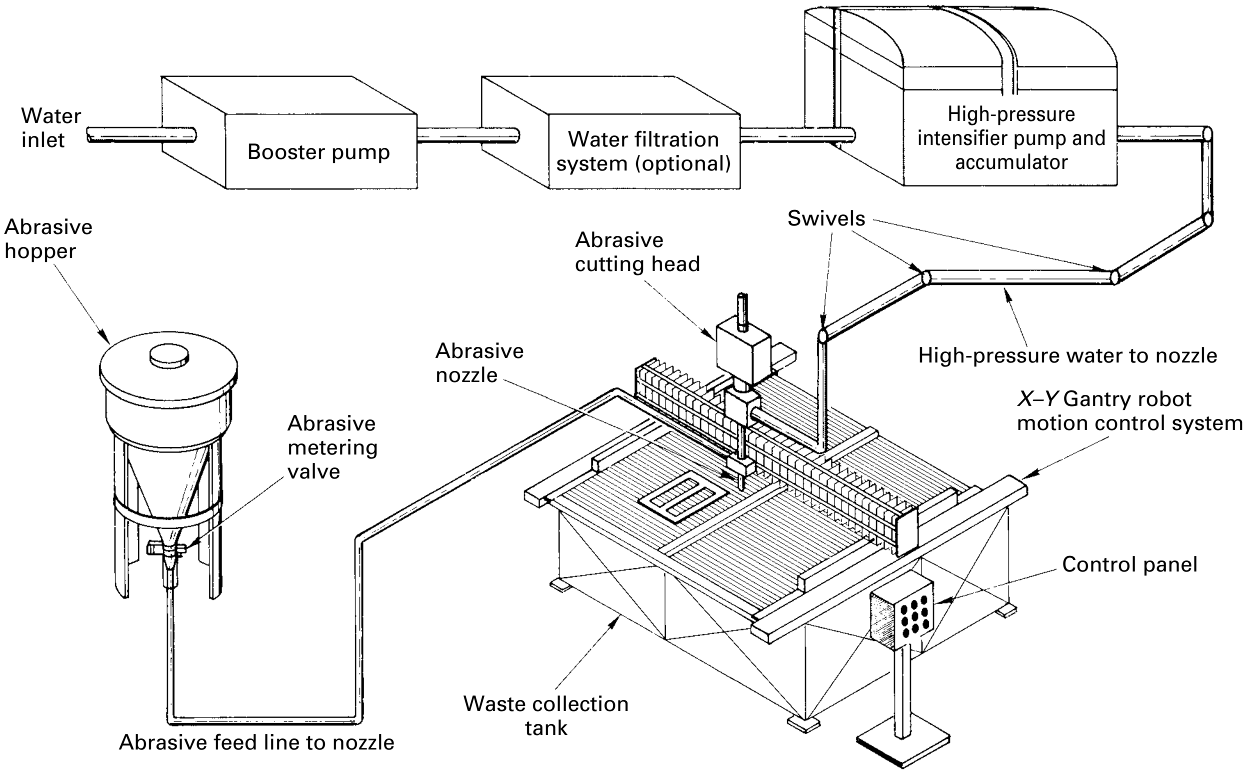
Nozzle materials include synthetic sapphire, due to its machinability and resistance to wear. Tool life on the order of several hundred hours is typical. Mechanisms for tool failure include chipping from contaminants or constriction due to mineral deposits. This emphasizes the need for high levels of filtration prior to pressure intensification. In the past, long-chain polymers were added to the water to make the jet more coherent (i.e., not come out of the jet dispersed). However, with proper nozzle design, a tight, coherent water jet may be produced without additives.

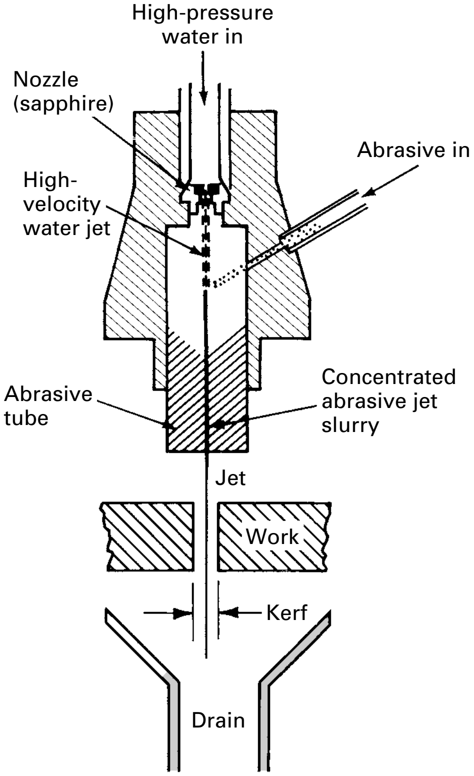
The advantages of WJC include the ability to cut materials without burning or crushing the material being cut. Figure 28-30 shows a comparison (end view) of cutting corrugated boxboard with a mechanical knife and with WJC. The mechanism for material removal is simply the impinging pressure of the water exceeding the compressive strength of the material. This limits the materials that can be cut by the process to leather, plastics, and other soft nonmetals, which is the major disadvantage of the process. Alternative fluids (alcohol, glycerine, cooking oils) have been used in processing meats, baked goods, and frozen foods. Other disadvantages include that the process is noisy and requires operators to have hearing protection.

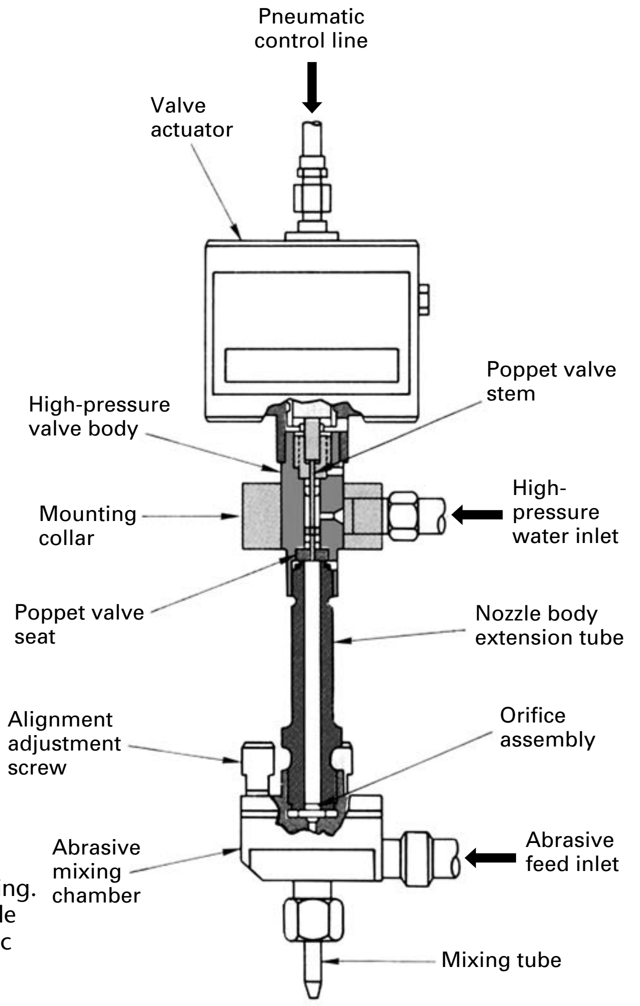
The majority of the metalworking applications for waterjet cutting require the addition of abrasives. This process is known as *abrasive waterjet cutting* (AWC). A full range of materials, including metals, plastics, rubber, glass, ceramics, and composites, can be machined by AWC. Cutting feed rates vary from 20 in./min for acoustic tile to 50 in./min for epoxies and 500 in./min for paper products.

Abrasives are added to the waterjet in a mixing chamber on the downstream side of the waterjet orifice. A single, central waterjet with side feeding of abrasives into a mixing chamber is shown in Figure 28-30. In the mixing chamber, the momentum of the water is transferred to the abrasive particles, and the water and particles are forced out through the AWC nozzle orifice, also called the mixing tube. This design can be made quite compact; however, it also experiences rapid wear in the mixing tube. An alternate configuration is to feed the abrasives from the center of the nozzle with a converging set of angled water jets imparting momentum to the abrasives. This nozzle design produces better mixing of the water and abrasives as well as increased nozzle life. The inside diameter of the mixing tube is normally from 0.04 to 0.125 in. in diameter. These tubes are normally made of carbide.

Generally, the kerf of the cut is about 0.001 in. greater than the nozzle orifice. AWC requires control of additional process parameters over waterjet machining, including abrasive material (density, hardness, shape), abrasive size or grit, abrasive flow rate (pounds per minute), abrasive feed mechanism (pressurized or suction), and AWC







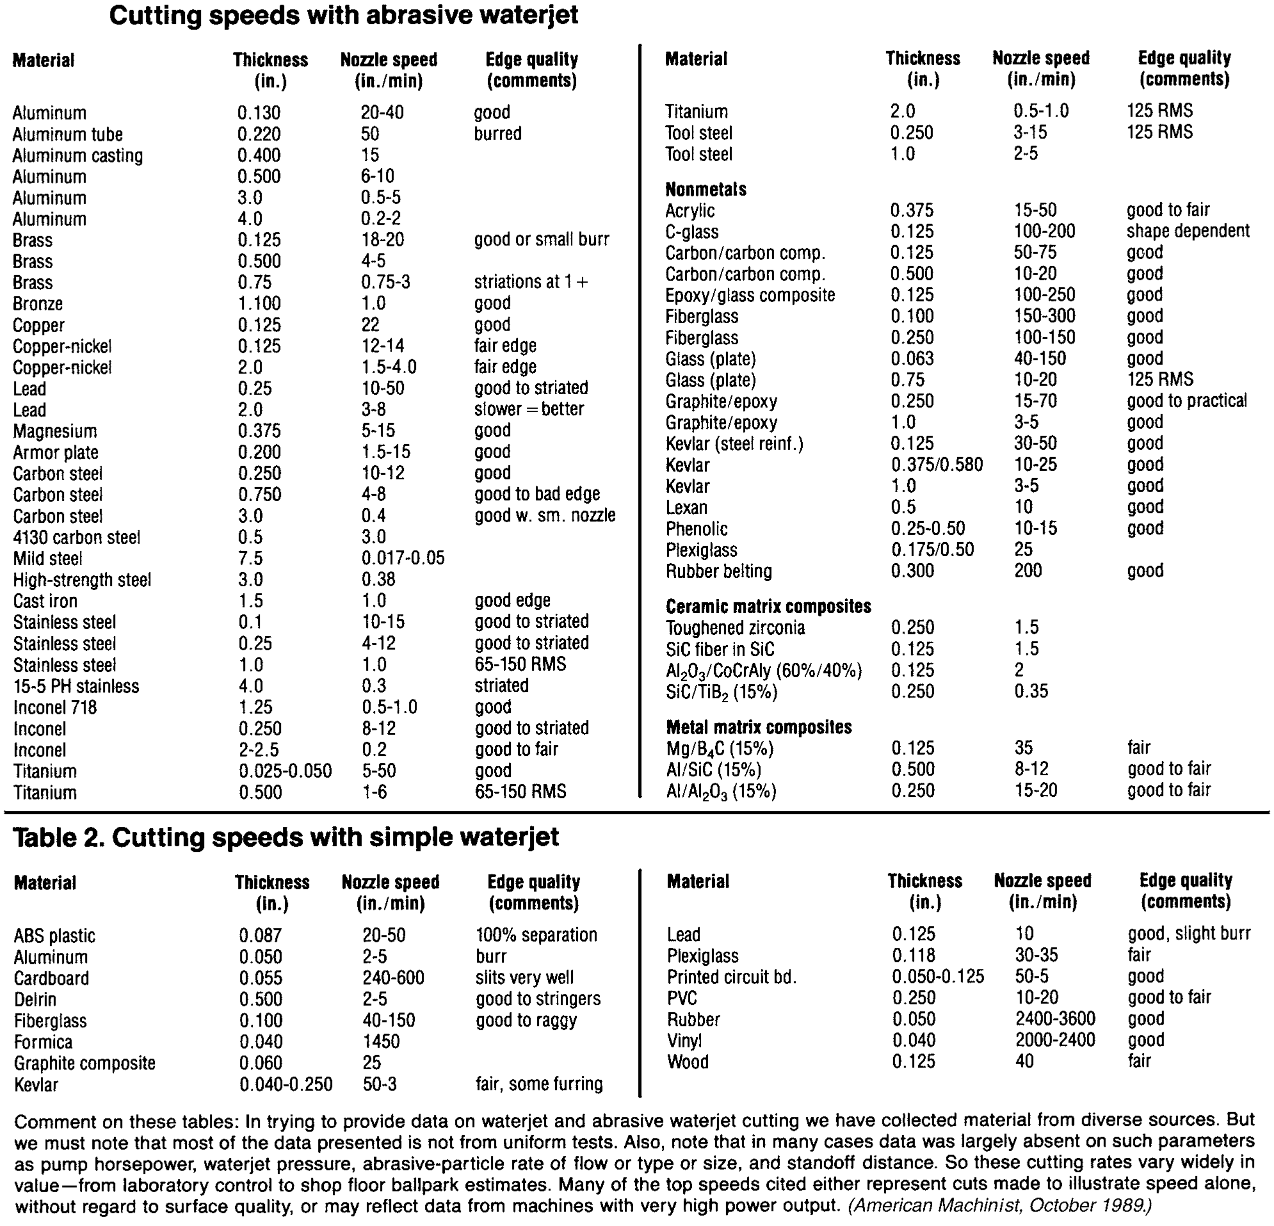
Abrasive cutting head

FIGURE 28-30 Schematic diagram of hydrodynamic jet machining. The intensifier elevates the fluid to the desired nozzle pressure while the accumulator smoothes out the pulses in the fluid jet. Schematic of an abrasive waterjet machining nozzle is shown on the right.

nozzle (design, orifice diameter, and material). Typical AWC systems operate under the following conditions: water pressures of 30,000 to 50,000 psi; water orifice diameters from 0.01 to 0.022 in.; and working distances of 0.02 to 0.06 in. Working distances are much smaller than in WJC to minimize the dispersion of the abrasive water jet prior to entering the material. Abrasive materials used include garnet, silica, silicon carbide, or aluminum oxide. Abrasive grit sizes range from 60 to 120 and abrasive flow rates from 0.5 to 3 lb/min. For many applications, the AWC tool is combined with a CNC controlled *X–Y* table, which permits contouring and surface engraving.

AWC can be used to cut any material through the appropriate choice of the abrasive, waterjet pressure, and feed rate. Table 28-6 gives cutting speeds for various metals. The ability of the abrasive waterjet to cut through thick materials (up to 8 in.) is attributed to the reentrainment of abrasive particles in the jet by the workpiece material. AWC is particularly suited for composites because the cutting rates are reasonable and they do not delaminate the layered material. In particular, AWC is used in the airplane industry to cut carbon-fiber composite sections of the airplane after autoclaving.

TABLE 28-6 Typical Values for Through-cutting Speeds for Simple Waterjet and Abrasive Waterjet of Machining Metals and Nonmetals.



Cutting speeds with abrasive waterjet

Material	Thickness (in.)	Nozzle speed (in./min)	Edge quality (comments)
Aluminum	0.130	20-40	good

Rubber	0.050	2400-3600	good
Vinyl	0.040	2000-2400	good
Wood	0.125	40	fair

Comment on these tables: In trying to provide data on waterjet and abrasive waterjet cutting we have collected material from diverse sources. But we must note that most of the data presented is not from uniform tests. Also, note that in many cases data was largely absent on such parameters as pump horsepower, waterjet pressure, abrasive-particle rate of flow or type or size, and standoff distance. So these cutting rates vary widely in value—from laboratory control to shop floor ballpark estimates. Many of the top speeds cited either represent cuts made to illustrate speed alone, without regard to surface quality, or may reflect data from machines with very high power output. *(American Machinist, October 1989.)*

ABRASIVE JET MACHINING

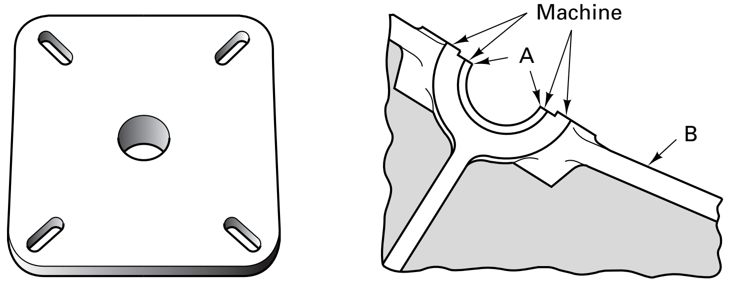
One of the least expensive of the nontraditional processes is *abrasive jet machining* (AJM). AJM removes material by a focused jet of abrasives and is similar in many respects to AWC, with the exception that momentum is transferred to the abrasive particles by a jet of inert gas. Abrasive velocities on the order of 1000 ft/sec are possible with AJM. The small mass of the abrasive particles produces a microscale chipping action on the workpiece material. This makes AJM ideal for processing hard, brittle materials, including glass, silicon, tungsten, and ceramics. It is not compatible with soft, elastic materials.

Key process parameters include working distance, abrasive flow rate, gas pressure, and abrasive type. Working distance and feed rate are controlled by hand. If necessary, a hard mask can be placed on the workpiece to control dimensions. Abrasives are typically smaller than those used in AWC. Abrasives are typically not recycled, since the abrasives are cheap and are used only on the order of several hundred grams per hour. To minimize particulate contamination of the work environment, a dust-collection hood should be used in concert with the AJM system.

DESIGN CONSIDERATIONS IN GRINDING

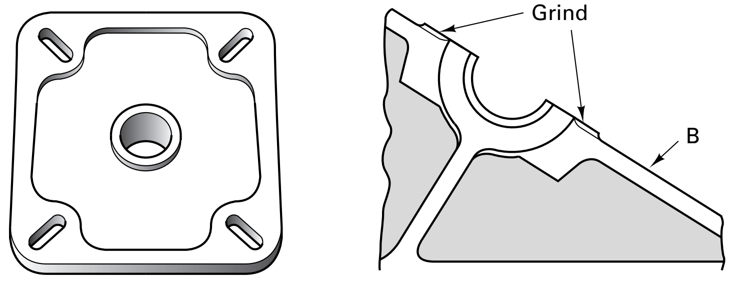
Almost any shape and size of work can be finished on modern grinding equipment, including flat surfaces, straight or tapered cylinders, irregular external and internal surfaces, cams, antifriction bearing races, threads, and gears. For example, the most accurate threads are formed from solid cylindrical blanks on special thread grinding machines. Gears that must operate without play are hardened and then finish ground to close tolerances. Two important design recommendations are to reduce the area to be ground and to keep all surfaces that are to be ground in the same or parallel planes (Figure 28-31). This is an example of *design for manufacturing* (DFM).

Abrasive machining can remove scale as well as parent metal. Large allowances of material, needed to permit conventional metalcutting tools to cut below hard or abrasive inclusions, are not necessary for abrasive machining. An allowance of 0.015 in. is adequate, assuming, of course, that the part is not warped or out of round. This small allowance requirement results in savings in machining time, in material (often 60% less metal is removed), and in shipping of unfinished parts.



Original design of base plate

Original design of crankshaft bearing bracket



Redesigned to reduce weight and grinding time

Redesign eliminated shoulders and made part suitable for grinding in single setup

FIGURE 28-31 Reducing area to be ground and keeping all surface to be ground in the same or parallel planes are two important design recommendations. *(From* Machine Design, *June 1, 1972, p. 87.)*

Review Questions

1. What are machining processes that use abrasive particles for cutting tools called?
2. What is attrition in an abrasive grit?
3. Why is friability an important grit property?
4. Explain the relationship between grit size and surface finish.
5. Why is aluminum oxide used more frequently than silicon carbide as an abrasive?
6. Why is CBN superior to silicon carbide as an abrasive in some applications?
7. What materials commonly are used as bonding agents in grinding wheels?
8. Why is the grade of a bond in a grinding wheel important?
9. How does grade differ from structure in a grinding wheel?
10. What is crush dressing?
11. How does loading differ from glazing?
12. What is meant by the statement that grinding is a mixture of processes?
13. What is accomplished in dressing a grinding wheel?
14. How does abrasive machining differ from ordinary grinding?
15. What is a grinding ratio or *G* ratio?
16. How is the feed of the workpiece controlled in centerless grinding?
17. Why is grain spacing important in grinding wheels?
18. Why should a cutting fluid be used in copious quantities when doing wet grinding?
19. How does plunge-cut grinding compare to cylindrical grinding?
20. If grinding machines are placed among other machine tools, what precautions must be taken?
21. What is the purpose of low-stress grinding?
22. How is low-stress grinding done compared to conventional grinding?
23. The number of grains per square inch which actively contact and cut a surface decreases with increasing grain diameter. Why is this so?
24. Why are centerless grinders so popular in industry compared to center-type grinders?
25. Explain how a SEM micrograph is made. Check the Internet or the library to find the answer.
26. Why are vacuum chucks and magnetic chucks widely used in surface grinding but not in milling?
27. How does creep feed grinding differ from conventional surface grinding?
28. Why does a lap not wear, since it is softer than the material being lapped?
29. How do honing stones differ from grinding wheels?
30. What is meant by "charging" a lap?
31. Why is a honing head permitted to float in a hole that has been bored?
32. How does a coated abrasive differ from an abrasive wheel?
33. Figure out why the bottoms of chips shown in Figure 28-9 are so smooth. The magnification of the micrograph is 4800×. How thick are these chips?
34. What is the inclined angle in honing and what determines it?
35. What are the common causes of grinding accidents?
36. What other machine tool does a surface grinder resemble?
37. Figure 28-11 showed residual stress distributions produced by surface grinding. What is a residual stress?
38. In grinding, what is infeed versus cross feed?
39. One of the problems with waterjet cutting is that the process is very noisy. Why?
40. In AWC, what keeps the abrasive jet from machining the orifice?

Problems

1. Perhaps you have observed the following wear phenomena: A set of marble or wooden steps shows wear on the treads in the regions where people step when they climb (or descend) the steps. The higher up the steps, the less the wear on the tread. Given that soles of shoes (leather, rubber) are far softer than marble or granite, explain:
   a. Why and how the steps wear.
   b. Why the lower steps are more worn than the upper steps.
2. Explain why it is that a small particle of a material can be used to abrade a surface made of the same material (i.e., why does the small particle act harder or stronger than the bulk material)?
3. In grinding, both the wheel and workpiece are moving (or rotating). Using the data in Figure 28-11 and assuming that you are doing surface grinding (see Figure 28-1), what are some typical MRR values? How do these compare to MRR values for other machining processes, such as milling? What is the significance of this?

Chapter 28 CASE STUDY

Overhead Crane Installation

Nickolas has been given the task of installing an overhead crane (Figure CS 28) in one bay of the vonTurkovich Manufacturing Company and assembly plant. Brackets for the rails of the crane are to be mounted on eight columns, four on each side of the bay area facing each other. The rails for the crane will span four columns. Each bracket on each column will need six holes in a circular pattern. The holes must be accurately spaced within 5 minutes of arc of each other. The axis of the holes must be parallel and normal to the face of the columns. The center of the bolt hole circle must be at a height of at least 20 ft from the floor, but the centers of all eight bolt hole circles must be on the same parallel plane, so that the rails for the crane are level and parallel with each other. Four of the columns along the wall have their faces flush with the wall surface so that mechanical clamping or attachments cannot be used. The building code will permit no welding of anything to these columns.

1. How would Nickolas proceed to get the bolt holes located in the right position on the beams?
2. How would he get the hole patterns located properly with respect to each other on all eight beams?
3. List the equipment he will need.
4. Make a sketch of any special tool you recommend. (Hint: Check Chapter 25 for drill jig designs and ask your favorite civil engineer for suggestions regarding surveying.)

CHAPTER 29

THREAD AND GEAR MANUFACTURING

29.1 INTRODUCTION

Screw threads and gears are important machine elements. *Threading*, *thread cutting*, or *thread rolling* refers to the manufacture of threads on external diameters. *Tapping* refers to machining threads in (drilled) holes. Without these processes, our present technological society would come to a grinding halt. More screw threads are made each year than any other machined element. They range in size from those used in small watches to threaded shafts 10 in. in diameter. They are made in quantities ranging from one to several million duplicate threads. Their precision varies from that of inexpensive hardware screws to that of lead screws for the most precise machine tools. Consequently, it is not surprising that many very different procedures have been developed for making screw threads and that the production cost by the various methods varies greatly. Fortunately, some of the most economical methods can provide very accurate results. However, as in the design of most products, the designer can greatly affect the ease and cost of producing specified screw threads. Thus, understanding thread-making processes permits the designer to specify and incorporate screw threads into designs while avoiding needless and excessive cost.

Gears transmit power or motion mechanically between parallel, intersecting, or nonintersecting shafts. Although usually hidden from sight, gears are one of the most important mechanical elements in our civilization, possibly even surpassing the wheel, since most wheels would not be turning were power not being applied to them through gears. They operate at almost unlimited speeds under a wide variety of conditions. Millions are produced each year in sizes from a few millimeters up to more than 30 ft in diameter. Often the requirements that must be, and are routinely, met in their manufacture are amazingly precise. Consequently, many special machines and processes have been developed for producing gears. Let us begin by discussing threads.

SCREW-THREAD STANDARDIZATION AND NOMENCLATURE

A screw thread is a ridge of uniform section in the form of a helix on the external or internal surface of a cylinder, or in the form of a conical spiral on the external or internal surface of a frustrum of a cone. These are called *straight* or *tapered* threads, respectively. Tapered threads are used on pipe joints or other applications where liquid-tight joints are required. Straight threads, on the other hand, are used in a wide variety of applications, most commonly on fastening devices, such as bolts, screws, and nuts, and as integral

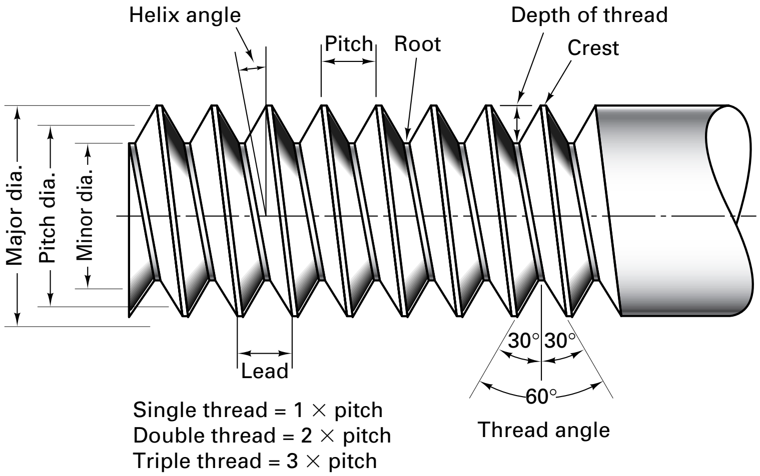

FIGURE 29-1 Standard screw-thread nomenclature.

elements on parts that are to be fastened together. But, as mentioned previously, they find very important applications in transmitting controlled motion, as in lead screws and precision measuring equipment.

The standard nomenclature for screw-thread components is illustrated in Figure 29-1. The symbol P, the pitch, refers to the distance from a point on one screw thread to the corresponding point on the next thread, measured parallel to the length axis of the part. In 1948, representatives of the United States, Canada, and Great Britain adopted the Unified and American Screw Thread Standards, based on the form shown in Figure 29-2. In 1968 the International Organization for Standards (ISO) recommended the adoption of a set of metric standards based on the basic thread profile. It appears likely that both types of threads will continue to be used for some time to come. In both the *Unified* and *ISO systems*, the crests of external threads may be flat or rounded. The root is usually made rounded to minimize stress concentrations at this critical area. The internal thread has a flat crest in order to mate with either a rounded or V-root of the external thread. A small round is used at the root to provide clearance for the flat crest of the external thread.

In the metric system, the *pitch* is always expressed in millimeters, whereas in the American (Unified) system, it is a fraction having as the numerator 1 and as the denominator the number of threads per inch. Thus, 16 threads per inch, $^{1}/_{16}$, is a 16 pitch. Consequently, in the Unified system, threads are more commonly described in terms of threads per inch rather than by the pitch.

While all elements of the thread form are based on the *pitch diameter*, screw-thread sizes are expressed in terms of the *outside*, or *major* diameter and the *pitch* or *number of threads per inch*. In threaded elements, *lead* refers to the axial advance of the element during one revolution; therefore, lead equals pitch on a single-thread screw.

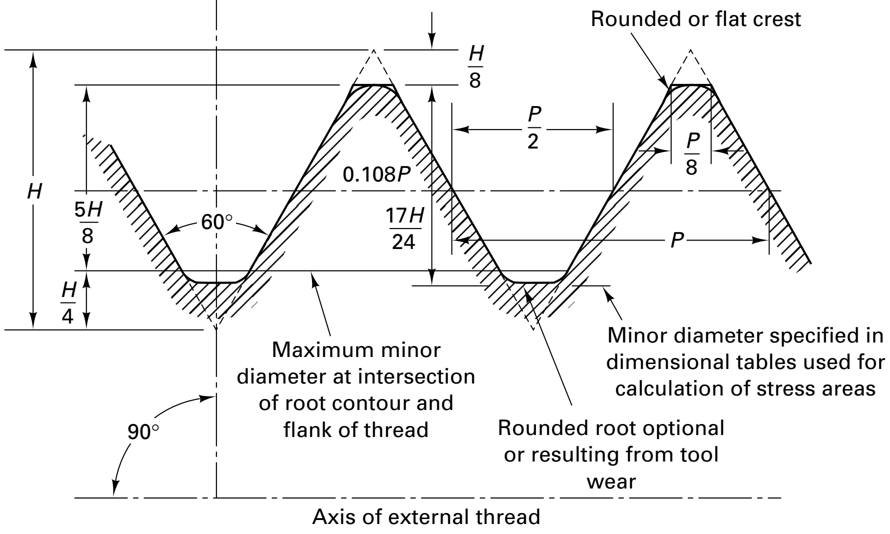
TYPES OF SCREW THREADS

Eleven types, or series, of threads are of commercial importance, several having equivalent series in the metric system and Unified systems. See Figure 29-3. As has been indicated, the Unified threads are available in a coarse (UNC and NC), fine (UNF and NF), extra-fine (UNEF and NEF), and three-“pitch” (8, 12, and 16) series, the number of threads per inch in accordance with an arbitrary determination based on the major diameter.

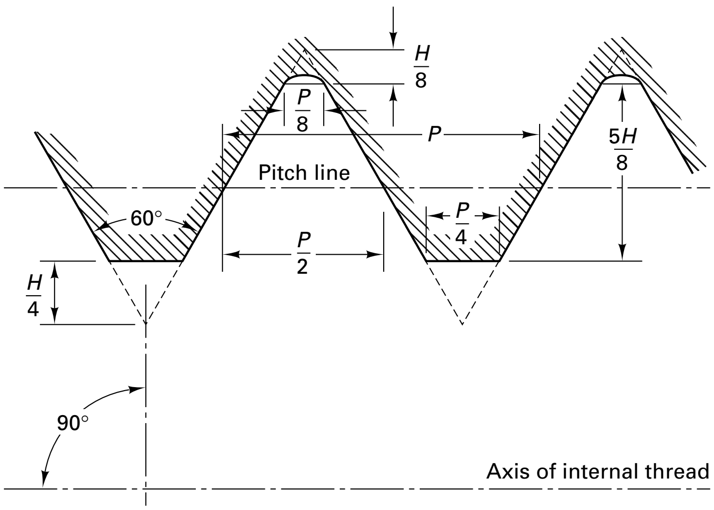
Many nations have now adopted ISO threads into their national standards. Besides metric ISO threads, there are also inch-based ISO threads, namely the UN series with which people in the United States, Canada, and Great Britain are familiar. ISO offers a wide range of metric sizes. Individual countries have the choice of accepting all or a selection of the ISO offerings.

The size listings of metric threads start with “M” and continue with the outside diameter in millimeters. Most ISO metric thread sizes come in coarse, medium, and fine

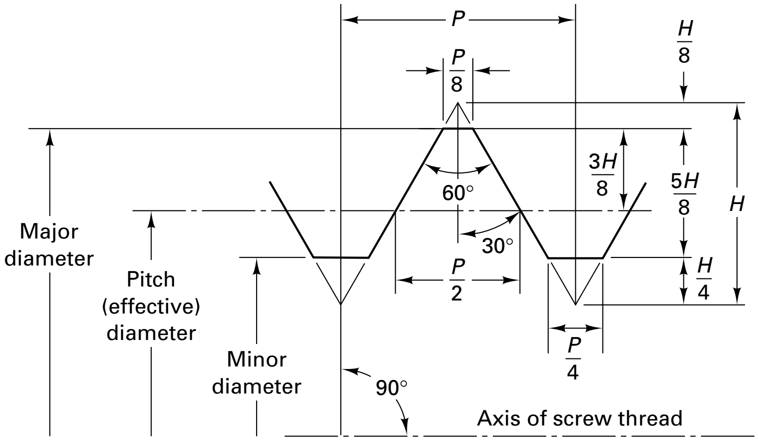
(a) External thread



(b) Internal thread



(c) Metric ISO/R68-1969



D = Major diameter of thread of nut } Normal diameter
d = Major diameter of screw } Normal diameter
D_1 = Minor diameter of thread of nut
d_1 = Minor diameter of screw
D_2 = Pitch diameter of thread of nut
d_2 = Pitch diameter of screw
H = Height of the complete theoretical thread profile
H_1 = Engagement
P = Pitch

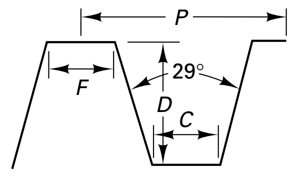
$$H = \frac{\sqrt{3}}{2}P$$

FIGURE 29-2 Basic profiles of Unified and American screw threads: (a) external, (b) internal, and (c) metric.

Types of Screw Threads

1. *Coarse-thread series* (UNC and NC). For general use where not subjected to vibration.
2. *Fine-thread series* (UNF and NF). For most automotive and aircraft work.
3. *Extra-fine-thread series* (UNEF and NEF). For use with thin-walled material or where a maximum number of threads are required in a given length.
4. *Eight-thread series* (8UN and 8N). Eight threads per inch for all diameters from 1 to 6 in. Used primarily for bolts on pipe flanges and cylinder-head studs where an initial tension must be set up to resist steam or air pressures.
5. *Twelve-thread series* (12UN and 12N). Twelve threads per inch for diameters from $\frac{1}{2}$ through 6 in. Not used extensively.
6. *Sixteen-thread series* (16UN and 16N). Sixteen threads per inch for diameters from $\frac{3}{4}$ through 6 in. Used for a wide variety of applications that require a fine thread.
7. *American Acme thread.* This thread and the following three are used primarily in transmitting power and motion.

American Acme thread



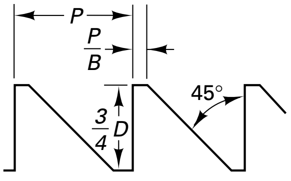
Min. depth $D = 0.5 \times P$

Width $F = 0.3707 \times P$

Width $C = F - 0.0052$

8. *Buttress thread.*

Buttress thread

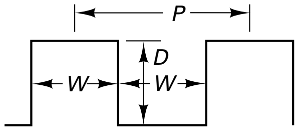


Depth $D = 0.750 \times P$
Width of flat
$= 0.125 \times P$

Flank angle = 45° in plane of axis

9. *Square thread.*

Square thread

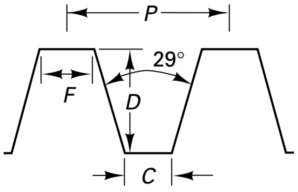


Depth $D = 0.5 \times P$
W for screw $= 0.5 \times P$

W for thread groove in nut $= 0.5 \times P$ plus 0.001 to 0.002″ clearance

10. *29° Worm thread.*

29° Worm thread



Depth $D = 0.6866 \times P$
Depth $F = 0.355 \times P$
Depth $C = 0.310 \times P$

Angle = 29° in plane of axis

11. *American, standard pipe thread.* This thread is the standard tapered thread used on pipe joints in this country. The taper on all pipe threads is $\frac{3}{4}$ in./ft.

American standard pipe thread

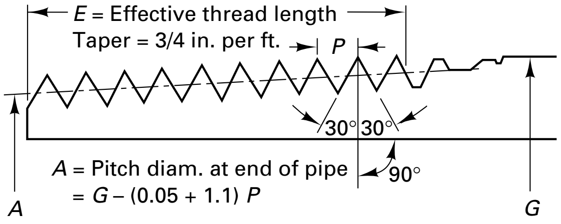


FIGURE 29-3 Types of screw threads.

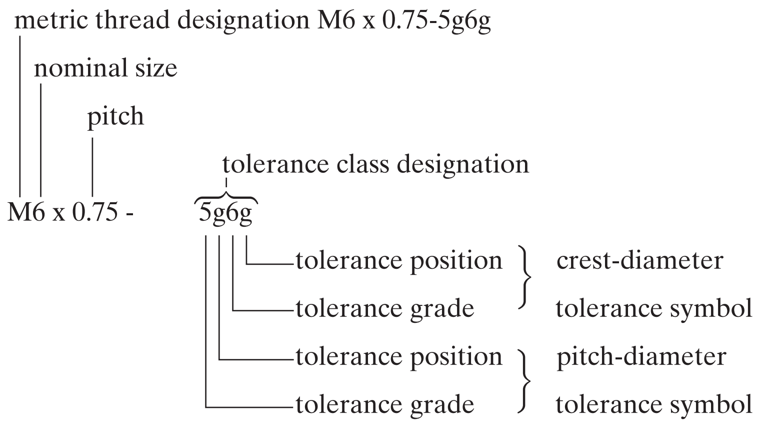
pitches. When a coarse thread is designated, it is not necessary to spell out the pitch. For example, a coarse 10-mm outside diameter (OD) thread is called out as “M 12.” This thread has a pitch of 1.75 mm, but the pitch may be omitted from the call-out. A fine 12-mm OD thread is available. It has a 1.25-mm pitch and must be designated “M12 x 1.25” an extra-fine 12-mm OD thread having 0.75 mm-pitch would receive the designation “M 12 x 0.75.”

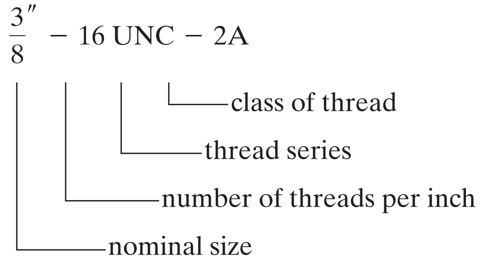
The symbol “x” is not employed as a multiplication symbol in metric practice; rather, it is used to relate these two attributes of the threads. The full description of a thread fastener obviously includes information beyond the thread specification. Head type, length, length of thread, design of end, thread runout, heat treatment, applied finishes, and other data may be needed to fully specify a bolt besides the designation of the thread. The “x” should not be used to separate any of the other characteristics.

Here is another example of an ISO thread designation:



In the ISO system, tolerances are applied to “positions” and “grades.” Tolerance positions denote the limits of pitch and crest diameters, using “e” (large), “g” (small), and “H” (no allowance) for internal threads. The grade is expressed by numerals 3 through 9. Grade 6 is roughly equivalent to U.S. grades 2A and B, medium-quality, general-purpose threads. Below 6 is fine quality and/or short engagement. Above 6 is coarse quality and/or long length of engagement.

In the Unified system, screw threads are designated by symbols as follows:



This type of designation applies to right-hand threads. For left-hand threads, the letters LH are added after the class of thread symbol.

In the Unified system, manufacturing tolerances are specified by three classes. Class 1 is for ordnance and other special applications. Class 2 threads are the normal production grade, and Class 3 threads have minimum tolerances where tight fits are required. The letters A and B are added after the class numerals to indicate external and internal threads, respectively.

The availability of fasteners, particularly nuts, containing plastic inserts to make them self-locking and thus able to resist loosening due to vibration, and the use of special coatings that serve the same purpose, have resulted in less use of finer-thread-series fasteners in mass production. Coarser-thread fasteners are easier to assemble and less subject to cross-threading (binding).

29.2 THREAD MAKING

Three basic methods are used to produce threads: *cutting*, *rolling*, and *casting*. Although both external and internal threads can be cast, relatively few are made in this manner, primarily in connection with die casting, investment casting, or the molding of plastics. Today, by far the largest number of threads are made by rolling. Both external and internal threads can be made by rolling, but the material must be ductile. Because rolling is a less flexible process than thread cutting, it is restricted essentially to standardized and simple parts. Consequently, large numbers of external and internal threads still are made by cutting processes, including grinding and tapping.

External Thread Cutting Methods	Internal Thread Cutting Methods
Threading on an engine lathe	Threading (on an engine lathe or NC lathe)
Threading on an NC lathe	With a tap and holder (manual NC, machine, semiautomatic, or automatic)
With a die held in a stock (manual)	With a collapsible tap (turret lathe, screw machine, or special threading machine)
With an automatic die (turret lathe or screw machine) or NC lathe	By milling
By milling	
By grinding	

CUTTING THREADS ON A LATHE

Lathes provided the first method for cutting threads by machine. Although most threads are now produced by other methods, lathes still provide the most versatile and fundamentally simple method. Consequently, they often are used for cutting threads on special workpieces where the configuration or nonstandard size does not permit them to be made by less costly methods.

There are two basic requirements for thread cutting on a lathe. First, an accurately shaped and properly mounted tool is needed because thread cutting is a form-cutting operation. The resulting thread profile is determined by the shape of the tool and its position relative to the workpiece. Second, the tool must move longitudinally in a specific relationship to the rotation of the workpiece, because this determines the *lead* of the thread. This requirement is met through the use of the *lead screw* and the *split nut*, which provide positive motion of the carriage relative to the rotation of the spindle.

To cut a thread, it is also essential that a constant positional relationship be maintained among the workpiece, the cutting tool, and the lead screw. If this is not done, the tool will not be positioned correctly in the thread space on successive cuts. Correct relationship is obtained by means of a *threading dial* (Figure 29-4), which is driven directly by the lead screw through a worm gear. Because the workpiece and the lead screw are directly connected, the threading dial provides a means for establishing the desired positional relationship between the workpiece and the cutting tool. The threading dial is graduated into an even number of major and half divisions. If the feed mechanism is engaged in accordance with the following rules, correct positioning of the tool will result:

1. *For even-number threads:* at any line on the dial
2. *For odd-number threads:* at any numbered line on the dial
3. *For threads involving $\frac{1}{2}$ numbers:* at any odd-numbered line on the dial
4. *For $\frac{1}{4}$ or $\frac{1}{8}$ threads:* return to the original starting line on the dial

To start cutting a thread, the tool usually is fed inward until it just scratches the work, and the cross-slide dial reading is then noted or set at zero. The split nut is engaged and the tool permitted to run over the desired thread length. When the tool reaches the end of the thread, it is quickly withdrawn by means of the cross-slide control. The split nut is then disengaged and the carriage returned to the starting position, where the tool is clear of the workpiece. At this point the future thread will be indicated by a fine scratch line. This permits the operator to check the thread lead by means of a scale or thread gage to assure that all settings have been made correctly.

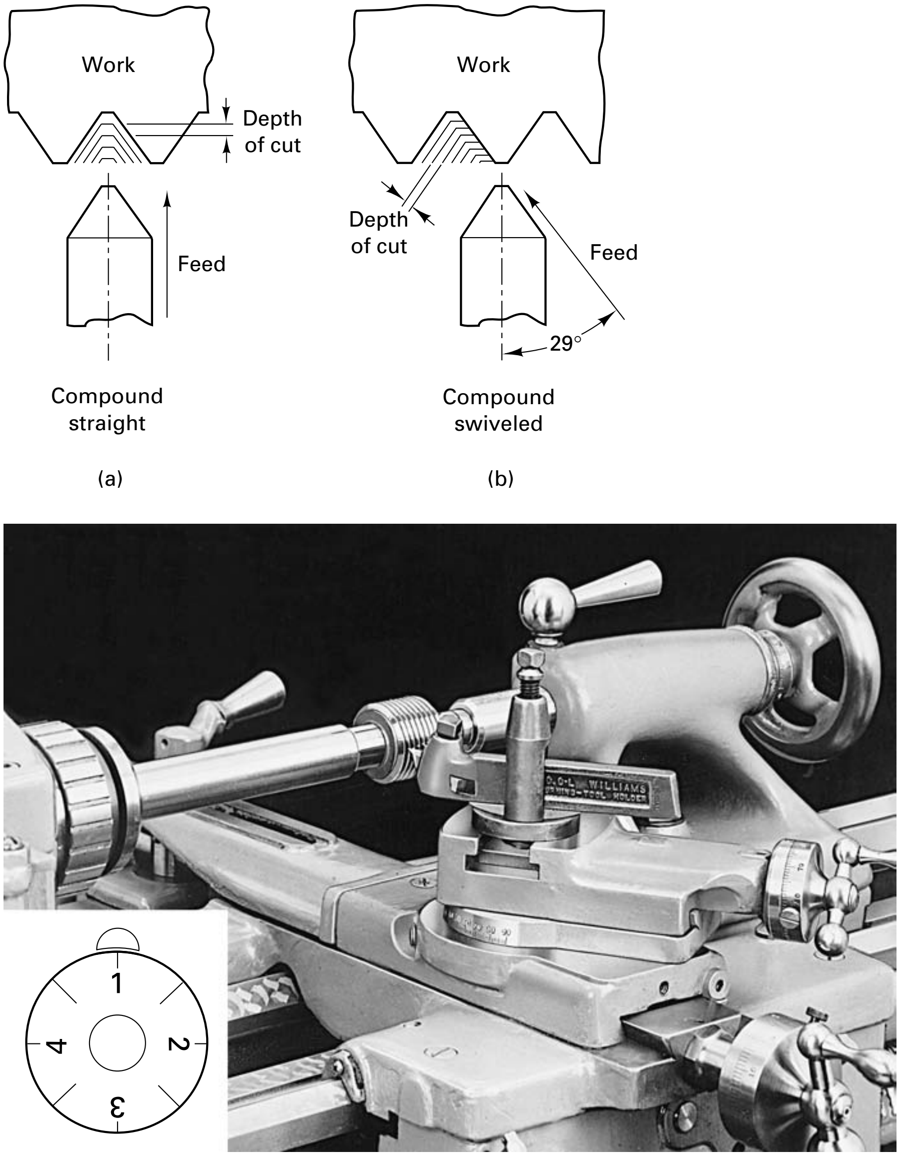


FIGURE 29-4 Cutting a screw thread on a lathe, showing the method of supporting the work and the relationship of the tool to the work with the compound swiveled. Inset shows face of threading dial.

Next, the tool is returned to its initial zero depth position by returning the cross slide to the zero setting. By using the compound rest, the tool can be moved inward the proper depth for the first cut. A depth of 0.010 to 0.025 in. is usually used for the first cut and smaller amounts on each successive cut, until the final cut is made with a depth of only 0.001 to 0.003 in. to produce a good finish. When the thread has been cut nearly to its full depth, it is checked for size by means of a mating nut or thread gage. Cutting is continued until a proper fit is obtained.

Figure 29-4 illustrates two methods of feeding the tool into the work. If the tool is fed radially, cutting takes place simultaneously on both sides of the tool. With this true form-cutting procedure, no rake should be ground on the tool, and the top of the tool must be horizontal and be set exactly in line with the axis of rotation of the work. Otherwise, the resulting thread profile will not be correct. An obvious disadvantage of this method is that the absence of side and back rake results in poor cutting (except on cast iron or brass).The surface finish on steel will usually be poor. Consequently, the second method commonly is used,with the compound swivelled 20°. The cutting then occurs primarily on the left-hand edge of the tool, and some side rake can be provided.

Proper speed ratio between the spindle and the lead screw is set by means of the gear-change box. Modern industrial lathes have ranges of ratios available so that nearly all standard threads can be cut merely by setting the proper levers on the quick-change gear box.

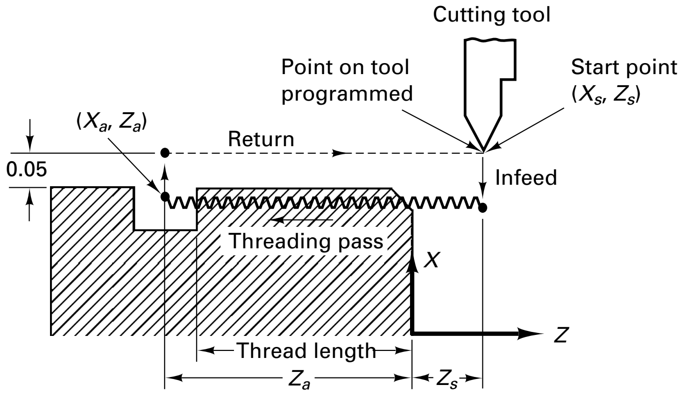

FIGURE 29-5 Canned subroutines called G codes are used on CNC lathes to produce threads. See Chapter 26 for CNC discussion.

X_a	Specifies the absolute X coordinate of the tool after axial infeed.
$G32$	Initiates the single-pass threading cycle.
Z_a	Specifies the absolute Z coordinate of the tool after the threading pass.
Fn	n specifies the feed rate
X_s Z_s	Specifies the absolute X and Z coordinates of the start point.

Cutting screw threads on a lathe is a slow, repetitious process that requires considerable operator skill. The cutting speeds usually employed are from one-third to one-half of regular speeds to enable the operator to have time to manipulate the controls and to ensure better cutting. The cost per part can be high, which explains why other methods are used whenever possible.

CUTTING THREADS ON A CNC LATHE

Computer numerical control (CNC) lathes and turning centers can be programmed to machine straight, tapered, or scroll threads. Threads machined using the same type of special tool have the thread shape shown in Figure 29-4. The tool is positioned at a specific starting distance from the end of the work (Figure 29-5). This distance will vary from machine to machine. Its value can be found in the machine's programming manual. The CNC software will have a set of preprogrammed machining routines (called G codes) specifically for threading. Beginning at the start point, the tool accelerates to the feed rate required to cut the threads. The tool creates the thread shape by repeatedly following the same path as axial infeed is applied. For standard V-threads, the infeed can be applied along a 0° or 29° angle. The depth of cut for the first pass is the largest. The cutting depth is then decreased for each successive pass until the required thread depth is achieved. A final finishing pass is then made with the tool set at the thread depth.

CUTTING THREADS WITH DIES

Straight and tapered external threads up to about $1\frac{1}{2}$ in. in diameter can be manually cut quickly by means of threading dies (Figure 29-6a). Basically, these dies are similar to hardened, threaded nuts with multiple cutting edges. The cutting edges at the starting end

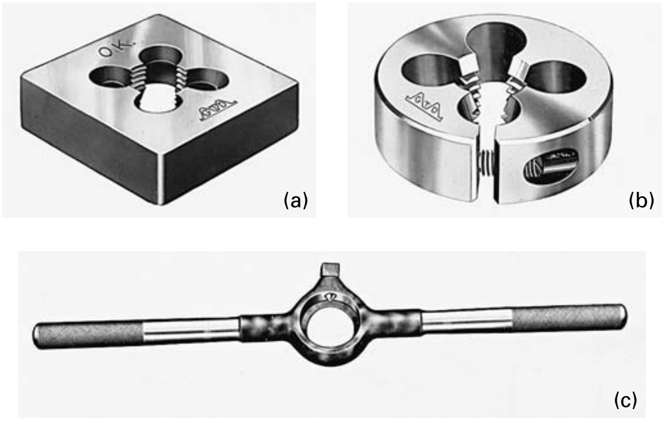

FIGURE 29-6 (a) Solid threading die; (b) solid-adjustable threading die; (c) threading-die stock for round die (die removed). *(Courtesy of TRW-Greenfield Tap & Die.)*

are beveled to aid in starting the dies on the workpiece. As a consequence, a few threads at the inner end of the workpiece are not cut to full depth. Such threading dies are made of carbon or high-speed tool steel.

Solid-type dies are seldom used in manufacturing because they have no provision for compensating for wear. The solid-adjustable type (Figure 29-6b) is split and can be adjusted over a small range by means of a screw to compensate for wear or to provide a variation in the fit of the resulting screw thread. These types of threading dies are usually held in a *stock* for hand rotation. A suitable lubricant is desirable to produce a smoother thread and to prolong the life of the die, since there is extensive friction during the cutting process.

SELF-OPENING DIE HEADS

A major disadvantage of solid-type threading dies is that they must be unscrewed from the workpiece to remove them. They are therefore not suitable for use on high-speed, production-type machines, and *self-opening die heads* are used instead on turret lathes, screw machines, numerically controlled (NC) lathes, and special threading machines for cutting external threads.

There are three types of self-opening die heads, all having four sets of adjustable, multiple-point cutters that can be removed for sharpening or for interchanging for different thread sizes. This permits one head to be used for a range of thread sizes (see Figure 29-7). The cutters can be positioned radially or tangentially, resulting in less tool flank contact and friction rubbing. In some self-opening die heads, the cutters are circular, with an interruption in the circular form to provide an easily sharpened cutting face. The cutters are mounted on the holder at an angle equal to the helix angle of the thread.

As the name implies, the cutters in self-opening die heads are arranged to open automatically when the thread has been cut to the desired length, thereby permitting the die head to be quickly withdrawn from the workpiece. On die heads used on turret lathes, the operator must usually reset the cutters in the closed position before making the next thread. The die heads used on screw machines and automatic threading machines are provided with a mechanism that automatically closes the cutters after the heads are withdrawn.

Cutting threads by means of self-opening die heads is frequently called *thread chasing*. However, some people apply this term to other methods of thread cutting, even to cutting a thread in a lathe.

■ 29.3 INTERNAL THREAD CUTTING–TAPPING

The cutting of an internal thread by means of a multiple-point tool is called *thread tapping*, and the tool is called a *tap*. A hole of diameter slightly larger than the minor diameter of the thread must already exist, made by drilling/reaming, boring, or die casting. For small holes, solid *hand taps* (Figure 29-8) are usually used. The flutes create cutting edges on the thread profile and provide space for the chips and the passage of cutting fluid. Such taps are made of either carbon or high-speed steel and are now routinely coated with TiN. The flutes can be either straight, helical, or spiral.

Hand taps (Figure 29-8) have square shanks and are usually made in sets of three. The *taper tap* has a tapered end that will enter the hole a sufficient distance to help align the tap. In addition, the threads increase gradually to full depth, and therefore this type of tap requires less torque to use. However, only a through-hole can be threaded completely with a taper tap because it cuts to full depth only behind the tapered portion. A blind hole can be threaded to the bottom using three types of taps in succession. After the taper tap has the thread started in proper alignment, a *plug tap*, which has only a few tapered threads to provide gradual cutting of the threads to depth, is used to cut the threads as deep into the hole as its shape will permit. A *bottoming tap*, having no tapered threads, is used to finish the few remaining threads at the bottom of the hole to full depth. Obviously, producing threads to the full depth of a blind hole is time-consuming, and it also frequently results in broken taps and defective workpieces. Such configurations usually can be avoided if designers will give reasonable thought to the matter.

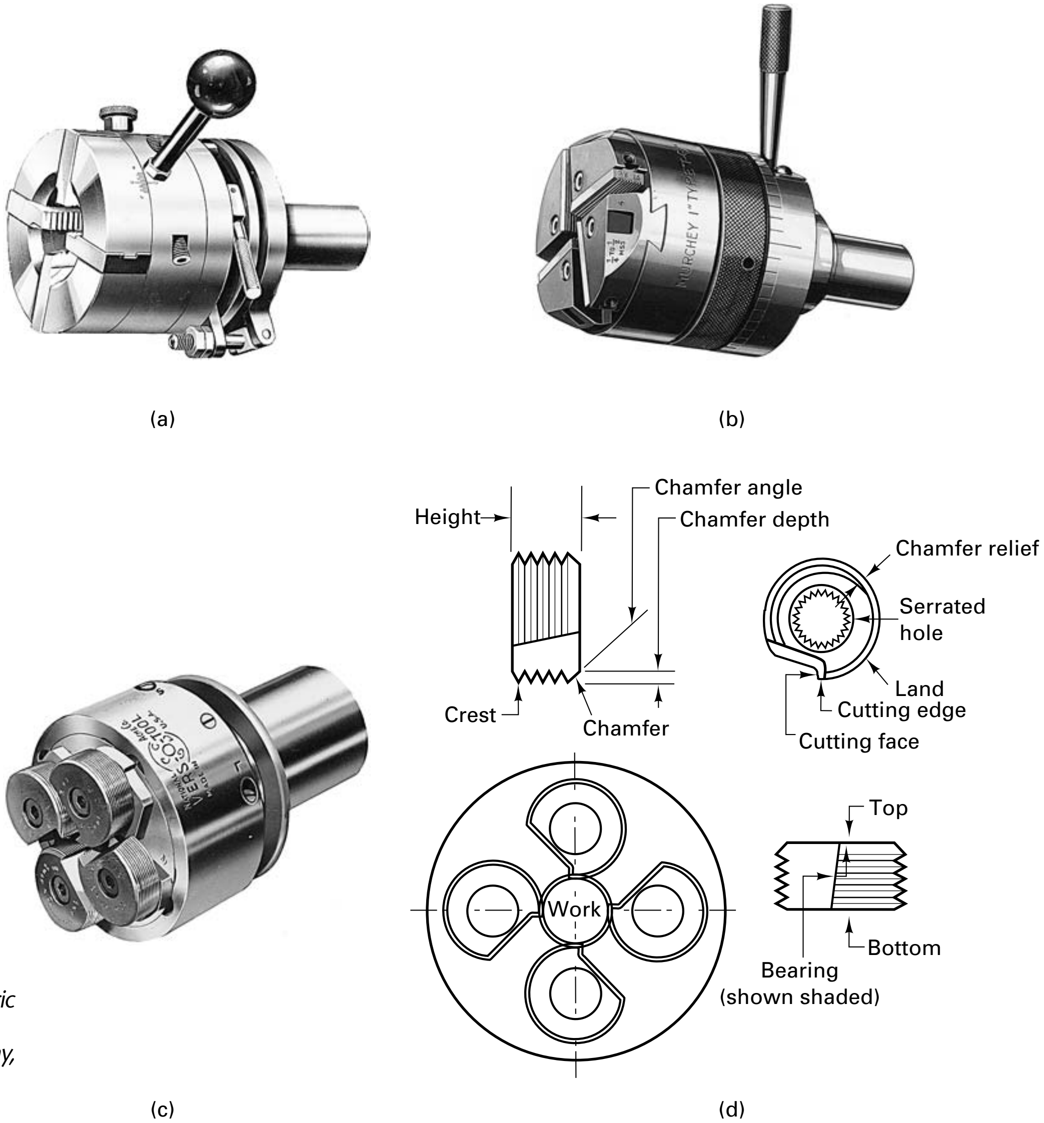

FIGURE 29-7 Self-opening die heads, with (a) radial cutter, (b) tangential cutters, (c) circular cutters, and (d) terminology of circular chasers and their relation to the work. *(Courtesy of Geometric Tool Company, Warner & Sawsey Company, National Acme Company, and TRW-Greenfield Tap & Die, respectively.)*

Taps operate under very severe conditions because of the heavy friction (high torque) involved and the difficulty of chip removal. Also, taps are relatively fragile. *Spiral-fluted taps* (Figure 29-9) provide better removal of chips from a hole, particularly in tapping materials that produce long, curling chips. They are also helpful in tapping holes where the cutting action is interrupted by slots or keyways. The *spiral point* cuts the thread with a shearing action that pushes the chips ahead of the tap so that they do not interfere with the cutting action and the flow of cutting fluid into the hole.

COLLAPSING TAPS

Collapsing taps are similar to self-opening die heads in that the cutting elements collapse inward automatically when the thread is completed. This permits withdrawing the tap from the workpiece without the necessity of unscrewing it from the thread. They can either be self-setting, for use on automatic machines, or require manual setting for each cycle. Figure 29-10 shows some of the types available.

HOLE PREPARATION

Drilling is the most common method of preparing holes for tapping, and when close control over hole size is required, reaming may also be necessary. The drill size determines the final thread contour and the drilling torque. Unless otherwise specified, the tap drill size for most materials should produce approximately 75% thread, that is, 75% of full thread depth.

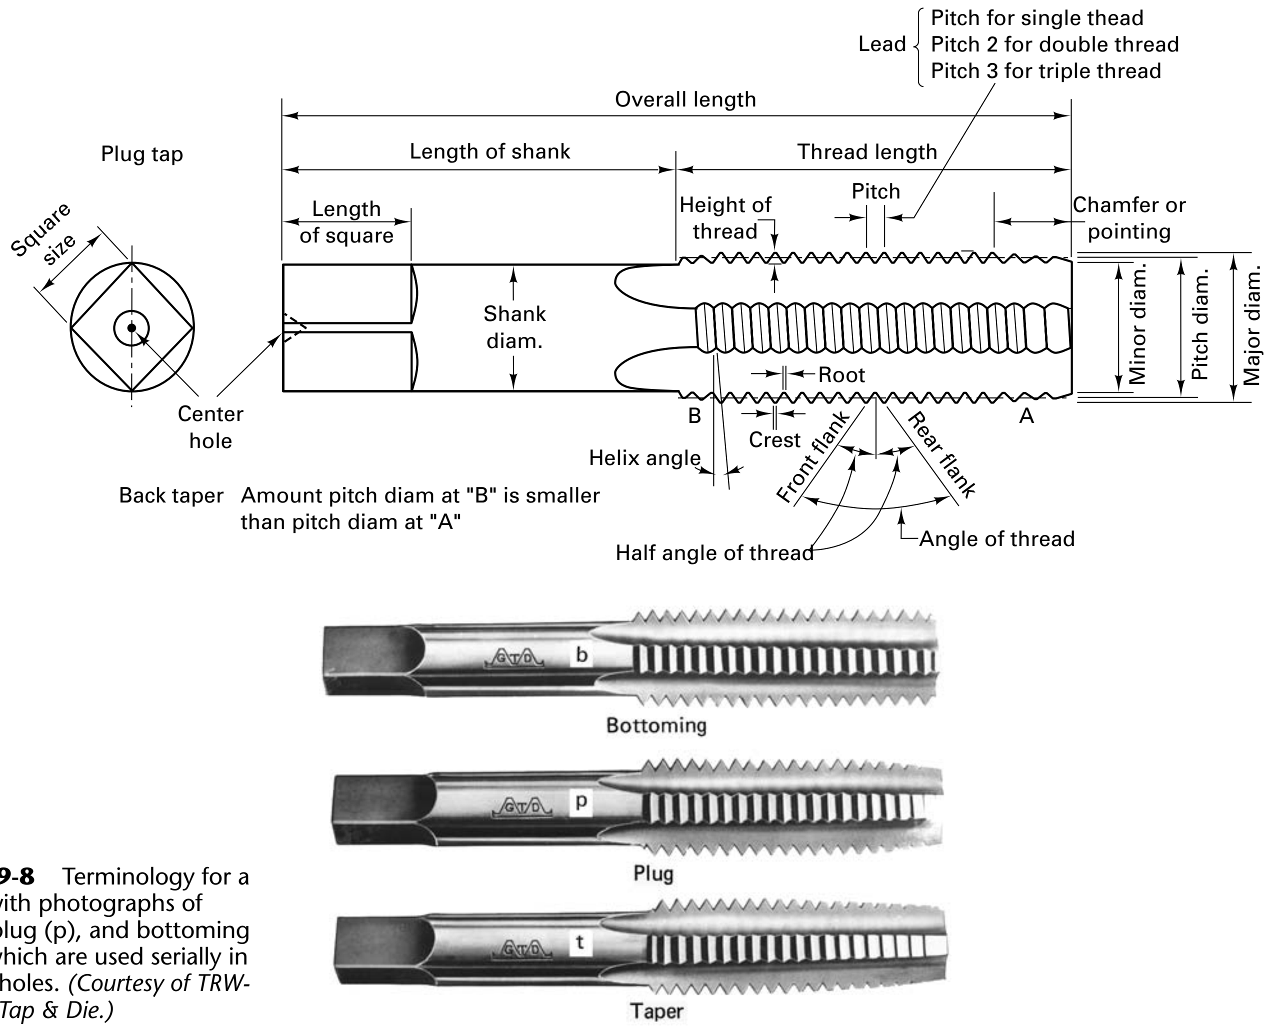

FIGURE 29-8 Terminology for a plug tap with photographs of taper (t), plug (p), and bottoming (b) taps, which are used serially in threading holes. *(Courtesy of TRW-Greenfield Tap & Die.)*

LL receding collapsible ELT collapsible CBLM receding collapsible

FIGURE 29-10 Solid-adjustable and collapsible taps. *(Courtesy of Teledyne Landis Machine.)*

TAPPING IN MACHINE TOOLS

Solid taps also are used in tapping operations on machine tools, such as lathes, drill presses, and special tapping machines. In tapping on a drill press, a tapping attachment is often used. These devices rotate the tap slowly when the drill press spindle is fed downward against the work. When the tapping is completed and the spindle raised, the tap is automatically driven in the reverse direction at a higher speed to reduce the time required to back the tap out of the hole. Some modern machine tools provide for extremely fast spindle reversal for backing taps out of holes.

When solid taps are used on a screw machine or turret, the tap is prevented from turning while it is being fed into the work. As the tap reaches the end of the hole, the tap is free to rotate with the work. The work is then reversed and the tap, again prevented from rotating, is backed out of the hole.

The machine should have adequate power, rigidity, speed and feed ranges, cutting fluid supply, and positive drive action. Chucks, tap holders, and collets should be checked regularly for signs of wear or damage. Accurate alignment of the tap holder, machine spindle, and workpiece is vital to avoid broken taps or bell-mouthed, tapered, or oversized holes.

TAPPING CUTTING TIME

The equation to calculate the cutting time for tapping is (approximately)

$$T_m = \frac{Ln}{N} = \frac{\pi DLn}{12V} + A_L + A_R \tag{29-1}$$

where

N = spindle rpm
T_m = cutting time (min)
D = tap diameter (in.)
L = depth of tapped hole or length of cut (in.)
N = number of threads per inch (tpi)(feed rate)
V = cutting speed (sfpm)
A_L = allowance to start the tap (min)
A_R = allowance to withdraw the tap (min)

SPECIAL THREADING AND TAPPING MACHINES

Special machines are available for production threading and tapping. Threading machines usually have one or more spindles on which a self-opening die head is mounted, with suitable means for clamping and feeding the workpiece. Special tapping machines using self-collapsing taps substituted for the threading dies are also available. More commonly, tapping machines resemble drill presses, modified to provide spindle feeds both upward and downward, with the speed and feed more rapid on the upward motion.

COMMON TAPPING PROBLEMS

Tap overloading is often caused by poor lubrication, lands that are too wide, chips packed in the flutes, or tap wear. Surface roughness in the threads has many causes. A negative grind on the heel will prevent the tap from tearing the threads when backing out.

When a tap loses speed or needs more power, it generally indicates that the tap is dull (or improperly ground) or the chips are packed in flutes (loaded).The flutes may be too shallow or the lands too deep. When tapping soft ductile metals, loading can usually be overcome by polishing the tap before usage.

Improper hole size due to drill wear increases the percentage of threads being cut. Dull tools can also produce a rough finish or workharden the hole surface and cause the tap to dull more quickly. Check to see that the axis of the hole and tap are aligned. If the tap cuts when backing out, check to see if the hole is oversize.

TAPPING HIGH-STRENGTH MATERIALS

High-strength, thermal-resistant materials, sometimes called “exotics,” cause special problems in tapping. A variety of materials are classified as exotics: stainless steel, precipitation-hardened stainless steel, high-alloy steels, iron-based superalloys, titanium, Inconcel, Hastelloy, Monel, and Waspalloy. Their most important attribute is their high strength-to-weight ratio.

Each material presents different problems to efficient tapping, but they all share certain similarities. Toughness and general abrasiveness top the list. It is also difficult to impart a good surface finish to exotics; heat tends to localize in the shear zone, and exotics tend to workharden and grab the tool.

A tap’s chamfer and first full thread do virtually all the cutting. The remaining ground threads serve merely as chasers. Because of this, taps to thread exotics are increasingly manufactured with short threads and reduced necks. They diminish problems caused by material closure and provide more space for coolant and chip ejection.

When tapping exotics, the largest tap core diameter possible should be applied. Cutting 75 or 65% threads places less stress on the taps, lengthening tool life and reducing breakage. To cut threads in exotic alloys successfully, taps must combine geometries specifically tailored for those materials and be made of premium tool steels subjected to precisely controlled heat-treatment processes.

Stainless steel is known to workharden and to have slow heat-dissipation characteristics; stainless steel requires a tap geometry with a positive 6° to 9° rake, preventing workhardening and reducing torque. Grinding an appropriate eccentric thread and back-taper relief onto the tap will reduce friction. A surface treatment promotes lubricity. That is, the tool should be made from high-vanadium, high-cobalt tool steel and have a surface treatment so that coolant adheres to it. Stainless steel generates long chips and requires a tap with a 38° helix angle and adequate flute depth to promote chip evacuation. Proper hook and radial relief guarantee accurate thread-hole size and long tool life.

When tapping a titanium alloy, the material’s tendency to concentrate heat in a small contact area must be considered. Concentrated heat often leads to excessive cutting-edge wear. Titanium generates average-to-short chips, is abrasive, and is prone to chip welding and high friction. These characteristics degrade tap performance and shorten tool life.

Taps for threading titanium are constructed of premium tool steel, nitrided for hardness. Titanium nitride (TiN) coatings cannot be used because they react chemically with the workpiece material, causing rapid tap failure. For tapping through-holes, a 3° to 5° rake and short thread design with high eccentric relief will promote efficient chip evacuation.

Nickel-based Inconel, Monel, Waspalloy, and Hastelloy present severe tapping problems. Among their machining characteristics are toughness, workhardening, heat retention, and built-up-edge (BUE). Taps designed to thread these materials need tremendous stability and a strong cross-sectional construction. The most popular tap materials for nickel alloys are high-vanadium, high-cobalt tool steel or powdered metal (PM) tool steel. Tapping blind holes in these alloys requires a 3° to 5° rake to shear and deflect the cutting forces downward toward the tap's root, its strongest area. A 26° helix angle promotes chip evacuation, and a nitride or TiN coating reduces friction and tool wear. Because of nickel alloys' toughness, taps to cut them should have the longest taper possible. This allows the cutting edges to progressively gain thread height before the first full thread begins its cut, distributing the load over a wider area. Spiral-pointed, straight-flute taps have a four- to five-thread taper. For tapping blind holes, the first two or three threads—more if possible—should be tapered.

CUTTING FLUID FOR TAPPING

Cutting fluids should be kept as clean as possible and should be supplied in copious quantities to reduce heat and friction and to aid in chip removal. Long tap life has been reported to result from routing high-pressure coolants through the tap to flush out the chips and cool the cutting edges. Recommended cutting fluids are listed in Table 29-1.

■ 29.4 THREAD MILLING

Highly accurate threads, particularly in larger sizes, are often form milled. Either a single- or a multiple-form cutter may be used. A single-form cutter having a single annular row of teeth is tilted at an angle equal to the helix angle of the thread and is fed inward radially to full depth while the work is stationary. The workpiece then is rotated slowly, and the cutter simultaneously is moved longitudinally, parallel with the axis of the work (or vice versa), by means of a lead screw, until the thread is completed. The thread can be completed in a single cut, or roughing and finish cuts can be used. This process is used primarily for large-lead or multiple-lead threads.

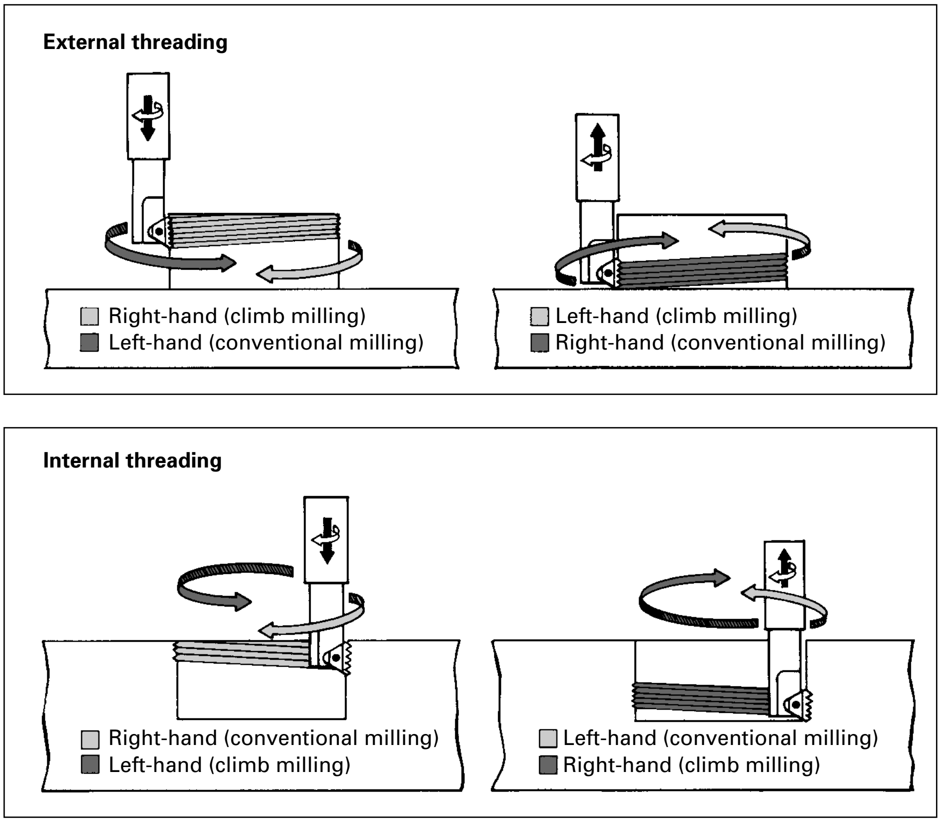
Some threads can be milled more quickly by using a multiple-form cutter having multiple rows of teeth set perpendicular to the cutter axis (the rows having no lead). The cutter must be slightly longer than the thread to be cut. It is set parallel with the axis of the workpiece and fed inward to full-thread depth while the work is stationary. The work then is rotated slowly for a little over one revolution, and the rotating cutter is simultaneously moved longitudinally with respect to the workpiece (or vice versa) according to

TABLE 29-1 Cutting Fluids for Tapping (HSS Tools)

Work Material	Cutting Fluid
Aluminum	Kerosene and lard oil; kerosene and light-base oil
Brass	Soluble oil or light-base oil
Naval brass	Mineral oil with lard or light-base oil
Manganese bronze	Mineral oil with lard or light-base oil
Phosphor bronze	Mineral oil with lard or light-base oil
Copper	Mineral oil with lard or light-base oil
Iron, cast malleable	Dry or soluble oil
	Soluble oil or sulfur-base oil
Magnesium	Light-base oil diluted with kerosene
Monel metal	Sulfur-base oil
Steels:	
Up to 0.25 carbon	Sulfur-base or soluble oil
Free machining	Sulfur-base or soluble oil
0.30–0.60 carbon, annealed	Chlorinated sulfur-base oil
0.30–0.60 carbon, heat treated	Sulfur-base oil
Tool, high-carbon, HSS	Chlorinated sulfur-base oil
Stainless	Chlorinated sulfur-base oil
Titanium	Chlorinated sulfur-base oil
Zinc die castings	Kerosene and lard oil

the thread lead. When the work has revolved one revolution, the thread is complete. This process cannot be used on threads having a helix angle greater than about 3°, because clearance between the sides of the threads and the cutter depends on the cutter diameter's being substantially less than that of the workpiece. Thus, although the process is rapid, its use is restricted to threads of substantial diameter and not more than about 2 in. long.

As shown in Figure 29-11, advances in CNC computer controls have led to thread milling on three-axis machines. Today's CNC can helically interpolate the axial feed controlling the thread pitch with circular feed controlling the circumference of the thread.



Thread milling on machining centers with multitooth indexable-carbide-insert cutters was introduced about twenty years ago. The cutter can produce a finished thread in one helical pass.

FIGURE 29-11 Thread milling on a three-axis NC machine can produce a complete thread in a single feed revolution. *(Fred Mason, American Machinist, November, 1988.)*

The cutter has teeth shaped like the desired thread form. The cutter rotates at high speeds while its axis slowly moves around the part in a planetary arc just over 360°. The cutter advances axially a distance equal to one pitch to generate the helical path. Thread milling has advantages in diameters over 1.5 in., including better surface finish and concentricity and the ability to produce right- or left-hand threads with the same tool. Thrilling (drilling plus threading) produces threaded holes by combining short hole drilling with thread milling using a combination tool with a drill point and a thread mill body. The details of the process are shown in Figure 29-12 and can be done on any CNC machining center. Compared to tapping, the process eliminates two tools, two tool holders, and two tool change cycles as the single tool combines the drill ream and tap functions into one tool. Threaded-hole depths are limited to about three hole diameters.

■ 29.5 THREAD GRINDING

Grinding can produce very accurate threads, and it also permits threads to be produced in hardened materials. Three basic methods are used. *Center-type grinding with axial feed* is the most common method, being similar to cutting a thread on a lathe. A shaped grinding wheel replaces the single-point tool. Usually, a single-ribbed grinding wheel is employed, but multiple-ribbed wheels are used occasionally. The grinding wheels are shaped by special diamond dressers or by crush dressing and must be inclined to the helix angle of the thread. Wheel speeds are in the high range. Several passes are usually required to complete the thread.

Center-type infeed thread grinding is similar to multiple-form milling in that a multiple-ribbed wheel, as wide as the length of the desired thread, is used. The wheel is fed inward radially to full thread depth, and the thread blank is then turned through about $1^1/_2$ turns as the grinding wheel is fed axially a little more than the width of one thread. *Centerless thread grinding* is used for making headless setscrews. The blanks are hopper fed to the regulating wheel, which causes them to traverse the grinding wheel face, from which they emerge in completed form. Production rates of 60 to 70 screws of $^1/_2$–in. length per minute are possible.

■ 29.6 THREAD ROLLING

Thread rolling is used to produce threads in substantial quantities. This is a cold-forming process operation in which the threads are formed by rolling a thread blank between hardened dies that cause the metal to flow radially into the desired shape. Because no metal is removed in the form of chips, less material is required, resulting

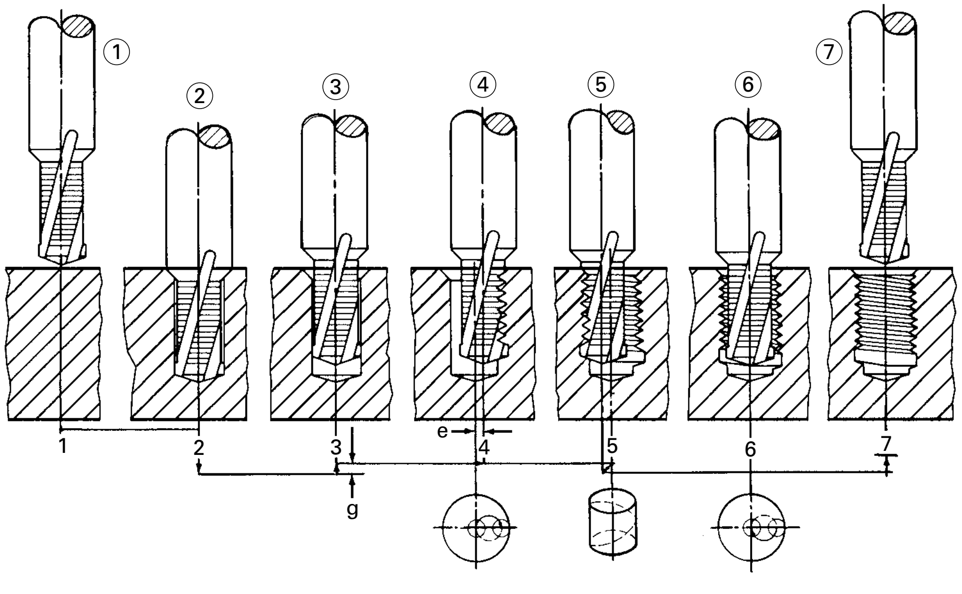


FIGURE 29-12 The process of high-speed thrilling (drilling plus threading) a hole includes (1) approach, (2) drill plus chamfer, (3) retract one thread pitch, (4) radially ramp to the major thread diameter, (5) thread-mill with helical interpolation, (6) return the tool to the centerline of the hole, and (7) retract from the finished hole. At 20,000 rpm, a hole can be thrilled in aluminum in less than two seconds. *(Fred Mason, American Machinist, November, 1988.)*

in substantial savings. In addition, because of cold working, the threads have greater strength than cut threads, and a smoother, harder, and more wear-resistant surface is obtained. In addition, the process is fast, with production rates of one per second being common. The quality of cold-rolled products is consistently good. Chipless operations are cleaner and there is a savings in material (15% to 20% savings in blank stock weight is typical).

Thread rolling is done by four basic methods. The simplest of these employs one fixed and one movable flat rolling die (Figure 29-13). After the blank is placed in position on the stationary die, movement of the moving die causes the blank to be rolled between the two dies and the metal in the blank is displaced to form the threads. As the blank rolls, it moves across the die parallel with its longitudinal axis. Prior to the end of the stroke of the moving die, the blank rolls off the end of the stationary die, its thread being completed.

One obvious characteristic of a rolled thread is that its major diameter always is greater than the diameter of the blank. When an accurate class of fit is desired, the diameter of the blank is made about 0.002 in. larger than the thread-pitch diameter. If it is desired to have the body of a bolt larger than the outside diameter of the rolled thread, the blank for the thread is made smaller than the body.

Thread rolling can be done with cylindrical dies. Figure 29-13 illustrates the three-roll method commonly employed on turret lathes and screw machines. Two variations are used. In one, the rolls are retracted while the blank is placed in position. The rolls then move inward radially, while rotating, to form the thread. More commonly the three rolls are contained in a self-opening die head similar to the conventional type used for cutting external threads. The die head is fed onto the blank longitudinally and forms the thread progressively as the blank rotates. With this procedure, as in the case of cut threads, the innermost $1^1/_2$ to 2 threads are not formed to full depth because of the progressive action of the rollers.

The two-roll method is commonly employed for automatically producing large quantities of externally threaded parts up to 6 in. in diameter and 20 in. in length. The planetary-type machine is for mass production of rolled threads on diameters up to 1 in. Not only is thread rolling very economical, the threads are excellent as to form and strength. The cold working contributes to increased strength, particularly at the critical root areas. There is less likelihood of surface defects (produced by machining), which can act as stress raisers.

Large numbers of threads are rolled on thin, tubular products. In this case external and internal rolls are used. The threads on electric lamp bases and sockets are examples of this type of thread.

CHIPLESS TAPPING

Unfortunately, most internal threads cannot be made by rolling; there is insufficient space within the hole to permit the required rolls to be arranged and supported, and the required forces are too high. However, many internal threads, up to about $1^1/_2$ in. in diameter, are coldformed in holes in ductile metals by means of *fluteless taps*. Such a tap and its special cross section are shown in Figure 29-9. The forming action is essentially the same as in rolling external threads. Because of the forming involved and the high friction, the torque required is about double that for cutting taps. Also, the hole diameter must be controlled carefully to obtain full thread depth without excessive torque. However, fluteless taps produce somewhat better accuracy than cutting taps, and tap life is often greater than that of high-speed-steel (HSS) machine taps. A lubricating fluid should be used, water-soluble oils being quite effective. Fluteless taps are especially suitable for forming threads in dead-end holes because no chips are produced. They come in both plug and bottoming types.

MACHINING VERSUS ROLLING THREADS

Threads are machined or cut when full thread depth is needed (more than one pass necessary) for short production runs, when the blanks are not very accurate, when proximity to the shoulder in end threading is needed, for tapered threads, or when the workpiece material is not adaptable for rolling.

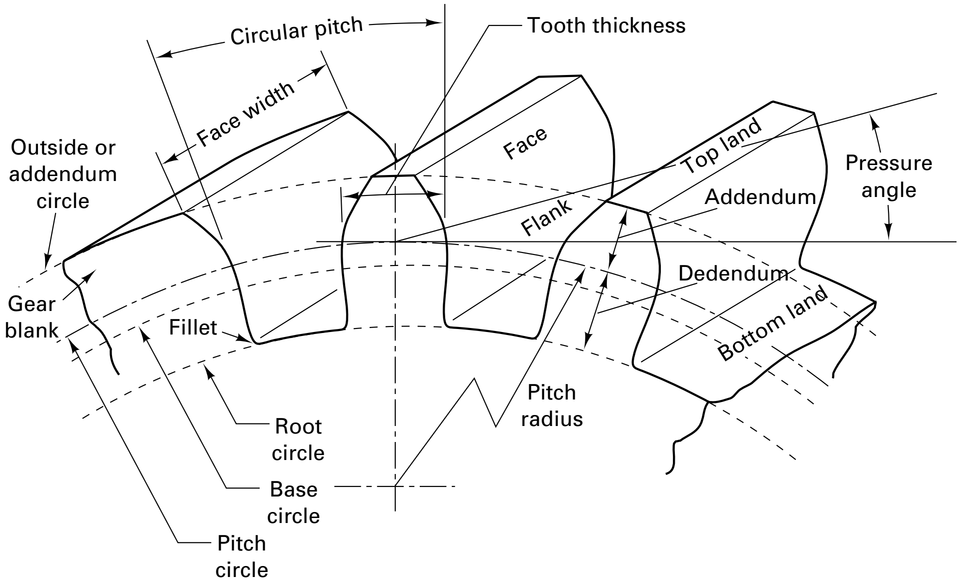

FIGURE 29-14 Gear-tooth nomenclature.

29.7 GEAR MAKING

As with threads, we need to have an introductory understanding of the product before we can understand the process.

GEAR THEORY AND TERMINOLOGY

Basically, gears are modifications of wheels, with *gear teeth* added to prevent slipping and to ensure that their relative motions are constant. However, it should be noted that the relative surface velocities of the wheels (and shafts) are determined by the diameters of the wheels. Although wooden teeth or pegs were attached to disks to make gears in ancient times, the teeth of modern gears are produced by machining or forming teeth on the outer portion of the wheel. The *pitch circle* (Figures 29-14 and 29-15) corresponds to the diameter of the wheel. Thus the angular velocity of a gear is determined by the diameter of this imaginary pitch circle. All design calculations relating to gear performance are based on the pitch-circle diameter or, more simply, the *pitch diameter* (PD).

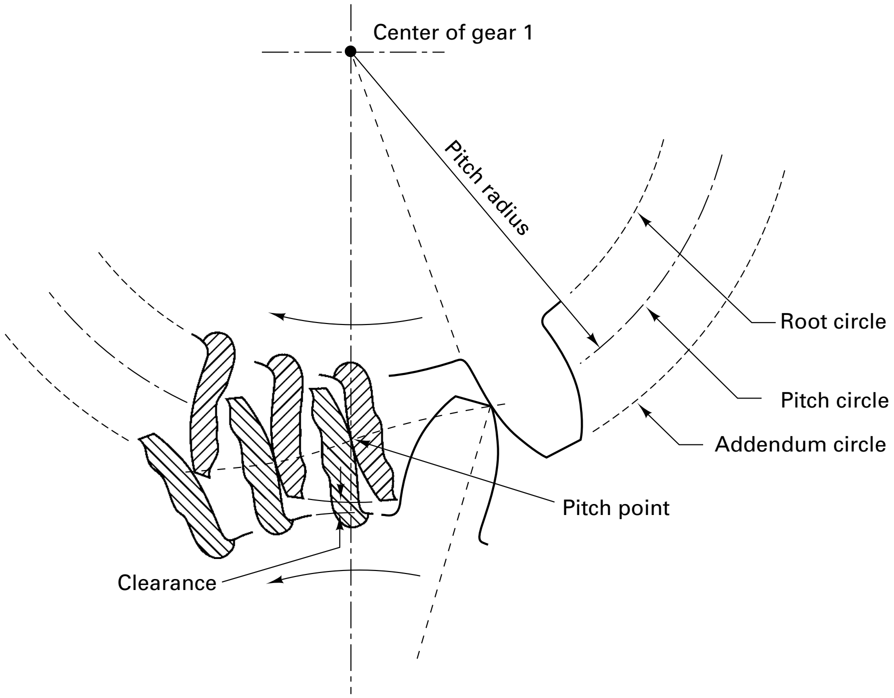

FIGURE 29-15 Tangent pitch circles between two gears produce a pitch point.

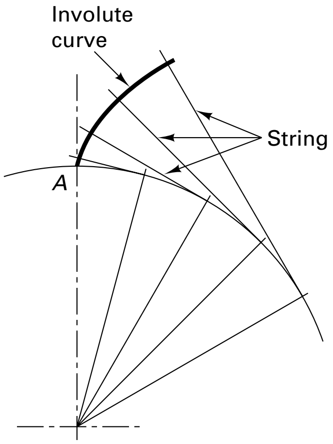

FIGURE 29-16 Method of generating an involute curve by unwinding a string from a cylinder.

For two gears to operate properly, their pitch circles must be tangential to each other. The point at which the two pitch circles are tangent, at which they intersect the centerline connecting their centers of rotation, is called the *pitch point*. The common normal at the point of contact of mating teeth must pass through the pitch point. This condition is illustrated in Figure 29-15.

To provide uniform pressure and motion and to minimize friction and wear, gears are designed to have rolling motion between mating teeth rather than sliding motion. To achieve this condition, most gears utilize a tooth form that is based on an *involute curve*. This is the curve that is generated by a *point* on a straight line when the line rolls around a *base circle*. A somewhat simpler method of developing an involute curve is that shown in Figure 29-16. By unwinding a tautly held string from a point on the base circle, point A, an involute curve is generated.

There are three other reasons for using the involute form for gear teeth. First, such a tooth form provides the desired pure rolling action. Second, even if a pair of involute gears is operated with the distance between the centers slightly too large or too small, the common normal at the point of contact between mating teeth will always pass through the pitch point. Obviously, the theoretical pitch circles in such cases will be increased or decreased slightly. Third, the *line of action* or *path of contact*—that is, the locus of the points of contact of mating teeth—is a straight line that passes through the pitch point and is tangent to the base circles of the two gears.

Cutting an involute shape in gear blanks can be done by simple form cutting (i.e., milling the shape into the workpiece) or by generating. Generating involves relative motion between the workpiece and the cutting tool. True involute tooth form can be produced by a cutting tool that has straight-sided teeth. This permits a very accurate involute tooth profile to be obtained through the use of a simple and easily made cutting tool. The straight-sided teeth are given a rolling motion relative to the workpiece to create the curved gear-tooth face, that is, the involute shape.

The basic size of gear teeth may be expressed in two ways. The common practice, especially in the United States and England, is to express the dimensions as a function of the *diametral pitch* (DP). DP *is the number of teeth (N) per unit of pitch diameter* (PD); thus (PD) = N/PD. Dimensionally, DP involves inches in the English system and millimeters in the SI system, and it is a measure of tooth size. Metric gears use the module system *(M)*, defined as *the pitch diameter divided by the number of teeth*, or $M =$ PD/N. It thus is the reciprocal of diametral pitch and is expressed in millimeters. Any two gears having the same diametral pitch or module will mesh properly if they are mounted so as to have the correct distances and relationship. The important tooth elements can be specified in terms of the diametral pitch or the module and are as follows:

1. *Addendum:* the radial distance from the pitch circle to the outside diameter.

$$addendum = \frac{1}{DP}\, inches$$

2. *Dedendum:* the radial distance from the pitch circle to the root circle. It is equal to the addendum plus the *clearance*, which is provided to prevent the outer corner of a tooth from touching against the bottom of the tooth space.
3. *Circular pitch:* the distance between corresponding points of adjacent teeth, measured along the pitch circle:

$$\pi/\text{diametral pitch}$$

4. *Tooth thickness:* the thickness of a tooth, measured along the pitch circle. When tooth thickness and the corresponding *tooth space* are equal, no *backlash* exists in a pair of mating gears.
5. *Face width:* the length of the gear teeth in an axial plane.
6. *Tooth face:* the mating surface between the pitch circle and the addendum circle.
7. *Tooth flank:* the mating surface between the pitch circle and the root circle.
8. *Pressure angle:* the angle between a tangent to the tooth profile and a line perpendicular to the pitch surface.

Four shapes of involute gear teeth are used in the United States:

1. $14\frac{1}{2}^\circ$ pressure angle, full depth (used most frequently)
2. $14\frac{1}{2}^\circ$ pressure angle, composite (seldom used)
3. 20° pressure angle, full depth (seldom used)
4. 20° pressure angle, stub tooth (second most common)

In the $14\frac{1}{2}^\circ$ full-depth system, the tooth profile outside the base circle is an involute curve. Inward from the base circle, the profile is a straight radial line that is joined with the bottom land by a small fillet. With this system, the teeth of the basic rack have straight sides. The composite system and the 20° full-depth system provide somewhat stronger teeth. However, with the 20° full-depth system considerable undercutting occurs in the dedendum area; therefore, stub teeth often are used. The addendum is shortened by 20%, thus permitting the dedendum to be shortened a similar amount. This results in very strong teeth without undercutting. Table 29-2 gives the formulas for computing the dimensions of gear teeth in the $14^1/_2^\circ$ full-depth and 20° stub-tooth systems.

PHYSICAL REQUIREMENTS OF GEARS

A consideration of gear theory leads to five requirements that must be met in order for gears to operate satisfactorily:

1. The actual tooth profile must be the same as the theoretical profile.
2. Tooth spacing must be uniform and correct.
3. The *actual* and theoretical pitch circles must be coincident and be concentric with the axis of rotation of the gear.
4. The face and flank surfaces must be smooth and sufficiently hard to resist wear and prevent noisy operation.
5. Adequate shafts and bearings must be provided so that desired center-to-center distances are retained under operational loads.

The first four of these requirements are determined by the material selection and manufacturing process. The various methods of manufacture that are used represent attempts to meet these requirements to varying degrees with minimum cost, and their effectiveness must be measured in terms of the extent to which the resulting gears embody these requirements.

Before looking at the ways to manufacture gears, let's look at some examples of gears.

TABLE 29-2 Formula for Calculating the Standard Dimensions for Involute Gear Teeth

	$14^1/_2^\circ$ Full Depth	20°, Stub Tooth
Pitch diameter (PD)	$\frac{N}{\text{DP}}$	$\frac{N}{\text{DP}}$
Addendum	$\frac{1}{\text{DP}}$	$\frac{0.8}{\text{DP}}$
Dedendum	$\frac{1.157}{\text{DP}}$	$\frac{1}{\text{DP}}$
Outside diameter	$\frac{N+2}{\text{DP}}$	$\frac{N+1.6}{\text{DP}}$
Clearance	$\frac{0.157}{\text{DP}}$	$\frac{0.2}{\text{DP}}$
Tooth thickness	$\frac{1.508}{\text{DP}}$	$\frac{1.508}{\text{DP}}$

DP = Number of teeth (N) per unit of pitch diameter (PD).

29.8 GEAR TYPES

The more common types of gears are shown in Figure 29-17. *Spur gears* have straight teeth and are used to connect parallel shafts. They are the most easily made and the cheapest of all types.

The teeth on *helical gears* lie along a helix, the angle of the helix being the angle between the helix and a pitch cylinder element parallel with the gear shaft. Helical gears can connect either parallel or nonparallel nonintersecting shafts. Such gears are stronger and quieter than spur gears because the contact between mating teeth increases more gradually and more teeth are in contact at a given time. Although they usually are slightly more expensive to make than spur gears, they can be manufactured in several ways and are produced in large numbers.

Helical gears have one disadvantage. When they are in use, a side thrust is created that must be absorbed in the bearings. *Herringbone gears* neutralize this side thrust by having, in effect, two helical-gear halves, one having a right-hand and the other a left-hand helix. The *continuous* herringbone type is rather difficult to machine but is very strong. A modified herringbone type is made by machining a groove, or gap, around the gear blank where the two sets of teeth would come together. This provides a runout space for the cutting tool in making each set of teeth.

Different types of gears

Skew bevels

Spiral bevels

Hypoid gears

Spiral gears

Worm gears

Internal gear

FIGURE 29-17 There are many different types of gears for transmitting motion, resulting in a wide variety of gear-making processes.

A *rack* is a gear with infinite radius, having teeth that lie on a straight line on a plane. The teeth may be normal to the axis of the rack or helical so as to mate with spur or helical gears, respectively.

A *worm* is similar to a screw. It may have one or more threads, the multiple-thread type being very common. Worms usually are used in conjunction with a *worm gear*. High gear ratios are easily obtainable with this combination. The axes of the worm and worm gear are nonintersecting and are usually at right angles. If the worm has a small helix angle, it cannot be driven by the mating worm gear. This principle is frequently employed to obtain nonreversible drives. Worm gears are usually made with the top land concave to permit greater area of contact between the worm and the gear. A similar effect can be achieved by using a *conical worm*, in which the helical teeth are cut on a double-conical blank, thus producing a worm that has an hourglass shape.

Bevel gears, teeth on a cone, are used to transmit motion between intersecting shafts. The teeth are cut on the surface of a truncated cone. Several types of bevel gears are made, the types varying as to whether the teeth are straight or curved and whether the axes of the mating gears intersect. On *straight-tooth* bevel gears the teeth are straight, and if extended all would pass through a common apex. *Spiral-tooth* bevel gears have teeth that are segments of spirals. Like helical gears, this design provides tooth overlap so that more teeth are engaged at a given time and the engagement is progressive. *Hypoid* bevel gears also have a curved-tooth shape but are designed to operate with nonintersecting axes. Rear-drive automobiles used hypoid gears in the rear axle so that the drive-shaft axis can be below the axis of the axle and thus permit a lower floor height. Z*erol* bevel gears have teeth that are circular arcs, providing somewhat stronger teeth than can be obtained in a comparable straight-tooth gear. They are not used extensively. When a pair of bevel gears are the same size and have their shafts at right angles, they are termed *miter gears*.

A *crown gear* is a special form of bevel gear having a 180° cone apex angle. In effect, it is a disk with the teeth on the side of the disk. It may also be thought of as a rack that has been bent into a circle so that its teeth lie in a plane. The teeth may be straight or curved. On straight-tooth crown gears the teeth are radial. Crown gears are seldom used, but they have the important quality that they will mesh properly with a bevel gear of any cone angle, provided that the bevel gear has the same tooth form and diametral pitch. This important principle is incorporated in the design and operation of two very important types of gear-generating machines that will be discussed later.

Most gears are of the external type, the teeth forming the outer periphery of the gear. Internal gears have the teeth on the inside of a solid ring, pointing toward the center of the gear.

29.9 GEAR MANUFACTURING

Whether produced in large or small quantities, in cells, or in job shop batches, the sequence of processes for gear manufacturing requires four sets of operations. See Figure 29-18.

1. Blanking (turning)
2. Gear cutting (hobbing and shaving)
3. Heat treatment
4. Grinding

Blanking refers to the initial forming or machining operations that produce a semifinished part ready for gear cutting, starting from a piece of raw material. Turning on chuckers or lathes, facing and centering of shafts, milling, and sometimes grinding fall into this category of operations. Good-quality blanks are essential in precision gear manufacturing.

Hobbing, shaping, and shaving machines are the most frequently used machines for gear cutting, producing gears for automotive, truck, agricultural, and construction equipment. Other processes used in industrial gear production include broaching, rolling, grinding, milling, and shaving. The process selected depends on finding a cost-effective application based on quality specification, production volumes, and economic conditions.

Shaving cutter and gear

(b) Hobbing

(c) Shaving

FIGURE 29-18 The typical gear-making process (for very accurate gears) involves both hobbing and shaving followed by grinding after heat treating.

The gear-cutting or -machining operations can be divided into operations executed prior to heat treatment, when the material is still soft and easily machinable, and after heat treatment, performed on parts that have acquired high hardness and strength.

Heat treatment gives the material the strength and durability to withstand high loads and wear but results in a reduction in dimensional and geometrical accuracy. The metallurgical transformations that occur during hardening, quenching, and tempering cause a general quality deterioration in the gears. Therefore, precision grinding operations are used on external and internal bearing diameters, critical length dimensions, and fine surface finishes after heat treatment. Cylindrical grinders, angle-head grinders, internal grinders, and surface grinders are commonly used.

Gears are made in very large numbers by cold-roll forming; in addition, significant quantities are made by extrusion, by blanking, by casting, and some by powder metallurgy and by a forging process. However, it is only by machining that all types of gears can be made in all sizes, and although roll-formed gears can be made with accuracy sufficient for most applications, even for automobile transmissions, machining still is unsurpassed for gears that must have very high accuracy. Also, roll forming can be used only on ductile metals.

■ 29.10 MACHINING OF GEARS

FORM MILLING

Form cutting or *form milling* on a horizontal milling machine is illustrated in Figure 29-19. The multiple-tooth form cutter has the same form as the *space* between adjacent teeth. The tool is fed radially toward the center of the gear blank to the desired tooth depth, then across the tooth face to obtain the required tooth width. When one tooth space has been completed, the tool is withdrawn, the gear blank is indexed using a dividing head, and the next tooth space is cut. In machining gears by the form-cutting process, the form cutter is mounted on the machine arbor, and the gear blank is mounted on a mandrel held between the centers of some type of indexing device. Basically, form cutting is a simple and flexible method of machining gears. The equipment and cutters required are relatively

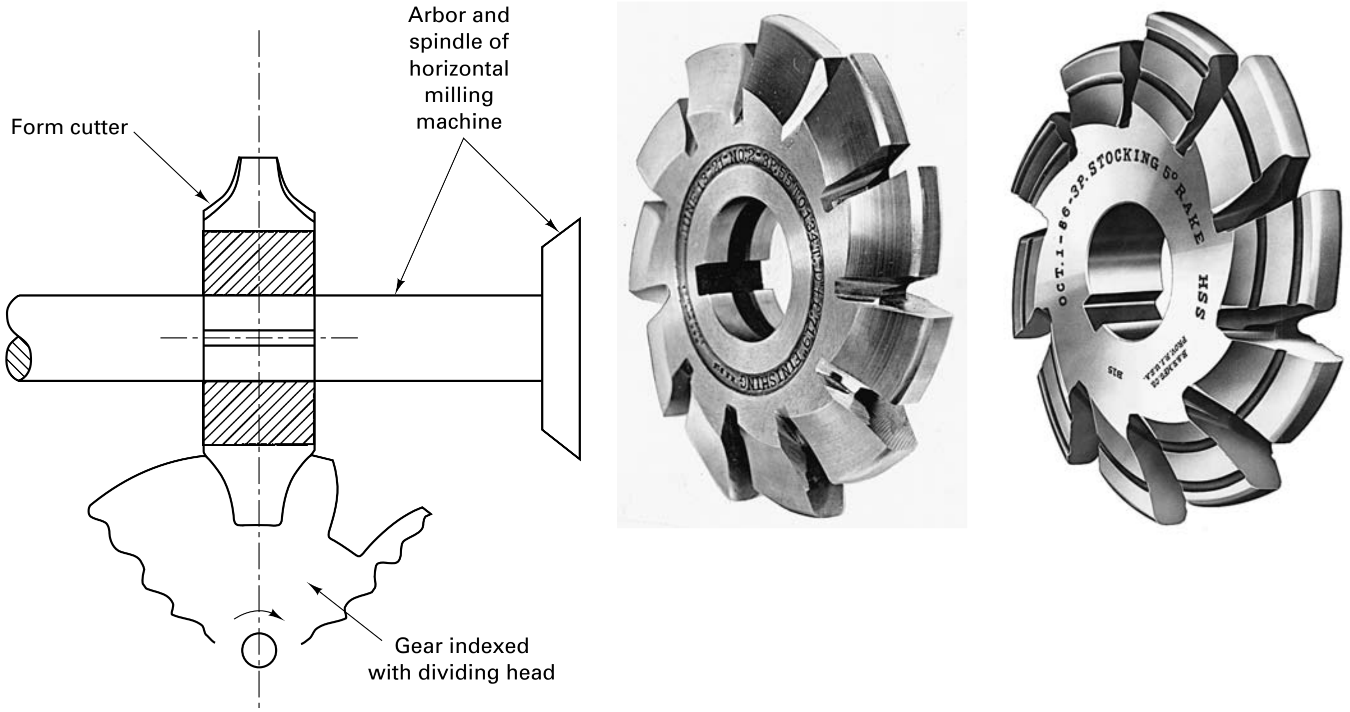

FIGURE 29-19 The basic method of machining a gear using a form cutter (left) to mill out the space between the teeth using the form cutter (middle) or the stocking cutter (right) to machine the gear. *(Courtesy of Brown and Sharpe Manufacturing Company.)*

simple, and standard machine tools (milling machines) are often used. However, in most cases the procedure is quite slow, and considerable care is required on the part of the operator. Therefore, this process is usually employed where only one or a few gears are to be made. When a helical gear is to be cut, the table must be set at an angle equal to the helix angle, and the dividing head is geared to the longitudinal feed screw of the table so that the gear blank will rotate as it moves longitudinally.

Standard cutters are usually employed in form-cutting gears. In the United States, these come in eight sizes for each diametral pitch and will cut gears having any number of teeth. A single cutter will not produce a theoretically perfect tooth profile for all sizes of gears in the range for which it is intended. However, the change in tooth profile over the range covered by each cutter is very slight, and most of the time satisfactory results can be achieved. When greater accuracy is required, half-number cutters can be obtained. Cutters are available for all common diametral pitches and for $14^1/_2°$ and 20° pressure angles. If the amount of metal that must be removed to form a tooth space is large, roughing cuts may be taken with a *stocking cutter*. The stepped sides of the stocking cutter remove most of the metal and leave only a small amount to be removed subsequently by the regular form cutter in a finish cut.

Straight-tooth bevel gears can be form cut on a milling machine, but this is seldom done. Because the tooth profile in bevel gears varies from one end of the tooth to the other, after one cut is taken to form the correct tooth profile at the smaller end, the relationship between the cutter and the blank must be altered. Shaving cuts are then taken on the side of each tooth to form the correct profile throughout the entire tooth length.

Although the form cutting of gears on a milling machine is a flexible process and is suitable for gears that are not to be operated at high speeds or that need not operate with extreme quietness, the process is slow and requires skilled labor. Semiautomatic machines are available for making gears by the form-cutting process. The procedure utilized is essentially the same as on a milling machine, except that, after setup, the various operations are completed automatically. Gears made on such machines are no more accurate than those produced on a milling machine, but the possibility of error is less, and they are much cheaper because of reduced labor requirements. For large quantities, however, form cutting is not used.

BROACHING

Broaching is another way to form cut teeth. All the tooth spaces are cut simultaneously, and the tooth is formed progressively. The circular table in Figure 29-20 holds 10 sets of progressive tooling. The table rotates, moving one set of tooling at a time under two workpieces. The arms load and unload a set of parts every 15 seconds, so the cycle time is very quick. Excellent gears can be made by *broaching*. However, a separate broach must be provided for each size of gear. The tooling tends to be expensive, restricting this method to large volumes.

GEAR GENERATING

Most high-quality gears that are made by machining are made by the *generating process*. This process is based on the principle that any two involute gears, or any gear and a rack, of the same diametral pitch will mesh together properly. Utilizing this principle, one of the gears (or the rack) is made into a cutter by proper sharpening. It can be used to cut into a mating gear blank and thus generate teeth on the blank. The two principal methods for gear generating are *shaping* and *hobbing*.

SHAPING

To carry out the shaping process, the cutter and the gear blank must be attached rigidly to their respective shafts, and the two shafts must be interconnected by suitable gearing so that the cutter and the blank rotate positively with respect to each other and have the same pitch-line velocities. To start cutting the gear, the cutter is reciprocated vertically and is fed radially into the blank between successive strokes. When the desired tooth depth has been obtained, the cutter and blank are then slightly indexed after each cutting stroke. The resulting generating action is indicated schematically in Figure 29-21a and shown in the cutting of an actual gear tooth in Figure 29-21b. Figure 29-22 shows a machine called a gear shaper. *Gear shapers* generate gears by a reciprocating tool motion. The gear blank is mounted on the rotating table (or vertical spindle) and the cutter on the end of a vertical, reciprocating spindle. The spindle and the table are connected by means of gears so that the cutter and gear blank revolve with the same pitch-line velocity. Cutting occurs on the downstroke (sometimes on the upstroke). At the end of each cutting stroke, the spindle carrying the blank retracts slightly to provide clearance between work and tool on the return stroke.

The conventional cutter for gear shaping is made from high-speed steel, which can be coated to improve wear life with a superhard layer of titanium nitride (TiN) using the physical vapor deposition (PVD) process. Recently, new throwaway disk-shaped insert tools have been developed for gear shaping, eliminating regrinding and recoating operations on the conventional tools. Regrinding the conventional cutter requires two adjustments (resetting operations) on the machine tool. Because the throwaway blades are all sized the same, machine resetting after cutting tool changeover is eliminated.

FIGURE 29-21 (Top) Generating action of a Fellows gear shaper cutter. (Bottom) Series of photographs showing various stages in generating one tooth in a gear by means of a gear shaper, action taking place from right to left, corresponding to the diagram above. One tooth of the cutter was painted white. *(Courtesy of Fellows Gear Shaper Company.)*

Either straight- or helical-tooth gears can be cut on gear shapers. To cut helical teeth, both the cutter and the blank are given an oscillating rotational motion during each stroke of the cutter, turning in one direction during the cutting stroke and in the opposite direction during the return stroke. Because the cutting stroke can be adjusted to end at any desired point, gear shapers are particularly useful for cutting cluster gears. Some machines can be equipped with two cutters simultaneously to cut two gears, often of different diameters. Gear shapers can also be adapted for cutting internal gears.

Special types of gear shapers have been developed for mass-production purposes. The *rotary gear shaper* is essentially 10 shaper units mounted on a rotating base and having a single drive mechanism. Nine gears are cut simultaneously while a finished gear is removed and a new blank is put in place on the tenth unit. *Planetary gear shapers* holding six gear blanks move in planetary motion about a large, central gear cutter. The cutter has no teeth in one portion to provide a space where the gear can be removed and a new blank placed on the empty spindle.

CNC gear shapers are now available with hydromechanical stroking systems that produce a uniform cutting velocity during the cutting portion of the downstroke. These machines can operate at 500 to 1700 rpm and use TiN-coated cutters to enhance tool life. *Vertical shapers* for gear generating have a vertical ram and a round table that can be rotated in a horizontal plane by either manual or power feed. These machine tools are sometimes called *slotters*. Usually, the ram is pivoted near the top so that it can be swung outward from the column through an arc of about 10°.

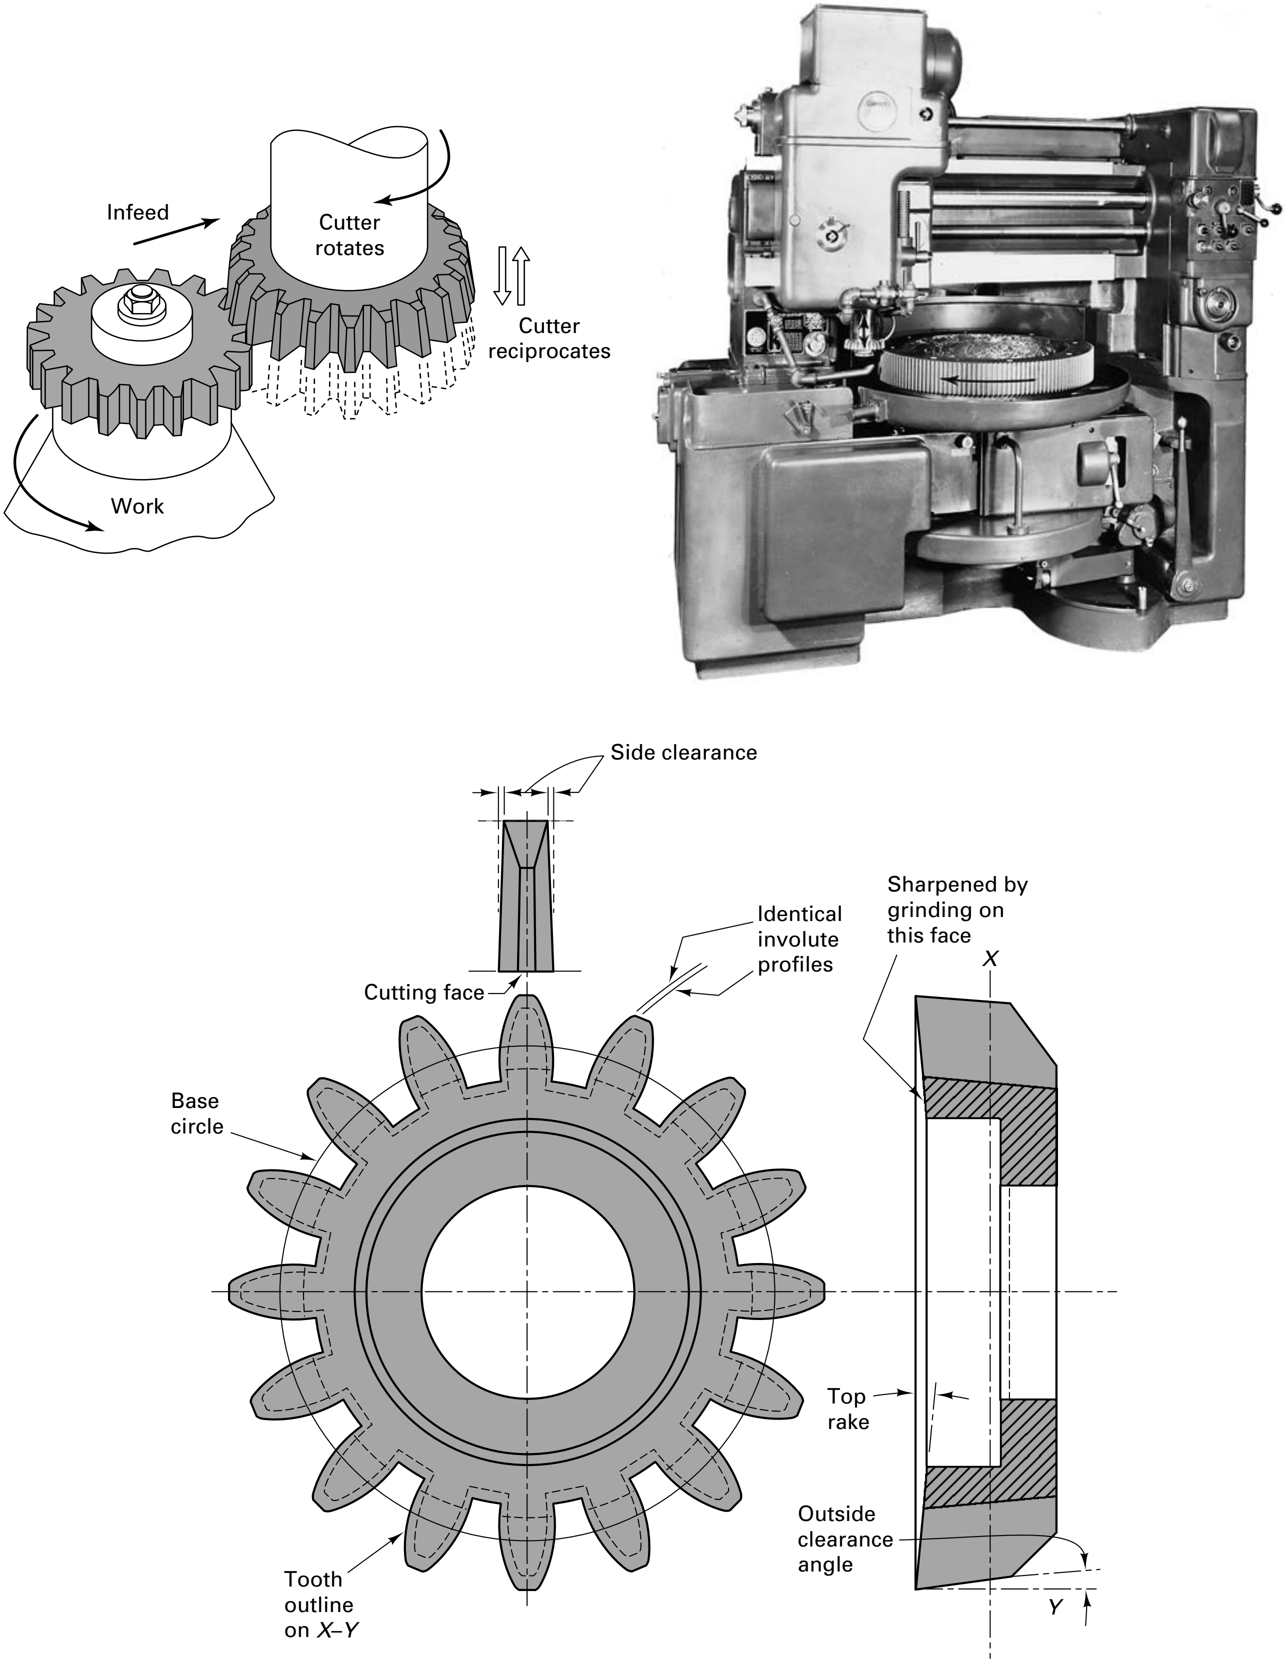

FIGURE 29-22 This machine tool is a gear shaper. The blank is rotating while the cutter is reciprocating vertically, as shown in the inset. The tool is very complex and is shown in detail below. *(Courtesy Fellows Gear Shaper Company.)*

Because one circular and two straight-line motions and feeds are available, vertical shapers are very versatile tools and thus find considerable use in one-of-a-kind manufacturing. Not only can vertical and inclined flat surfaces be machined, but external and internal cylindrical surfaces can be generated by circular feeding of the table between strokes. This may be cheaper than turning or boring for very small lot sizes. A vertical shaper can be used for generating gears or machining curved surfaces, interior surfaces, and arcs by using a stationary tool and rotating the workpiece. A *keyseater* is a special type of vertical shaper designed and used exclusively for machining keyways on the inside of wheel and gear hubs. For machining continuous herringbone gears, a *Sykes gear-generating machine* is used.

HOBBING

Involute gear teeth could be generated by a cutter that has the form of a rack. Such a cutter would be simple to make but has two major disadvantages. First, the cutter (or the blank) would have to reciprocate, with cutting occurring only during one stroke direction. Second, because the rack would have to move longitudinally as the blank rotated, the rack would need to be very long (or the gear very small) or the two would not be in mesh after a few teeth were cut. A *hob* overcomes the preceding two difficulties. As shown in Figure 29-23, a hob can be thought of, basically, as one long rack tooth that has been wrapped around a cylinder in the form of a helix and fluted at intervals to provide a number of cutting edges. Relief is provided behind each of the teeth. The cross section of each tooth, normal to the helix, is the same as that of a rack tooth. (A hob can also be thought of as a gashed worm gear.)

The action of a *hobbing* machine cutting a spur gear is illustrated in Figure 29-23. To cut a spur gear, the axis of the hob must be set off from the normal to the rotational axis of the blank by the helix angle of the hob. In cutting helical gears, the hob must be set over an additional amount equal to the helix angle of the gear. The cutting of a gear by means of a hob is a continuous action. The hob and the blank are connected by proper gearing so that they rotate in mesh. To start cutting a gear, the rotating hob is fed inward until the proper setting for tooth depth is obtained. The hob is then fed in a direction parallel with the axis of rotation of the blank. As the gear blank rotates, the teeth are generated and the feed of the hob across the face of the blank extends the teeth to the desired tooth-face width.

Hobbing is rapid and economical. More gears are cut by this process than by any other. The process produces excellent gears and can also be used for splines and sprockets. Single-, double-, and triple-thread hobs are used. Multiple-thread types increase the production rate but do not produce accuracy as high as single-thread hobs.

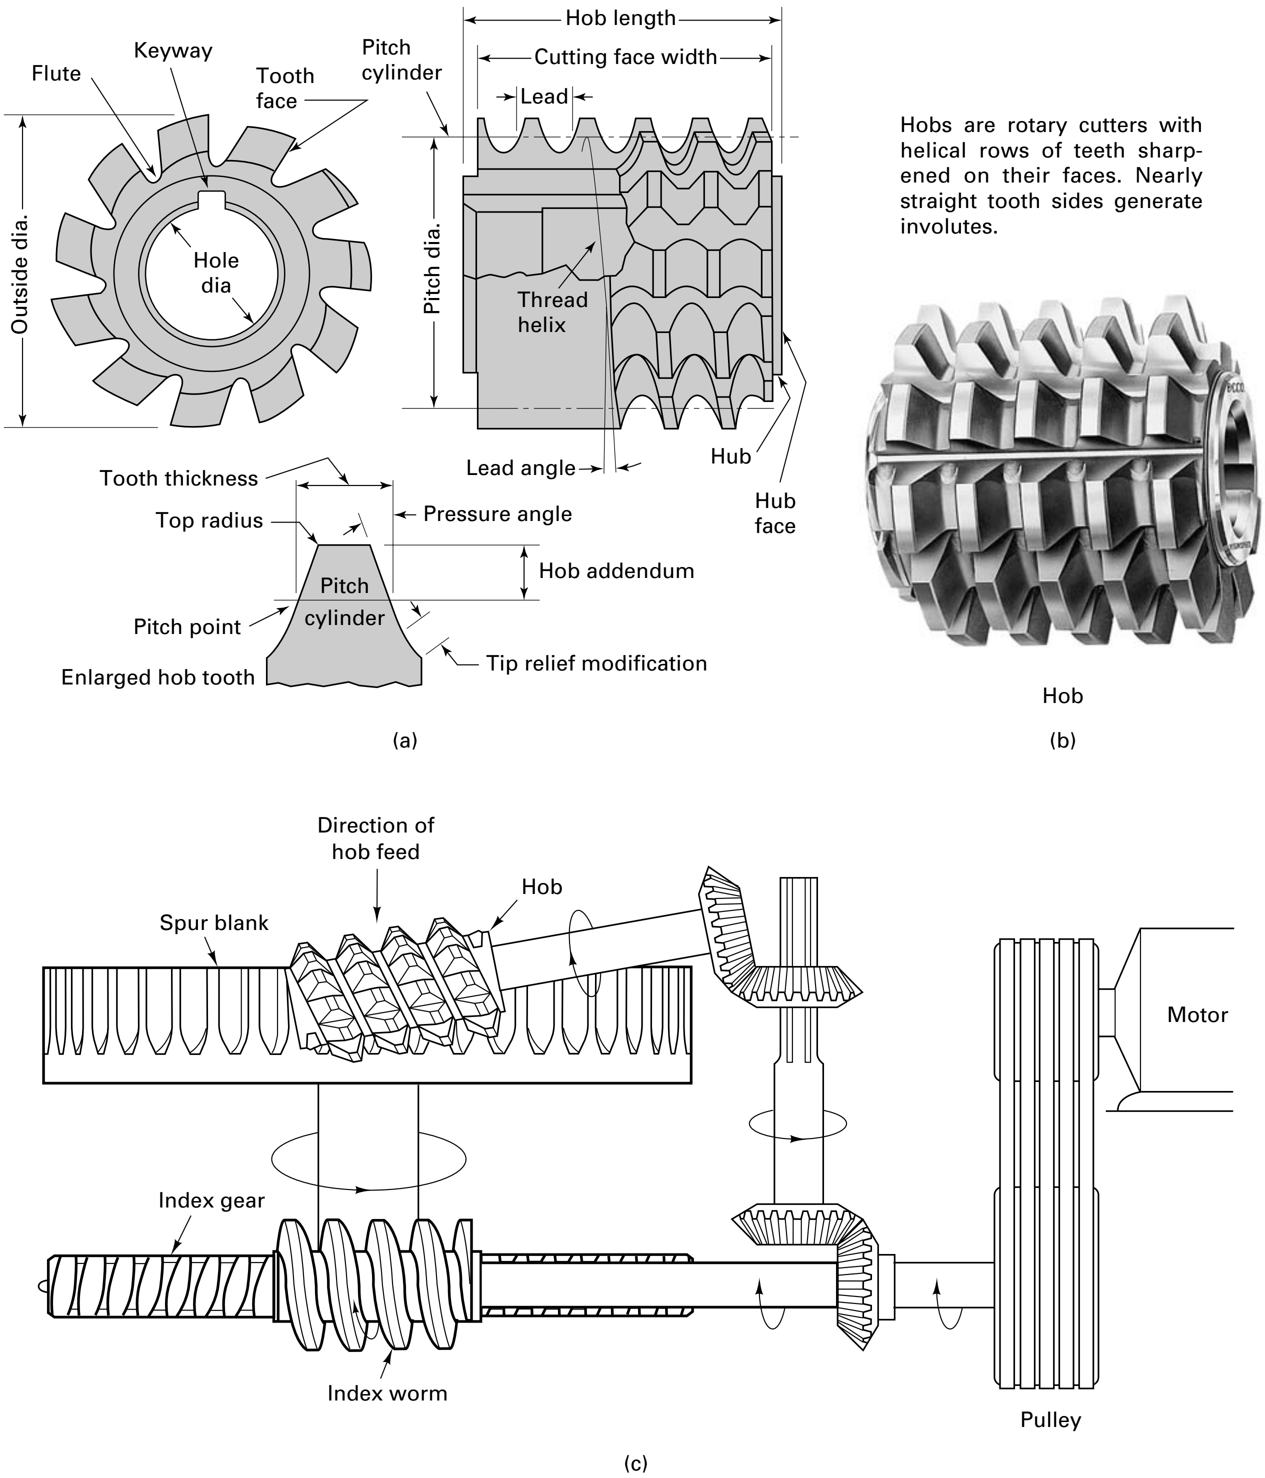
Gear-hobbing machines are made in a wide range of sizes. Machines for cutting accurate large gears are frequently housed in temperature-controlled rooms, and the temperature of the cutting fluid is controlled to avoid dimensional change due to variations in temperature.

COLD-ROLL FORMING

The manufacture of gears by *cold-roll forming* has been highly developed and widely adopted in recent years. Currently, millions of high-quality gears are produced annually by this process; many of the gears in automobile transmissions are made this way. As indicated in Figure 29-24, the process is basically the same as that by which screw threads are roll formed, except that in most cases the teeth cannot be formed in a single rotation of the forming rolls; the rolls are fed inward gradually during several revolutions.

Because of the metal flow that occurs, the top lands of roll-formed teeth are not smooth and perfect in shape; a depressed line between two slight protrusions can often be seen, as shown encircled in Figure 29-24. However, because the top land plays no part in gear-tooth action, if there is sufficient clearance in the mating gear, this causes no difficulty. Where desired, a light turning cut is used to provide a smooth top land and correct addendum diameter.

The hardened forming rolls are very accurately made, and the roll-formed gear teeth usually have excellent accuracy. In addition, because the severe cold working pro-



Hobs are rotary cutters with helical rows of teeth sharpened on their faces. Nearly straight tooth sides generate involutes.

duces tooth faces that are much smoother and harder than those on the typical machined gear, they seldom require hardening or further finishing, and they have excellent wear characteristics.

The process is rapid (up to 50 times faster than gear machining) and easily mechanized. No chips are made and thus less material is needed. Less skilled labor is required. Small gears are often made by rolling a length of shaft and then slicing off the individual gear blanks. Usually, soft steel is required and 4 to 5 in. in diameter is about the limit, with fewer than six teeth, coarser than 12 diametral pitch, and no pressure angle less than 20°.

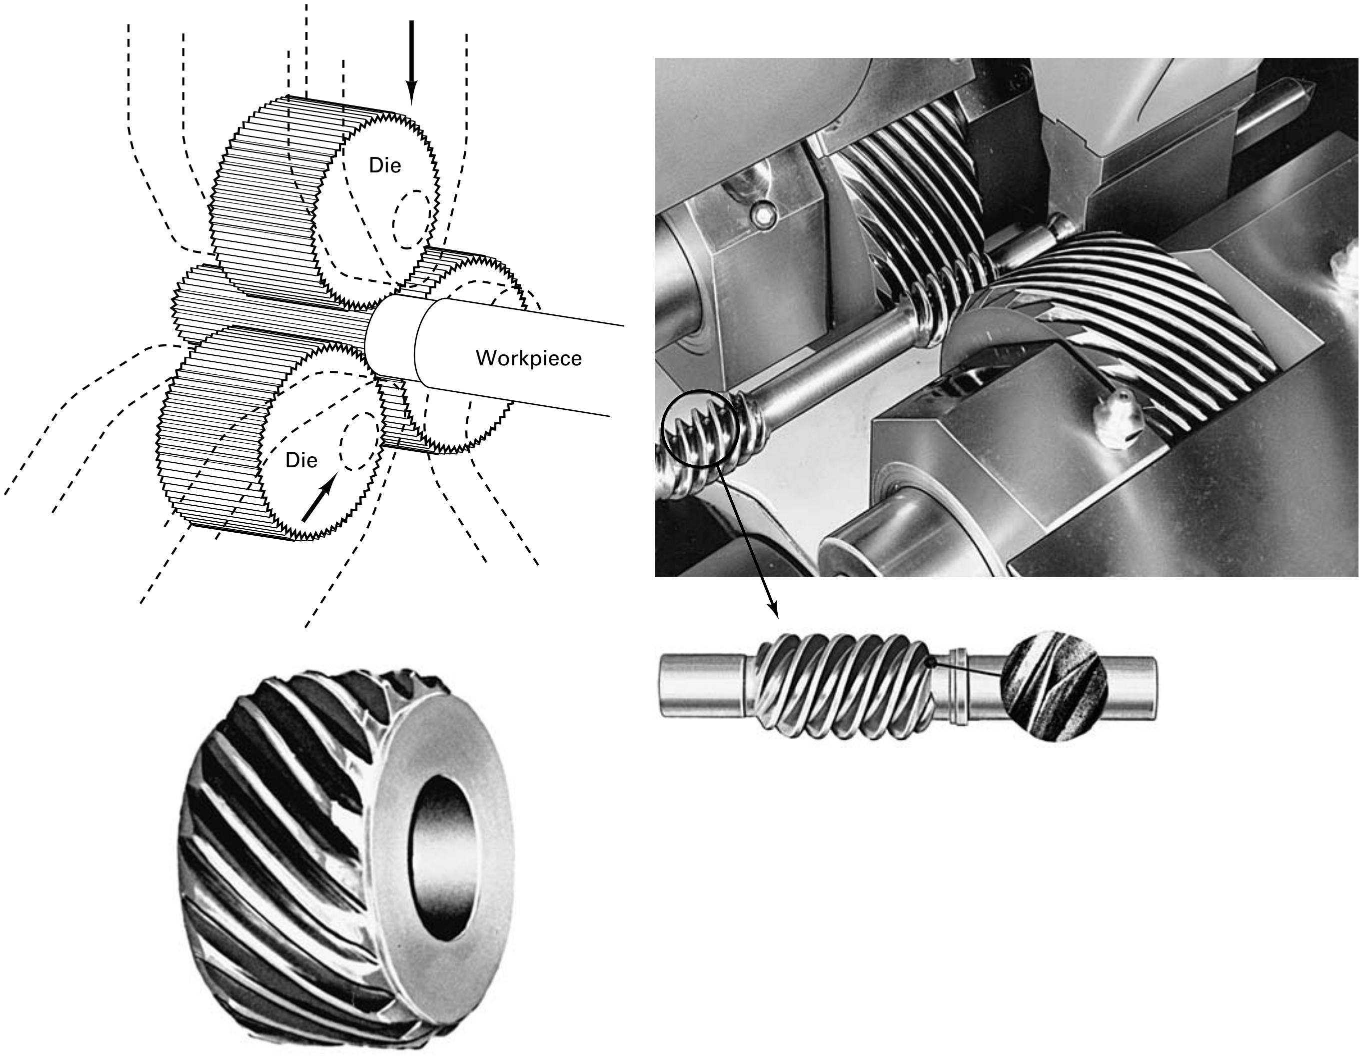

FIGURE 29-24 On the upper left, the method for cold forming gear teeth on a spline using three dies is shown. (Upper right) Worm gear being roll formed by means of two rotating rolling tools with typical worm made by rolling. (Lower left) Gear made by rolling. *(Courtesy of Landis Machine Company.)*

OTHER GEAR-MAKING PROCESSES

Gears can be made by the various casting processes. *Sand-cast gears* have rough surfaces and are not accurate dimensionally. They are used only for services where the gear moves slowly and where noise and inaccuracy of motion can be tolerated. Gears made by *die casting* are more accurate and have fair surface finish. They can be used to transmit light loads at moderate speeds. Gears made by *investment casting* may be accurate and have good surface characteristics. They can be made of strong materials to permit their use in transmitting heavy loads. In many instances, gears that are to be finished by machining are made from cast blanks, and in some larger gears the teeth can be cast to approximate shape to reduce the amount of machining.

Large quantities of gears are produced by *blanking* in a punch press. The thickness of such gears usually does not exceed about $^{1}/_{16}$ in. By shaving the gears after they are blanked, excellent accuracy can be achieved. Such gears are used in clocks, watches, meters, and calculating machines. *Fine blanking* is also used to produce thin, flat gears of good quality.

High-quality gears, both as to dimensional accuracy and surface quality, can be made by the *powder metallurgy process*. Usually, this process is employed only for small sizes, ordinarily less than 1 in. in diameter. However, larger and excellent gears are made by forging powder metallurgy preforms. This results in a product of much greater density and strength than usually can be obtained by ordinary powder metallurgy methods, and the resulting gears give excellent service at reduced cost. Gears made by this process often require little or no finishing.

Large quantities of plastic gears are made by *plastic molding*. The quality of such gears is only fair, and they are suitable only for light loads. Accurate gears suitable for heavy loads are frequently machined out of laminated plastic materials. When such gears are mated with metal gears, they have the quality of reducing noise.

Quite accurate small gears can be made by the *extrusion* process. Typically, long lengths of rod, having the cross section of the desired gear, are extruded. The individual gears are then sawed from this rod. Materials suitable for this process are brass, bronze, aluminum alloys, magnesium alloys, and, occasionally, steel.

Flame machining (oxyacetylene cutting) can be used to produce gears that are to be used for slow-moving applications wherein accuracy is not required.

A few gears are made by the hot-roll-forming process. In this process a cold master gear is pressed into a hot blank as the two are rolled together.

■ 29.11 GEAR FINISHING

To operate efficiently and have satisfactory life, gears must have accurate tooth profiles and the faces of the teeth must be smooth and hard. These qualities are particularly important when gears must operate quietly at high speeds. When they are produced rapidly and economically by most processes except cold-roll forming, the tooth profiles may not be as accurate as desired, and the surfaces are somewhat rough and subject to rapid wear. Also, it is difficult to cut gear teeth in a hardened gear blank, and therefore economy dictates that the gear be cut in a relatively soft blank and subsequently be heat treated to obtain greater hardness. Such heat treatment usually results in some slight distortion and surface roughness. Although most roll-formed gears have sufficiently accurate profiles, and the tooth faces are adequately smooth and frequently have sufficient hardness, this process is feasible only for relatively small gears. Consequently, a large proportion of high-quality gears are given some type of finishing operation after they have received primary machining or after heat treatment. Most of these finishing operations can be done quite economically because only minute amounts of metal are removed and they are fast and often automatic.

Gear shaving is the most commonly used method for finishing spur- and helical-gear teeth prior to hardening. The gear is run, at high speed, in contact with a shaving tool, usually of the type shown in Figure 29-25. Such a tool is a very accurate, hardened, and ground gear that contains a number of peripheral serrations, thus forming a series of sharp cutting edges on each tooth. The gear and shaving cutter are run in mesh with their

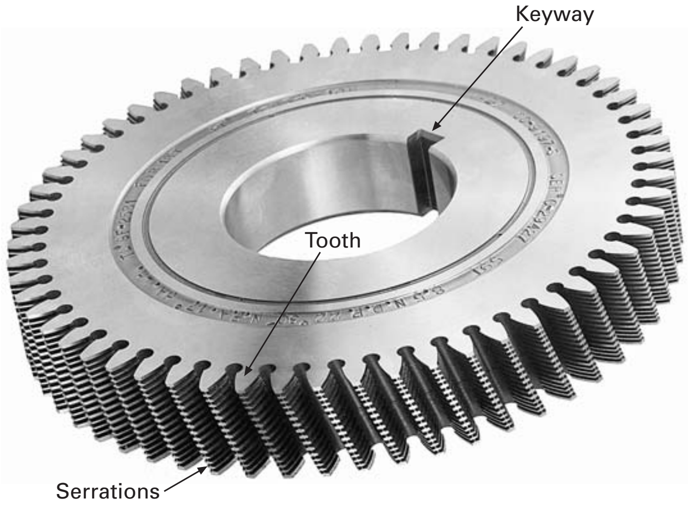

FIGURE 29-25 Rotary gear shaving cutter (see Figures 29-18 and 29-26).

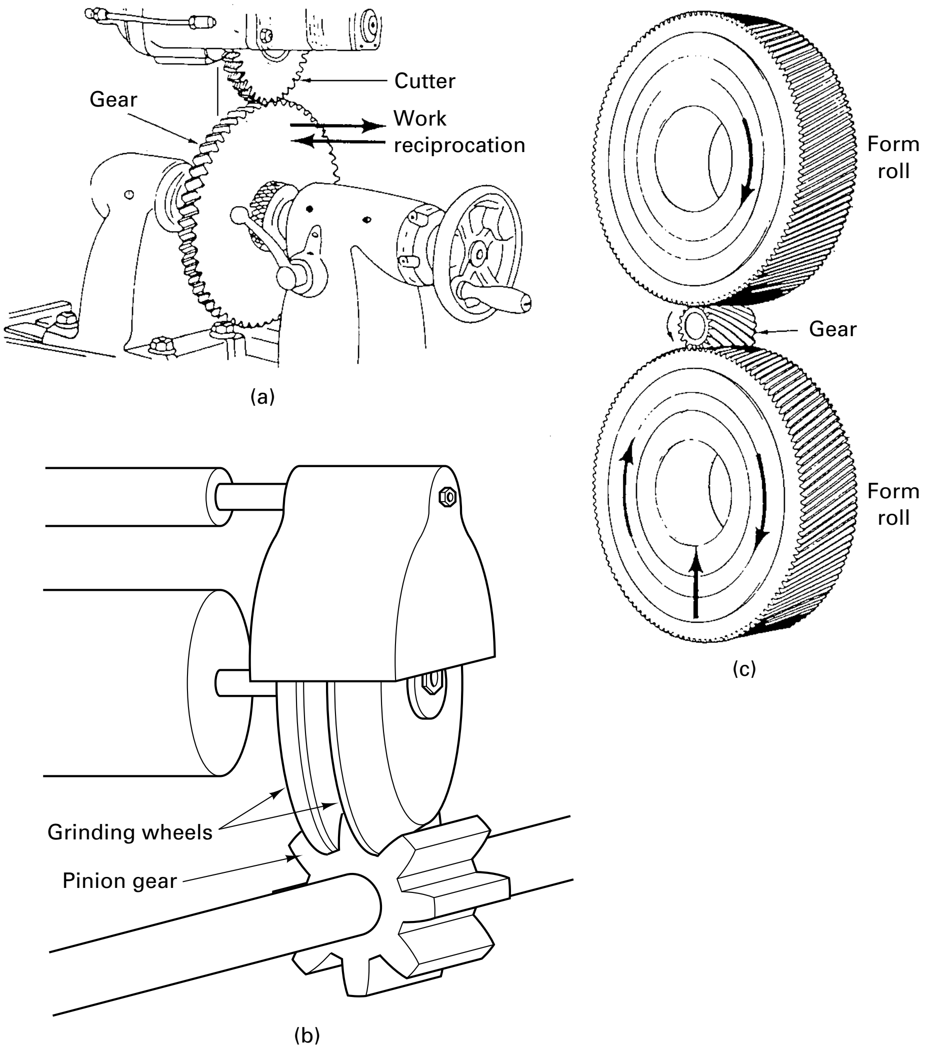

FIGURE 29-26 Three methods for gear finishing are (a) shaving using a special cutter—see Figure 29-25, (b) grinding using form grinding wheels, and (c) using form rolls, that is, roll forming/finishing.

axes crossed at a small angle, usually about 10° (Figure 29-26). As they rotate, the gear is reciprocated longitudinally across the shaving tool (or vice versa). During this action, which usually requires less than one minute, very fine chips are *shaved* from the gear-tooth faces, thus eliminating any high spots and producing a very accurate tooth profile.

Rack shaving cutters are sometimes used for shaving small gears, the cutter reciprocating lengthwise, causing the gear to roll along it, as it is moved sideways across the cutter and fed inward.

Although shaving cutters are costly, they have a relatively long life because only a very small amount of metal is removed, usually 0.001 to 0.004 in. Some gear-shaving machines produce a slight crown on the gear teeth during shaving. Some gears are not hardened prior to shaving, although it is possible to remove very small amounts of metal from hardened gears if they are not too hard. However, modern heat-treating equipment makes it possible to harden gears after shaving without harmful effects, and therefore this practice is followed if possible.

Roll finishing is a cold-forming process that is used to finish helical gears. The unhardened gear is rolled with two hardened, accurately formed rolling dies. The center distance between the dies is reduced to cold work the surfaces and produce highly accurate tooth forms. High points on the unhardened gear are plastically deformed so that a smoother surface and more accurate tooth form are achieved. Because the operation is one of localized cold working, some undesirable effects may accrue, such as localized residual stresses and nonuniform surface characteristics. Surface finishes of 6 to 8 μm have been achieved. If roll finishing is to be used, attention must be paid to the prerolled geometry. Designers should consult the manufacturers of gear-rolling machines for specific recommendations.

Grinding is used to obtain very accurate teeth on hardened gears. Two methods are used. One employs a formed grinding wheel that is trued to the exact form of a tooth by means of diamonds mounted on a special holder and guided by a large template. The other method is involute-generation grinding, which uses straight-sided grinding wheels that simulate one side of a rack tooth. The surface of the gear tooth is ground as the gear rolls (and reciprocates) past the grinding wheels. Grinding produces very accurate gears, but because it is slow and expensive, it is used only on the highest-quality, hardened gears.

Lapping can also be used for finishing hardened gears. The gear to be finished is run in contact with one or more cast iron lapping gears under a flow of very fine abrasive in oil. Because lapping removes only a very small amount of metal, it is usually employed on gears that have previously been shaved and hardened. This combination of processes produces gears that are nearly equal to ground gears in quality, but at considerably lower cost.

29.12 GEAR INSPECTION

As with all manufactured products, gears must be checked to determine whether the resulting product meets the design specifications and requirements. Because of their irregular shape and the number of factors that must be measured, inspection of gears is somewhat difficult. Among the factors to be checked are the linear tooth dimensions such as thickness, spacing, depth, and so on; tooth profile; surface roughness; and noise. Several special devices, most of them automatic or semiautomatic, are used for such inspection.

Gear-tooth vernier calipers can be used to measure the thickness of gear teeth on the pitch circle (Figure 29-27). CNC gear inspection machines (Figure 29-28) can quickly check several factors, including variations in circular pitch, involute profile, lead,

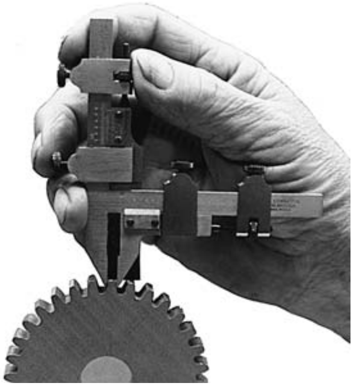

FIGURE 29-27 Using gear-tooth vernier calipers to check the tooth thickness at the pitch circle.

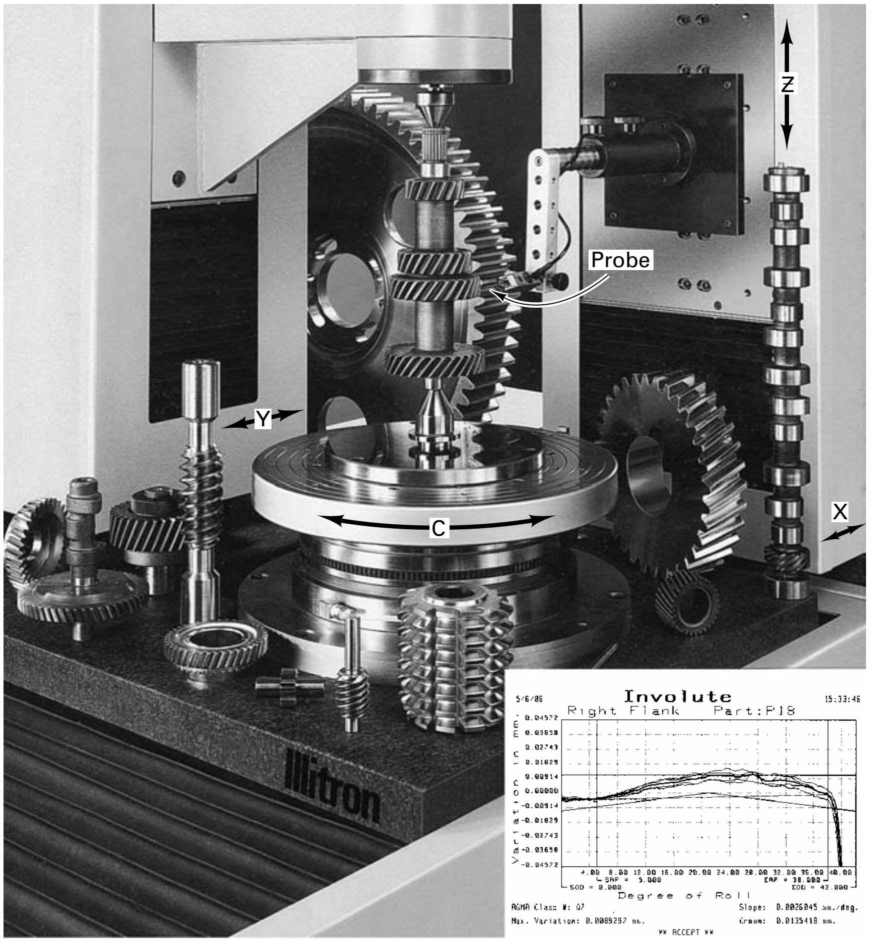

FIGURE 29-28 A CNC gear inspection machine has X, Y, Z motions plus a rotary table.

tooth spacing, and variations in pressure angle. The gear is usually mounted between centers. The probe is moved to the gear through X, Y, and Z translations. The gear is rotated between measurements. The inset in Figure 29-28 shows a typical display for an involute profile.

Because noise level is important in many applications, not only from the viewpoint of noise pollution but also as an indicator of probable gear life, special equipment for noise measurement is quite widely used, sometimes integrated into mass-production assembly lines.

■ Review Questions

1. How does the pitch diameter differ from the major diameter for a standard screw thread?
2. For what types of threads are the pitch and the lead the same?
3. What is the helix angle of a screw thread?
4. Why are pipe threads tapered?
5. What are three basic methods by which external threads are produced?
6. Explain the meaning of $^{1}/_{4}{}''$ -20 UNC-3A.
7. What is meant by the designation M20 x 2.5 6g6g? (What does the “x” mean?)
8. What are two reasons fine-series threads are being used less now than in former years?
9. In cutting a thread on a lathe, how is the pitch controlled?
10. What is the function of a threading dial on a lathe?
11. In Chapter 22, what figure(s) showed a threading dial?
12. What controls the lead of a thread when it is cut by a threading die?
13. What is the basic purpose of a self-opening die head?
14. What is the reason for using a taper tap before a plug tap in tapping a hole?
15. What difficulties are encountered if full threads are specified to the bottom of the dead-end hole?
16. Can a fluteless tap be used for threading a hole in gray cast iron? Why or why not?
17. What provisions should a designer make so that a dead-end hole can be threaded?
18. What is the major advantage of a spiral-point tap?
19. Can a fluteless tap be used for threading to the bottom of a dead-end hole? Why or why not?
20. Is it desirable for a tapping fluid to have lubricating qualities? Why?
21. How does thread milling differ from thread turning?
22. What are the advantages of making threads by grinding?
23. Why has thread rolling become the most commonly used method for making threads?
24. How can you determine whether a thread has been produced by rolling rather than by cutting?
25. Why is the involute form used for gear teeth?
26. What is the diametral pitch of a gear?
27. What is the relationship between the diametral pitch and the module of a gear?
28. On a sketch of a gear, indicate the pitch circle, addendum circle, dedendum circle, and circular pitch.
29. What five requirements must be met for gears to operate satisfactorily? Which of these are determined by the manufacturing process?
30. What are the advantages of helical gears compared with spur gears?
31. What is the principal disadvantage of helical gears?
32. What difficulty would be encountered in hobbing a herringbone gear?
33. What is the only type of machine on which full-herringbone gears can be cut?
34. What modification in design is made to herringbone gears to permit them to be cut by hobbing?
35. Why aren’t more gears made by broaching?
36. What is the most important property of a crown gear?
37. What are three basic processes for machining gears?
38. Which basic gear-machining process is utilized in a Fellows gear shaper?
39. When a helical gear is machined on a milling machine, the table lead screw and the universal dividing head have to be connected by a gear train. Why?
40. Why is a gear-hobbing machine much more productive than a gear shaper?
41. In gear shaping and gear hobbing, the tooth profiles are generated. What does that mean?
42. What are the advantages of cold-roll forming for making gears?

43. Why is cold-roll forming not suitable for making gray cast iron gears?
44. Under what conditions can shaving not be used for finishing gears?
45. What inherent property accrues from cold-roll forming of gears that may result in improved gear life?
46. Can lapping be used to finish cast iron gears?
47. What factors are usually checked in inspecting gears?
48. What are the basic methods for gear finishing?

Problems

1. Calculate the cutting time needed to tap a $^3/_4$-in.-diameter by 2-in.-deep hole using a cutting speed of 30 sfpm. The tap has 10 tpi.
2. The new manufacturing manager has recommended to you that chipless tapping be adopted for tapping holes in the deep, dead-end holes on the 2-cylinder engine blocks that the company makes. Chipless tapping can run at twice the speed of the conventional tapping process, works well on deep holes, and provides better quality and finish with longer tool life. The tapping process is the bottleneck process in machining all the cast iron engine blocks. In addition, 10% of the blocks have to be scrapped due to broken taps. What do you recommend?
3. A hob that has a pitch diameter of 76.2 mm is used to cut a gear having six teeth. If a cutting speed of 27.4 m/min is used, what will be the rpm value of the gear blank?
4. In Figure 29-19 a form-milling operation and cutters are shown. The gear is to be made from 4340 steel, R_c 50 prior to heat treat and final grind. Select the proper speeds and feeds for the job (the cutter is 4 in. in diameter) and compute the cutting time to mill this gear. Would you use up milling versus down milling?
5. A gear-broaching machine of the type shown in Figure 29-20 can do the gear in 15 seconds (about 240 parts per hour). How many additional gears per year are needed to cover the broaching tooling cost if each broach on the machine cost \$250? Do you think the broach tool life is sufficient to handle that number of parts? What about TiN coating the broaches (cost \$10.00 per broach)?
6. Assume that 10,000 spur gears, $1^1/_8$ in. in diameter and 1 in. thick, are to be made of 70-30 brass. What manufacturing method would you consider?
7. If only three gears described in problem 6 were to be made, what process would you select?
8. K.C. Stern, a design engineer for Boeing Commercial Airplane Group, is doing some design work and has a question regarding the hole size that is drilled before tapping internal threads. The book states, “A hole diameter slightly larger than the minor diameter of the thread must already exist, made by drilling/reaming, boring, or die casting.”

   Conventional wisdom would lead one to believe that a hole slightly smaller should exist before tapping threads. The *Machinery’s Handbook* seems to agree with this. Most tap drill sizes listed are smaller than the minimum minor diameter listed for a particular thread size in MIL-S-008879B. K.C. has found at least one exception to this, but the difference was only a couple of thousandths of an inch.

   K.C. consulted local sources on this matter, but no one would commit to the correctness or incorrectness of the book. A number of people are scratching their heads on this one. Your assistance in this matter is greatly appreciated. Should the hole be slightly smaller or slightly larger than the minor diameter of the thread and why?

www.wiley.com/college/degarmo

Chapter 29 CASE STUDY

Bevel Gear for a Riding Lawn Mower

Figure CS 29 is a bevel gear for the transaxle of a heavy duty riding lawn mower. The gear has an outer diameter of 3.50 inches and a maximum thickness of 1/2 inch. At the root of the teeth, the thickness is approximately 3/16 inch. The minimum material properties have been estimated to be a yield strength of 125 ksi and a surface hardness of Rockwell C 25. The maximum operating temperature should be less than 250°F.

Since the mower has a multi speed transmission, the transaxle gearing may be subject to sudden applications of load due to improper engagement of the clutch. The manufacturer has proposed a nonstandard test in which a 10 pound weight is dropped onto the gear from a height of 15 inches. While this does not translate to a Charpy test value, it is clear that impact resistance will be an important property.

The gear will operate in an oil-filled enclosure so corrosion resistance need not be outstanding. A smooth surface finish is desirable (especially on the teeth), and the total production run has been placed between 25,000 and 50,000 units.

1. Based on the size and shape of the product, describe at least three reasonable ways in which the component could be produced. For each method, briefly discuss its relative pros and cons.
2. What type of engineering materials might be able to meet the desired requirements? What would be the pros and cons of each general family?
3. For each of the shape generation methods in part 1, select an appropriate material from the alternatives discussed in part 2. (Note: Casting alloys should be matched for the casting processes, high machinability alloys would be favored for cutting applications, etc.).
4. Which of the above alternatives do you feel would be the "best" solution to the problem? Why? For this system, outline the specific steps that would be necessary to produce the part from reasonable starting material. Include any necessary heat treatments and/or surface treatments.
5. Your supervisor has asked you to evaluate the possibility of producing this part as a near net shape ferrous forging, with forged gear teeth. Investigate this process and determine if it would be a feasible approach. If so, would you recommend that the forging be performed cold, warm, or hot? Would subsequent heat treatment or surface treatment be required? What concerns might be associated with these processes?

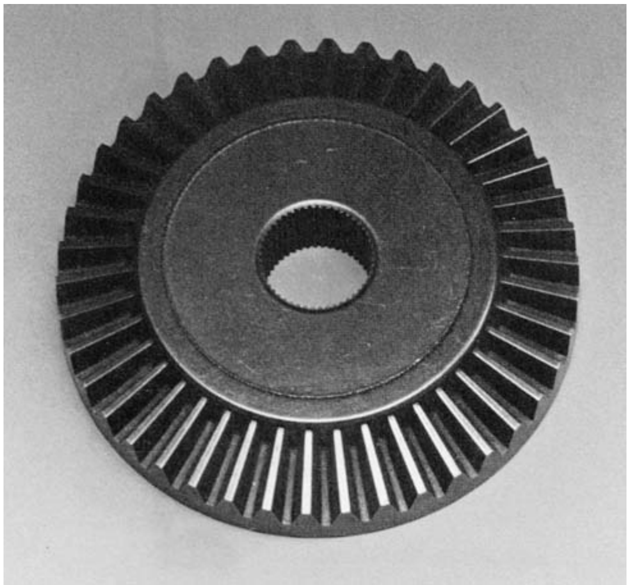

Figure CS 29

CHAPTER 30

FUNDAMENTALS OF JOINING

30.1 INTRODUCTION TO CONSOLIDATION PROCESSES

Large-size products, products with a high degree of shape complexity, or products with a wide variation in required properties are often manufactured as joined assemblies of two or more component pieces. These pieces may be smaller and therefore easier to handle, simpler shapes that are easier to manufacture, or segments that have been made from different materials. Assembly is an important part of the manufacturing process, and a wide variety of *consolidation processes* have been developed to meet the various needs.

Each of the methods has its own distinctive characteristics, strengths, and weaknesses. The metallurgical processes of welding, brazing, and soldering are usually used to join metals and often involve the solidification of molten material. The use of discrete fasteners (such as nuts, bolts, screws, and rivets) requires the creation of aligned holes and produces stress localization. While the holes may affect performance, disassembly and reassembly can often be performed with relative ease. Adhesive bonding has grown with new developments in polymeric materials and is being used extensively in automotive and aircraft production. Any material can be joined to any other material, and low-temperature joining is particularly attractive for composite materials. Production rates are often low, however, because of the time required for the adhesive to develop full strength. Lesser known joining techniques include shrink fits, slots and tabs, and a wide variety of other mechanical methods. From a technical viewpoint, powder metallurgy is another consolidation process, since the end product is built up by the joining of a multitude of individual particles.

Our survey of consolidation processes will begin with a spectrum of techniques known by the generic term of *welding*. Welding is the permanent joining of two materials, usually metals, by *coalescence*, which is induced by a combination of temperature, pressure, and metallurgical conditions. The particular combination of these variables can range from high temperature with no pressure to high pressure with no increase in temperature. Because welding can be accomplished under a wide variety of conditions, a number of different processes have been developed. Welding is the dominant method of joining in manufacturing, and a large fraction of metal products would have to be drastically modified if welding were not available.

Coalescence between two metals requires sufficient proximity and activity between the atoms of the pieces being joined to cause the formation of common crystals. The ideal metallurgical bond, for which there would be no noticeable or detectable interface, would require (1) perfectly smooth, flat, or matching surfaces; (2) surfaces that are clean and free from oxides, absorbed gases, grease, and other contaminants; (3) metals with no internal impurities; and (4) the joining of single crystals with identical crystallographic structure and orientation. These conditions would be difficult to obtain under laboratory conditions and are virtually impossible to achieve in normal production. Consequently, the various joining methods have been designed to overcome or compensate for the common deficiencies.

Surface roughness can be overcome either by force, causing plastic deformation and flattening of the high points, or by melting the two surfaces so that fusion occurs. The various processes also employ different approaches to cleaning the metal surfaces prior to welding and preventing further oxidation or contamination during the joining process. In solid-state welding, contaminated layers are generally removed by mechanical or chemical cleaning prior to welding or by causing sufficient metal flow along the interface so that new surface is created and existing impurities are displaced from the joint. In *fusion welding*, where molten material is produced and high temperatures accelerate the reactions between the metal and its surroundings, contaminants are often removed from the pool of molten metal through the use of fluxing agents. If welding is performed in a vacuum, the contaminants are removed much more easily, and coalescence is easier to achieve. In the vacuum of outer space, mating parts may weld under extremely light loads, even when welding is not intended.

When the process requires heat that is sufficient to induce melting, the structure of the metal may be significantly altered. Even when no melting occurs, the heating and cooling of the welding process can affect the metallurgical structure and quality of both the weld and the adjacent material. Since many of the changes are detrimental, the possible consequences of heating and cooling should be a major consideration when selecting a joining process.

To produce a high-quality weld, we will need (1) a source of satisfactory heat and/or pressure, (2) a means of protecting or cleaning the metals to be joined, and (3) caution to avoid, or compensate for, harmful metallurgical effects. These aspects will be developed in the sections that follow.

30.2 CLASSIFICATION OF WELDING AND THERMAL CUTTING PROCESSES

Wherever possible, this text will utilize the nomenclature of the American Welding Society (AWS). The various welding processes have been classified in the manner presented in Figure 30-1, and letter symbols have been assigned to facilitate process designation. The variety of processes provide multiple ways of achieving coalescence and make it possible to produce effective and economical welds in nearly all metals and combinations of metals. Chapter 31 will present the gas and arc welding processes; Chapter 32 will cover resistance and solid-state welding; and Chapter 33 will present a variety of other processes, including brazing and soldering.

For many years, welding equipment (such as oxyfuel torches and electric arc units) has also been used to cut metal sheets and plates. Developed originally for salvage and repair work, then used for preparing plates for welding, this type of equipment is now widely used to cut sheets and plates into desired shapes for a variety of uses and operations. Laser- and electron-beam equipment can now cut both metals and nonmetals at speeds up to 25 m/min (1000 in./min), with accuracies of up to 0.25 mm (0.01 in.). Figure 30-2 summarizes the commonly used *thermal cutting* processes and provides their AWS designations. Since cutting is often an adaptation of welding, the welding and cutting capabilities will be presented together as the individual processes are discussed.

30.3 SOME COMMON CONCERNS

Many of the problems that are inherent to welding and joining can be avoided by selecting the proper process and considering both general and process-specific characteristics and requirements. Proper design of the joint is extremely critical. Heating, melting, and resolidification can produce drastic changes in the properties of base and

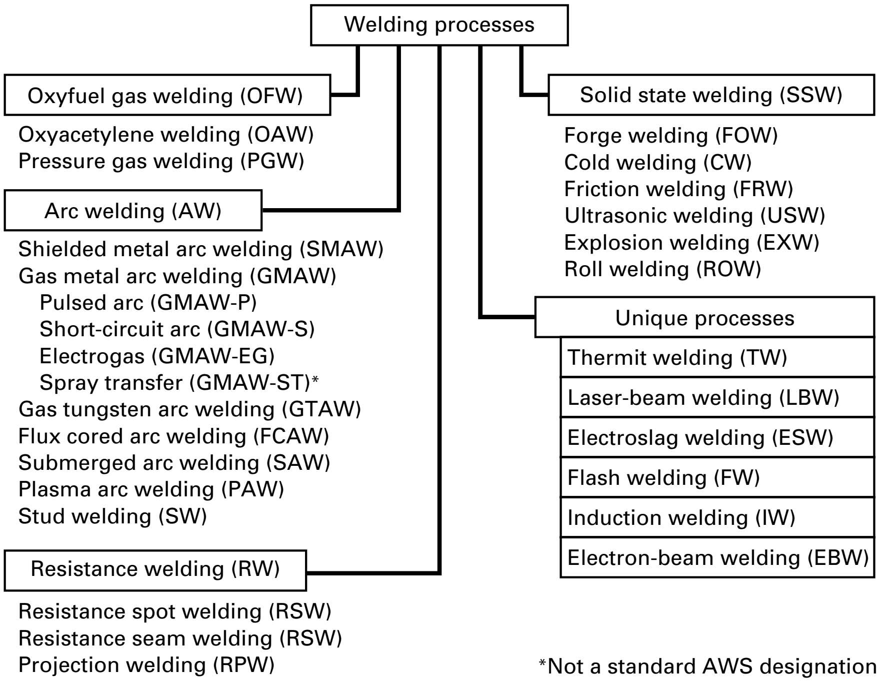

FIGURE 30-1 Classification of common welding processes along with their AWS (American Welding Society) designations.

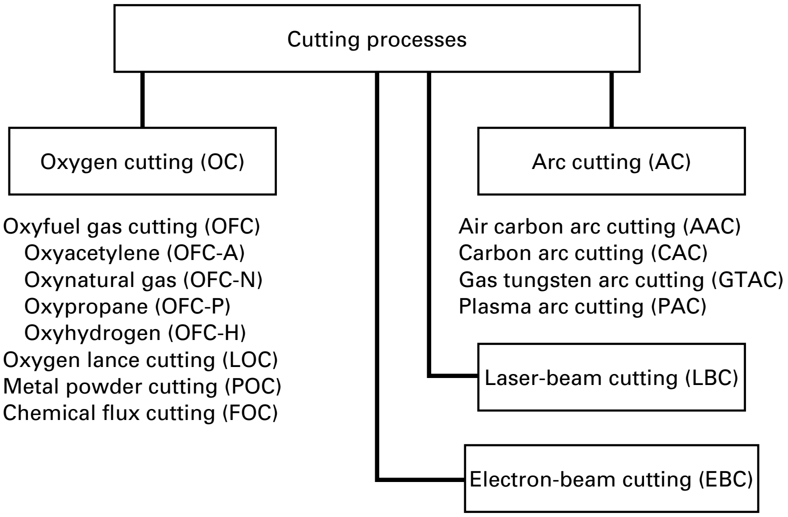

FIGURE 30-2 Classification of thermal cutting processes along with their AWS (American Welding Society) designations.

filler materials. Weld metal properties can also be changed by dilution of the filler by melted base metal, vaporization of various alloy elements, and gas–metal reactions.

Various types of weld defects can also be produced. These include cracks in various forms, cavities (both gas and shrinkage), inclusions (slag, flux, and oxides), *incomplete fusion* between the weld and base metals, *incomplete penetration* (insufficient weld depth), unacceptable weld shape or contour, arc strikes, spatter, undesirable metallurgical changes (aging, grain growth, or transformations), and excessive distortion. Figure 30-3 depicts several of these defects.

■ 30.4 TYPES OF FUSION WELDS AND TYPES OF JOINTS

Figure 30-4 illustrates four basic types of fusion welds. *Bead welds*, or surfacing welds, are made directly onto a flat surface and therefore require no edge preparation. Since the penetration depth is limited, bead welds are used primarily for joining thin sheets of metal, building up surfaces, and depositing hard-facing (wear-resistant) materials.

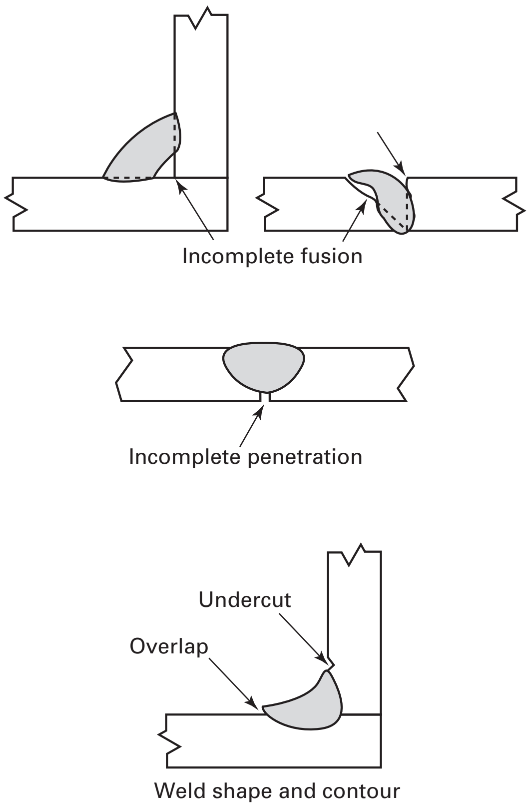

FIGURE 30-3 Some common welding defects.

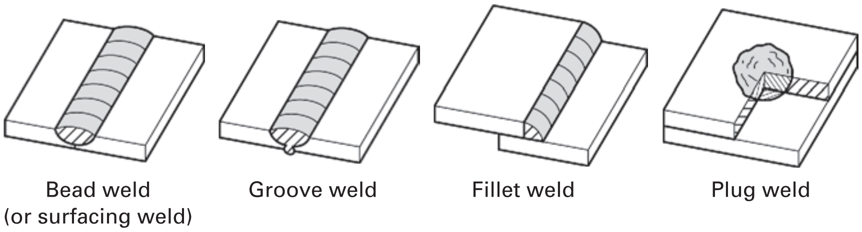

FIGURE 30-4 Four basic types of fusion welds.

Groove welds are used when full-thickness strength is desired on thicker material. Some sort of edge preparation is required to form a groove between the abutting edges. V, double-V (top and bottom), U, and J (one-sided V) configurations are most common and are often produced by oxyacetylene flame cutting. The specific type of groove usually depends upon the thickness of the joint, the welding process to be employed, and the position of the work. The objective is to obtain a sound weld throughout the full thickness with a minimum amount of additional weld metal. If possible, single-pass welding is preferred, but multiple passes may be required, depending upon the thickness of the material and the welding process being used. As shown in Figure 30-5, special consumable *inserts* can be used to ensure proper spacing between the mating edges and good quality in the root pass. These inserts are particularly useful in pipeline welding and other applications where welding must be performed from only one side of the work.

Fillet welds are used for tee, lap, and corner joints and require no special edge preparation. The size of the fillet is measured by the leg of the largest 45° right triangle that can be inscribed within the contour of the weld cross section. This is shown in

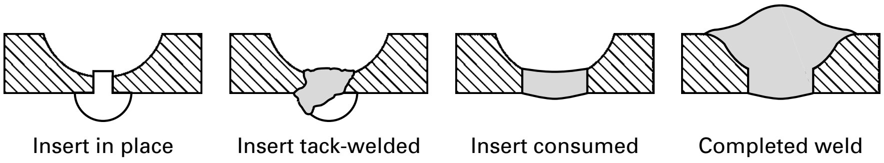

FIGURE 30-5 The use of a consumable backup insert in making a fusion weld. *(Courtesy Arcos Industries, Mount Carmel, PA).*

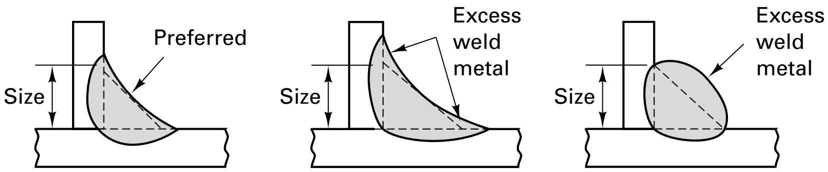

FIGURE 30-6 Preferred shape and the method of measuring the size of fillet welds.

Figure 30-6, which also depicts the proper shape for fillet welds to avoid excess metal deposition and reduce stress concentration.

Plug welds attach one part on top of another and are often used to replace rivets or bolts. A hole is made in the top plate and welding is started at the bottom of this hole.

Figure 30-7 shows five basic types of joints (*joint configurations*) that can be made with the use of bead, groove, and fillet welds, and Figure 30-8 shows some of the methods to construct these joints. In selecting the type of joint to be used, a primary consideration should be the type of loading that will be applied. A large portion of what are erroneously called "welding failures" can more accurately be attributed to inadequate consideration of loading. Cost and accessibility for welding are other important factors when specifying joint design but should be viewed as secondary to loading. Cost is affected by the amount of required edge preparation, the amount of weld metal that must be deposited, the type of equipment that must be used, and the speed and ease with which the welding can be accomplished.

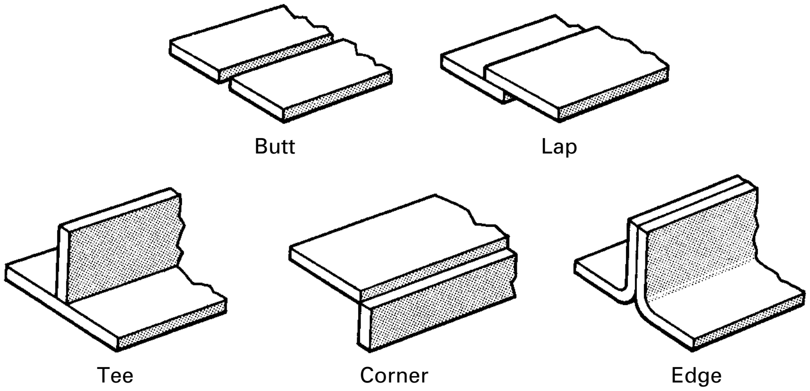

FIGURE 30-7 Five basic joint designs for fusion welding.

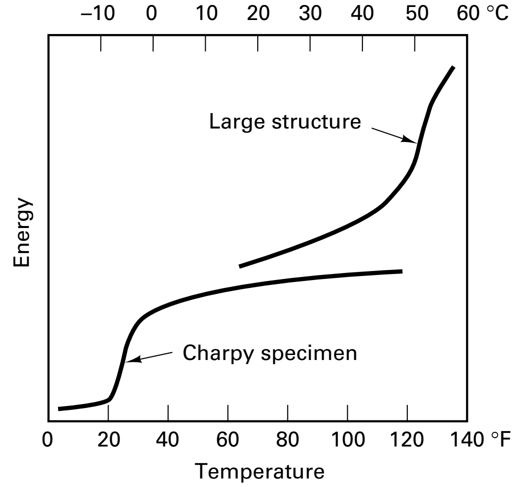

FIGURE 30-9 Effect of size on the transition temperature and energy-absorbing ability of a certain steel. While the larger structure absorbs more energy because of its size, it becomes brittle at a much higher temperature.

30.5 DESIGN CONSIDERATIONS

Welding is a unique process that cannot be directly substituted for other methods of joining without proper consideration of its particular characteristics and requirements. Unfortunately, welding is also easy and convenient, and the considerations of proper design and implementation are often overlooked.

One very important fact is that welding produces *monolithic*, or one-piece, structures. When two pieces are welded together, they become one continuous piece. This can cause significant complications. For example, a crack in one piece of a multipiece structure may not be catastrophic, because it will seldom progress beyond the single piece in which it occurs. However, when a large structure, such as a ship hull, pipeline, storage tank, or pressure vessel, consists of many pieces welded together, a crack that starts in a single plate or weld can propagate for a great distance and cause complete failure. Obviously, this kind of failure is not the fault of the welding process itself but is simply a reflection of the monolithic nature of the product.

It is also important to note that a given material in small pieces may not behave as it does in a larger size. This feature is clearly illustrated in Figure 30-9, which shows the relationship between the energy required to fracture and temperature for the same steel tested as a small Charpy impact specimen (see Chapter 2 and Figure 2-20) and as a large, welded structure. In the form of a small Charpy bar, the material exhibits ductile behavior and good energy absorption at temperatures down to 25°F (4°C). When welded into a large structure, however, brittle behavior is observed at temperatures as high as 110°F (43°C). More than one welded structure has failed because the designer overlooked the effect of size on the notch-ductility of metal.

Another common error is to make welded structures too rigid, thereby restricting their ability to redistribute high stresses and avoid failure. Considerable thought may be required to design structures and joints that provide sufficient flexibility, but the multitude of successful welded structures attests to the fact that such designs are indeed possible.

Accessibility, welding position, component match-up, and the specific nature of a joint are other important considerations in welding design.

30.6 HEAT EFFECTS

WELDING METALLURGY

Heating and cooling are essential and integral components of almost all welding processes and tend to produce metallurgical changes that are often undesirable. In *fusion welding*, the heat is sufficient to melt some of the *base metal*, and this is often followed by a rapid cooling. Thermal effects tend to be most pronounced for this type of welding, but they also exist to a lesser degree in processes where the heating–cooling cycle is less severe. If the thermal effects are properly considered, adverse results can usually be avoided or

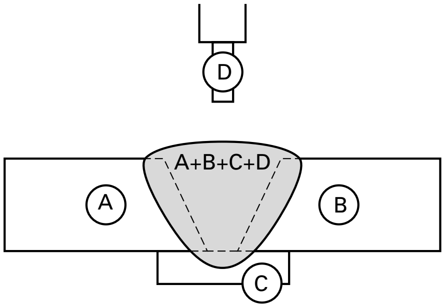

FIGURE 30-10 Schematic of a butt weld between a plate of metal A and a plate of metal B, with a backing plate of metal C and filler of metal D. The resulting weld nugget becomes a complex alloy of all four metals.

minimized, and excellent service performance can be obtained. If they are overlooked, however, the results can be disastrous.

Because such a wide range of metals are welded and a variety of processes are used, welding metallurgy is an extensive subject, and the material presented here serves only as an introduction. In fusion welding, a pool of molten metal is created, with the molten metal coming from either the parent plate alone (*autogenous welding*) or a mixture of parent and filler material. Figure 30-10 shows a butt weld between plates of material A and material B. A backing strip of material C is used with filler metal of material D. In this situation, the molten pool is actually a complex alloy of all four materials. The molten material is held in place by a metal "mold" formed by the surrounding solids. Since the molten pool is usually small compared to the surrounding metal, fusion welding can often be viewed as *a small metal casting in a large metal mold*. The resultant structure and its properties can be best understood by first analyzing the casting and then considering the effects of the associated heat on the adjacent base material.

Figure 30-11 shows a typical microstructure produced by a fusion weld. In the center of the weld is a region composed of metal that has solidified from the molten state. The material in this *weld pool*, or *fusion zone*, is actually a mixture of parent metal and electrode or filler metal, with the ratio depending upon the particular process, the type of joint, and the edge preparation. Figure 30-12 compares two butt-weld designs, where the weld pool in the upper design would contain a large percentage of base metal and the weld pool in the lower design would be largely filler material. The metal in the fusion zone is cast material with a microstructure reflecting the cooling rate of the weld. This region cannot be expected to have the same properties and characteristics as the wrought material being welded, since their processing histories and resulting structures

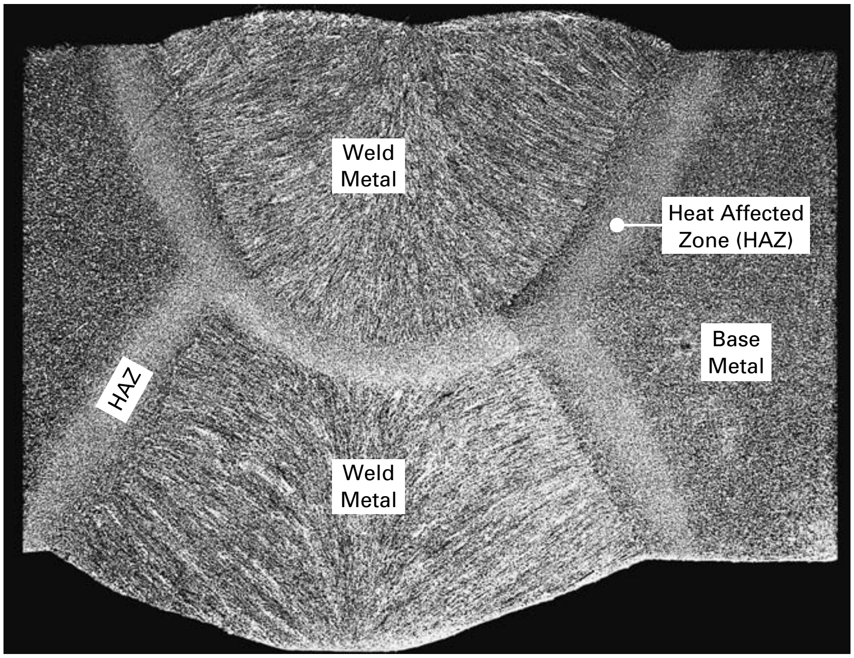

FIGURE 30-11 Grain structure and various zones in a fusion weld.

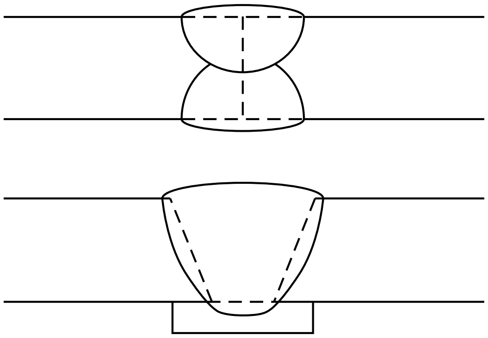

FIGURE 30-12 Comparison of two butt-weld designs. In the top weld, a large percentage of the weld pool is base metal. In the bottom weld, most of the weld pool is filler metal.

are usually different. Adequate mechanical properties, therefore, can only be achieved by selecting filler rods or electrodes, which have properties *in their as-deposited condition* that equal or exceed those of the wrought parent metal. It is not uncommon, therefore, for the filler metal to have a different chemistry from the metal being welded. The grain structure in the fusion zone may be fine or coarse, equiaxed or dendritic, depending upon the type and volume of weld metal and the rate of cooling, but most electrode and filler rod compositions tend to produce fine, equiaxed grains. The matching or exceeding of base metal strength, in the as-solidified condition, is the basis for several AWS specifications for electrodes and filler rods.

The pool of molten metal created by fusion welding is prone to all of the problems and defects associated with metal casting, such as gas porosity, inclusions, blowholes, cracks, and shrinkage. Since the amount of molten metal is usually small compared to the total mass of the workpiece, rapid solidification and rapid cooling of the solidified metal are quite common. Associated with these conditions may be the entrapment of dissolved gases, chemical segregation, grain size variation, grain shape problems, and orientation effects.

Adjacent to the fusion zone, and wholly within the base material, is the ever-present and generally undesirable *heat-affected zone (HAZ)*. In this region, the parent metal has not melted but has been subjected to elevated temperatures for a brief period of time. Since the temperature and its duration vary widely with location, fusion welding might be more appropriately described as "a metal casting in a metal mold, coupled with an abnormal and widely varying heat treatment." The adjacent metal may experience sufficient heat to bring about structure and property changes, such as phase transformations, recrystallization, grain growth, precipitation or precipitate coarsening, embrittlement, or even cracking. The variation in thermal history can produce a variety of microstructures and a range of properties. In steels, the structures can range from hard, brittle martensite all the way through coarse pearlite and ferrite.

Because of its altered structure, the heat-affected zone may no longer possess the desirable properties of the parent material, and since it was not melted, it cannot assume the properties of the solidified weld metal. Consequently, this is often the weakest area in the as-welded joint. Except where there are obvious defects in the weld deposit, most welding failures originate in the heat-affected zone. This region extends outward from the weld to the location where the base metal has experienced too little heat to be affected or altered by the welding process. Figure 30-13 presents a schematic of a fusion weld in steel, using standard terminology for the various regions and interfaces. Part of the heat-affected zone has been heated above the A_1 transformation temperature and could assume a totally new structure through phase transformation. The lower-temperature portion of the heat-affected zone (peak temperatures below the A_1 value) can experience diffusion-induced changes within the original structure.

Because of the melting, solidification, and exposure to a range of high temperatures, the structure and properties of welds can be extremely complex and varied. Through proper concern, however, associated problems can often be reduced or totally eliminated. Consideration should first be given to the thermal characteristics of the various processes. Table 30-1 classifies some of the more common welding processes with regard to their *rate of heat input*. Processes with low rates of heat input (slow heating) tend to produce large total heat content within the metal, slow cooling rates, large heat-affected zones, and

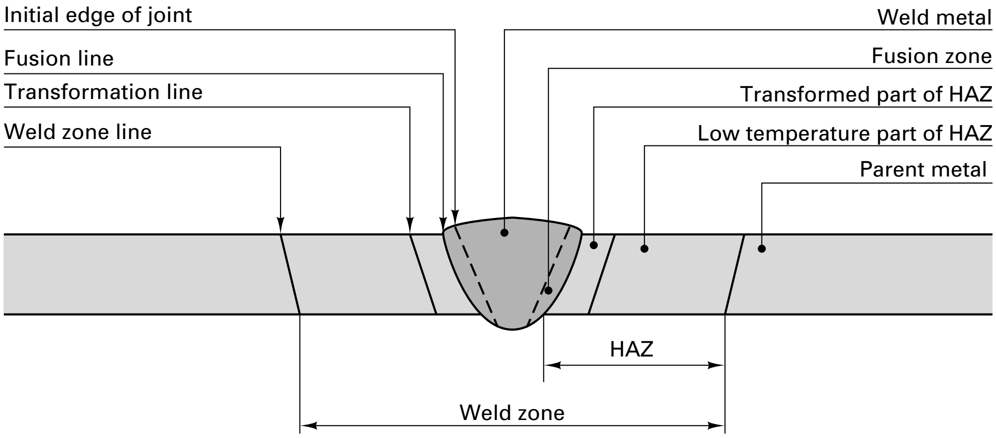

FIGURE 30-13 Schematic of a fusion weld in steel, presenting proper terminology for the various regions and interfaces. Part of the heat-affected zone has been heated above the transformation temperature and will form a new structure upon cooling. The remaining segment of the heat-affected zone experiences heat alteration of the initial structure. *(Courtesy Sandvik AB, Sandviken, Sweden)*

TABLE 30-1 Classification of Common Welding Processes by Rate of Heat Input

Low Rate of Heat Input	High Rate of Heat Input
Oxyfuel welding (OFW)	Plasma arc welding (PAW)
Electroslag welding (ESW)	Electron-beam welding (EBW)
Flash welding (FW)	Laser welding (LBW)
	Spot and seam resistance welding (RW)
	Percussion welding
Moderate Rate of Heat Input	
Shielded metal arc welding (SMAW)	
Flux cored arc welding (FCAW)	
Gas metal arc welding (GMAW)	
Submerged arc welding (SAW)	
Gas tungsten arc welding (GTAW)	

resultant structures with lower strength and hardness, but higher ductility. High-heat-input processes, on the other hand, have low total heats, fast cooling rates, and small heat-affected zones. The size of the heat-affected zone will also increase with increased starting temperature, decreased welding speed, increased thermal conductivity of the base metal, and a decrease in base metal thickness. Weld geometry is also important, with fillet welds producing smaller heat-affected zones than butt welds.

If the as-welded properties are unacceptable, the entire welded assembly might be heat treated after welding. Structure variations can be reduced or eliminated, but the results are restricted to those that can be produced through heat treatment. The structures and properties associated with cold working, for example, could not be achieved. In addition, problems may be encountered in trying to achieve controlled heating and cooling (heat treatment) within the large, complex-shaped structures commonly produced by welding. Moreover, furnaces, quench tanks, and related equipment may not be available to handle the full size of welded assemblies.

An alternative technique to reduce microstructural variation, or the sharpness of that variation, is to *preheat* either the entire base metal or material at least 10 centimeters (4 inches) on either side of the joint just prior to welding. This heating serves to reduce the cooling rate of both the weld deposit and the immediately adjacent metal in the heat-affected zone. The slower cooling produces a softer, more ductile structure and provides more time for the out-diffusion of harmful dissolved hydrogen. The welding stresses are distributed over a larger area, reducing the amount of weld distortion and the possibility of cracking. Preheating is more common with alloy steels and thicker sections, and it is particularly important with the high-thermal-conductivity metals, such as copper and aluminum, where the cooling rate would otherwise be extremely rapid.

If the carbon content of plain carbon steels is greater than about 0.3%, the cooling rates encountered in normal welding may be sufficient to produce hard, untempered martensite, with an accompanying loss of ductility. Since alloy steels possess higher hardenability, the likelihood of martensite formation will be even greater with these materials. Special pre- and postwelding heat cycles (*preheat* and *postheat*) may be required when welding the higher-carbon and alloy steels. For plain-carbon steels, a preheat temperature of 200° to 400°F (100° to 200°C) is usually adequate. Because they can be welded without the need for preheating or postheating, low-carbon, low-alloy steels are extremely attractive for welding applications.

In joining processes where little or no melting occurs, considerable pressure is often applied to the heated metal (as in forge or resistance welding). The weld region experiences deformation, and the resultant structure exhibits the characteristics of a wrought material.

Since steel is the primary metal that is welded, our discussion of metallurgical effects has largely focused on steel. It should be noted, however, that other metals also exhibit heat-related changes in their structure and properties. The exact effects of the heating and cooling associated with welding will depend upon the specific transformations and structural changes that can occur within the materials being joined.

THERMAL EFFECTS IN BRAZING AND SOLDERING

In brazing and soldering, there is no melting of the base metal, but the joint still contains a region of solidified liquid and heat-affected sections within the base material. For these processes, however, another thermal effect may become quite significant. The base and filler metals are usually of radically different chemistries, and the elevated temperatures of joining also promote interdiffusion. Intermetallic phases can form at the interface and alter the properties of the joint. If present in small amounts, they can enhance bonding and provide strength reinforcement. Most *intermetallic compounds*, however, are quite brittle. Too much intermetallic material can result in significant loss of both strength and ductility.

THERMAL-INDUCED RESIDUAL STRESSES

Another effect of heating and cooling is the introduction of *residual stresses*. In welding, these may be of two types and are most pronounced in fusion welding, where the greatest amount of heating occurs. Their effects can be observed in the form of dimensional changes, distortion, and cracking.

Residual welding stresses are the result of restraint to thermal expansion and contraction by the pieces being welded. Consider a rectangular bar of metal that is uniformly heated and cooled. When heated, the material expands and becomes larger in length, width, and thickness. Upon cooling, the material contracts, and each dimension returns to its original value. Now clamp the ends of the bar in a vise so that lengthwise expansion cannot take place and repeat the thermal cycle. Upon heating, all of the expansion is restricted to the width and thickness, but the contraction upon cooling will still occur uniformly. The resulting rectangle will be shorter, thicker, and wider than the original specimen.

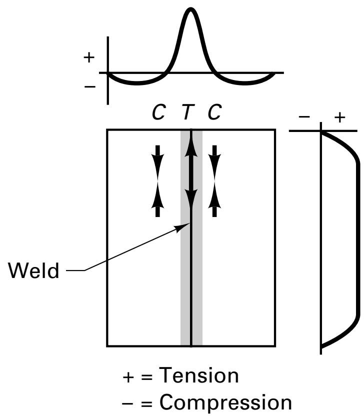

FIGURE 30-14 Schematic of the longitudinal residual stresses in a fusion-welded butt joint.

Now apply these principles to a weld being made between two plates, like that illustrated in Figure 30-14. As the weld is produced, the liquid region conforms to the shape of the "mold," and the adjacent material becomes hot and expands. The molten pool can absorb expansion of the plate perpendicular to the weld line, but expansion along the length of the weld tends to be restrained by the adjacent plate material that is cooler and stronger. This resistance or restraint is often sufficient to induce deformation of the hot, weak, and thermally expanding heat-affected zone, which now becomes thicker instead of longer.

After the weld pool solidifies, both the weld metal and adjacent heat-affected region cool and contract. The surrounding metal now resists this contraction. The weld region wants to contract but is restrained and forced to remain in a "stretched" condition, known as residual tension (region *T*). The cooling weld, in turn, exerts forces that try to squeeze the adjacent material, producing regions of residual compression (regions *C*). While the

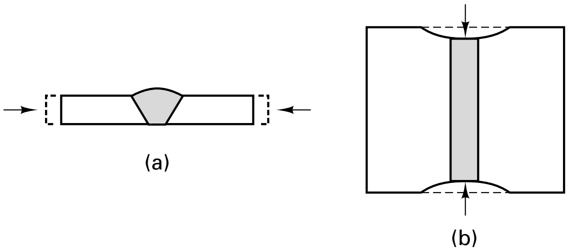

FIGURE 30-15 Shrinkage of a typical butt weld in the transverse (a) and longitudinal (b) directions as the material responds to the induced stresses. Note that restricting transverse motion will place the entire weld in transverse tension.

net force must remain at zero (in keeping with the equilibrium laws of physics and mechanics), the localized tensions and compressions can be substantial. As Figure 30-14 depicts, a high residual tension is observed in the weld metal, which becomes compressive and then returns to zero as one moves away from the weld centerline. The magnitude of the residual tension will be relatively uniform along the weld line, except at the ends, where the stresses can be relieved by a pulling in of the edges.

During cooling, the thermal contractions occur both parallel (longitudinal) and perpendicular (transverse) to the weld line. Lateral movement of the material being welded can often compensate for the transverse contractions. The width of the welded assembly simply becomes less than that of the positioned components at the time of welding. Figure 30-15a depicts this reduction in width, while Figure 30-15b illustrates the longitudinal contractions that generate the complex stresses of Figure 30-14.

Components being joined during fabrication typically have considerable freedom of movement, but welds made on nearly completed structures or repair welds often join components that are somewhat restrained. If the welded plates in Figure 30-15a are restrained from horizontal movement, *additional stresses will be induced*. These residual stresses are known as *reaction stresses*, and they can cause cracking of the hot weld or heat-affected material, or contribute to failure during subsequent use. Their magnitude will be an inverse function of the length between the weld joint and the point of restraint, and can be as high as the yield strength of the parent metal (since yielding would occur to relieve any higher stresses).

EFFECTS OF THERMAL STRESSES

Distortion or warping of the assembly can easily result from the nonuniform temperatures and thermal stresses induced by welding. Figure 30-16 depicts some of the distortions that can occur during various welding configurations. Since the causing conditions

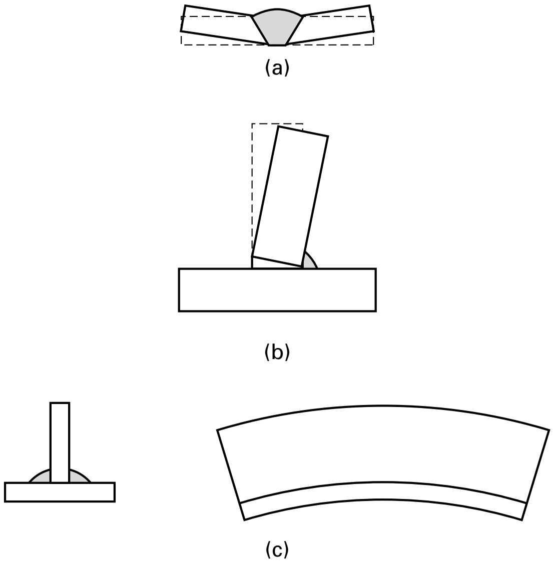

FIGURE 30-16 Distortions or warpage that may occur as a result of welding operations: (a) V-groove butt weld where the top of the joint contracts more than the bottom; (b) one-side fillet weld in a T-joint; (c) two-fillet weld in a T-joint with a high vertical web.

can vary widely, no fixed rules can be provided to assure the absence of warping. The following suggestions can help, however.

Total heat input to the weld should be minimized. Welds should be made with the least amount of weld metal necessary to form the joint. Overwelding is not an asset, since it actually increases residual stresses and distortion. Faster welding speeds reduce the welding time and also reduce the volume of metal that is heated. Welding sequences should be designed to use as few passes as possible, and the base material should be permitted to have a high freedom of movement. When constructing a multiweld assembly, it is beneficial to weld toward the point of greatest freedom, such as from the center to the edge.

The initial components can also be oriented out of position, so that the subsequent distortion will move them to the desired final shape. Another common procedure is to completely restrain the components during welding, thereby forcing some plastic flow in the joint and surrounding material. This procedure is used most effectively on small weldments where the reaction stresses will not be high enough to cause cracking.

Still another procedure is to balance the resulting thermal stresses by depositing the weld metal in a specified pattern, such as short lengths along a joint or on alternating sides of a plate. Warping can also be reduced by the use of *peening*. As the weld-bead surface is hammered with the peening tool or material, the metal is flattened and tries to spread. Being held back by the underlying material, the surface becomes compressed or squeezed. Surface rolling of the weld-bead area can have the same effect. In both processes, the compressive stresses induced by the surface deformation serve to offset the tensile stresses induced by welding.

Residual stresses should not have a harmful effect on the strength of weldments, except in the presence of notches or in very rigid structures where no plastic flow can occur. These two conditions should not exist if the welds have been properly designed and proper workmanship has been employed. Unfortunately, it is easy to inadvertently join heavy sections and produce rigid configurations that will not permit the small amounts of elastic or plastic movement required to reduce highly concentrated stresses. In addition, geometric notches, such as sharp interior corners, are often incorporated into welded structures. Other harmful "notches," such as gas pockets, rough beads, porosity, and arc "strikes," can serve as initiation sites for weld failures. These can generally be avoided by proper welding procedures, good workmanship, and adequate supervision and inspection.

The residual stresses of welding can also cause additional distortion when subsequent machining removes metal and upsets the stress equilibrium. For this reason, welded assemblies that are to undergo subsequent machining are frequently given a *stress-relief* heat treatment prior to that operation.

The reaction stresses that contribute to distortion are more often associated with cracking during or immediately following the welding operation (as the weld is cooling). This cracking is most likely to occur when there is great restraint to the shrinkage that occurs transverse to the direction of welding. When a multipass weld is being made, cracking tends to occur in the early beads where there is insufficient weld metal to withstand the shrinkage stresses. These cracks can be quite serious if they go undetected and are not chipped out and repaired, or melted and resolidified during subsequent passes. Figure 30-17 shows the various forms of cracking that can occur as a result of welding.

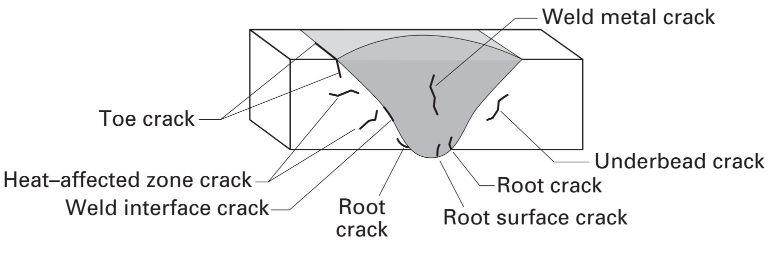

FIGURE 30-17 Various types and locations of cracking that can occur as a result of welding.

To minimize the possibility of fracture, welded joints should be designed to keep restraint to a minimum. The metals and alloys of the structure should be selected with welding in mind (more problems exist with higher-carbon steels, higher-alloy steels, and high-strength materials), and special consideration should be given when welding thicker materials. Crack-prevention efforts can also include maintaining the proper size and shape of the weld bead. While a concave fillet is desirable when machining, a concave weld profile has a greater tendency to crack upon cooling, since contraction actually increases the length of the surface. With a convex profile, the length of the surface will contract simultaneously with the volume, reducing the possibility of surface tension and cracking. Weld beads with high penetration (high depth–width ratio) are also more prone to cracking.

Still other methods to suppress cracking focus on reducing the stresses by making the cooling more uniform or relaxing them by promoting plasticity in the metals being welded. The metals to be welded may be preheated, and additional heat may be applied between the welding passes to retard cooling. Some welding codes also require the inclusion of a thermal stress relief after welding but prior to use. Hydrogen dissolved in the molten weld metal can also induce cracking. Slower welding and cooling will allow any hydrogen to escape, and the use of low-hydrogen electrodes and low-moisture fluxes will reduce the likelihood of hydrogen being present.

30.7 WELDABILITY OR JOINABILITY

It is important to note that not all joining processes are compatible with all engineering materials. While the terms *weldability* or *joinability* imply a reliable measure of a material's ability to be welded or joined, they are actually quite nebulous. One process might produce excellent results when applied to a given material, whereas another might produce a dismal failure. Within a given process, the quality of results may vary greatly with variations in the process parameters, such as electrode material, shielding gases, welding speed, and cooling rate.

Table 30-2 shows the compatibility of the various joining processes with some of the major classes of engineering materials. In each case, the process is classified as recommended (R), commonly performed (C), performed with some difficulty (D), seldom used (S), and not used (N). It should be noted, however, that the classifications are generalizations, and exceptions often exist within both the family of materials (such as the

various types of stainless steels) and the types of processes (arc welding here encompasses a large variety of specific processes). Nevertheless, the table can serve as a guideline to assist in process selection.

30.8 SUMMARY

If the potential benefits of welding are to be obtained and harmful side effects are to be avoided, proper consideration should be given to (1) the selection of the process, the process parameters, and the filler material; (2) the design of the joint; and (3) the effects of heating and cooling on both the weld and parent material. Joint design should consider manufacturability, durability, fatigue resistance, corrosion resistance, and safety. Welding metallurgy helps determine the structure and properties across the joint, as well as the need for additional thermal treatments. Further attention may be required to control or minimize residual stresses and distortion.

Parallel considerations apply to brazing and soldering operations, with additional attention to the effects of interdiffusion between the filler and base metals. Flame and arc-cutting operations involve localized heating and cooling, and they also create altered structures in the heat-affected zone. Since many cut products undergo further welding or machining, however, the regions of undesirable structure may not be retained in the final product.

Review Questions

1. What types of design features favor manufacture as a joined assembly?
2. What types of manufacturing processes fall under the classification of *consolidation processes*?
3. Define *welding*.
4. What four conditions are required to produce an ideal metallurgical bond?
5. What are some of the ways in which welding processes compensate for the inability to meet the conditions of an ideal bond?
6. What are some possible problems associated with the high temperatures that are commonly used in welding?
7. What are the three primary aspects required to produce a high-quality weld?
8. How are welding processes identified by the American Welding Society?
9. What is thermal cutting?
10. What are some of the common types of weld defects?
11. What are the four basic types of fusion welds?
12. What is the role of an insert in welding?
13. What types of weld joints commonly employ fillet welds?
14. What are the five basic joint types for fusion welding?
15. What are some of the factors that influence the cost of making a weldment?
16. Why is it important to consider welded products as monolithic structures?
17. How does the fracture resistance and temperature sensitivity of a steel vary with changes in material thickness?
18. How might excessive rigidity actually be a liability in a welded structure?
19. What is autogenous welding?
20. In what way is the weld-pool segment of a fusion weld like a small metal casting?
21. Why is it possible for the fusion zone to have a chemistry that is different from that of the filler metal?
22. Why is it not uncommon for the selected filler metal to have a chemical composition that is different from the material being welded?
23. What are some of the defects or problems that can occur in the molten metal region of a fusion weld?
24. Why can the resulting material properties vary widely within welding heat-affected zones?
25. What are some of the structure and property modifications that can occur in welding heat-affected zones?
26. Why do most welding failures occur in the heat-affected zone?
27. What are some of the characteristics and consequences of welding with processes that have low rates of heat input?
28. What are some of the difficulties or limitations encountered in heat treating large, complex welded structures?
29. What is the purpose of pre- and postheating in welding operations?

30. What heat-related metallurgical effects may produce adverse results when brazing or soldering?
31. What are some of the undesirable consequences of residual stresses?
32. What is the cause of reaction-type residual stresses?
33. How are reaction stresses affected by the distance between the weld and the point of fixed constraint?
34. What are some of the techniques that can reduce the amount of distortion in a welded structure?
35. Under what conditions might residual stresses have a harmful effect on load-bearing abilities?
36. Why might a welded structure warp if the structure is machined after welding?
37. What are some of the techniques that can be employed to reduce the likelihood of cracking in a welded structure?°
38. Why are the terms *weldability* and *joinability* somewhat nebulous?

Problems

1. Through the 1940s the hulls of oceangoing freighters were constructed by riveting plates of steel together. When the defense efforts of World War II demanded accelerated production of freighters to supply U.S. troops overseas, construction of the hulls was converted to welding. The resulting Liberty Ships proved quite successful but also drew considerable attention when minor or moderate impacts (usually under low-temperature conditions) produced cracks of lengths sufficient to scuttle the ship, often up to 50 feet or more. Since the material was essentially the same and the only significant process change had been the conversion from riveting to welding, the welding process was blamed for the failures.
   a. Is this a fair assessment?
   b. What do you think may have contributed to the problem?
   c. What evidence might you want to gather to support your beliefs?
2. Two pieces of AISI 1025 steel are being shielded-metal arc welded with E6012 electrodes. Some difficulty is being experienced with cracking in the weld beads and in the heat-affected zones. What possible corrective measures might you suggest?
3. Figure 30-A schematically depicts the design of a go-cart frame with cross bars and seat support. The assembly is to be constructed from hot-rolled, low-carbon, box-channel material with miter, butt, and fillet welds at the 12 numbered joints. Due to the solidification shrinkage and subsequent thermal contraction of the joint material, the welds are best made when one or more of the sections are unrestrained. If the structure is too rigid at the time of welding, the associated dimensional changes are restricted, causing the generation of residual stresses that can lead to distortion, cracking, or tears.
   a. Consider the 12 welds in the proposed structure and recommend a welding sequence that would minimize the possibility of hot tears and cracks due to the welding of a restrained joint.
   b. Your company is developing a computer-assisted design program. Suggest one or more rules that may be programmed to aid in the selection of an acceptable weld sequence.

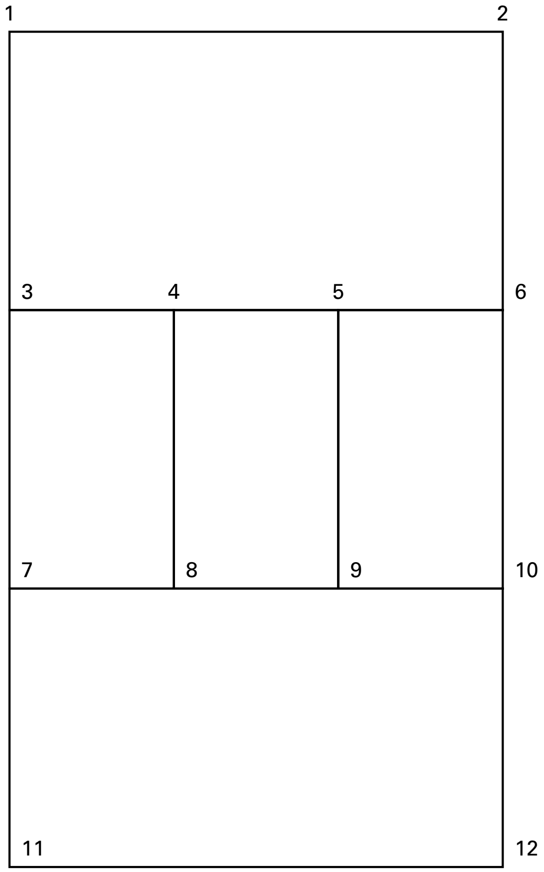

FIGURE 30-A

CHAPTER 31

GAS FLAME AND ARC PROCESSES

31.1 OXYFUEL-GAS WELDING

OXYFUEL-GAS WELDING PROCESSES

Oxyfuel-gas welding (OFW) refers to a group of welding processes that use the flame produced by the combustion of a fuel gas and oxygen as the source of heat. It was the development of a practical *torch* to burn acetylene and oxygen, shortly after 1900, that brought welding out of the blacksmith's shop, demonstrated its potential, and started its development as a manufacturing process. Other processes have largely replaced gas-flame welding in large-scale manufacturing, but the process is still popular for small-scale and repair operations because of its portability, versatility (most ferrous and nonferrous metals can be welded), and the low capital investment required. Acetylene is still the principal fuel gas.

The combustion of oxygen and *acetylene* (C_2H_2) by means of a welding torch of the type shown in Figure 31-1 produces a temperature of about 3250°C (5850°F) in a

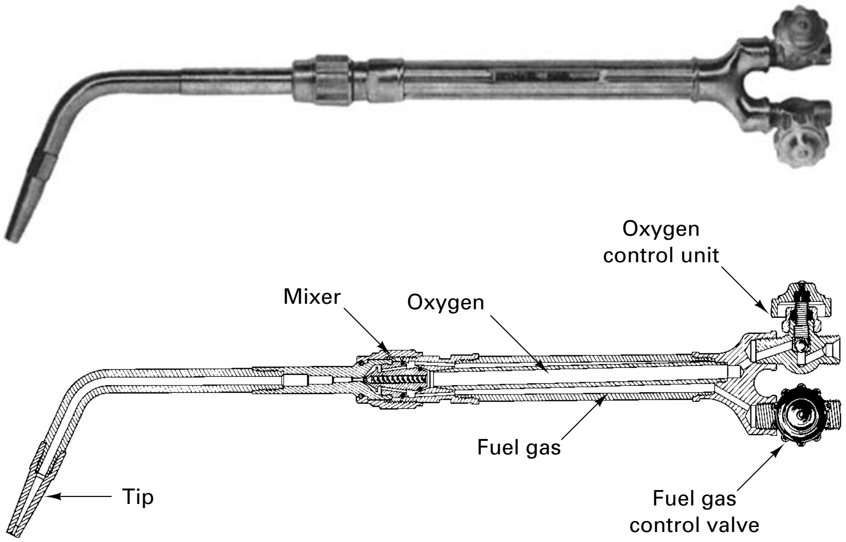

FIGURE 31-1 Typical oxyacetylene welding torch and cross-sectional schematic. *(Courtesy of Victor Equipment Company, Denton, TX)*

two-stage reaction. In the first stage, the supplied oxygen and acetylene react to produce carbon monoxide and hydrogen:

$$C_2H_2 + O_2 \rightarrow 2CO + H_2 + \text{heat}$$

This reaction occurs near the tip of the torch and generates intense heat. The second stage of the reaction involves the combustion of the CO and H_2 and occurs just beyond the first combustion zone. The specific reactions of the second stage are:

$$2CO + O_2 \rightarrow 2CO_2 + \text{heat}$$

$$H_2 + \frac{1}{2}O_2 \rightarrow H_2O + \text{heat}$$

The oxygen for these secondary reactions is generally obtained from the surrounding atmosphere.

The two-stage combustion process produces a flame having two distinct regions. As shown in Figure 31-2, the maximum temperature occurs near the end of the inner cone, where the first stage of combustion is complete. Most welding should be performed with the torch positioned so that this point of maximum temperature is just above the metal being welded. The outer envelope of the flame serves to preheat the metal and, at the same time, provides shielding from oxidation, since oxygen from the surrounding air is consumed in the secondary combustion.

Three different types of flames can be obtained by varying the oxygen–acetylene (or oxygen–fuel gas) ratio. If the ratio is between 1:1 and 1.15:1, all reactions are carried to completion and a *neutral flame* is produced. Most welding is done with a neutral flame, since it will have the least chemical effect on the heated metal.

A higher ratio, such as 1.5:1, produces an *oxidizing flame*, which is hotter than the neutral flame (about 3600°C or 6000°F) but similar in appearance. Such flames are used when welding copper and copper alloys but are generally considered harmful when

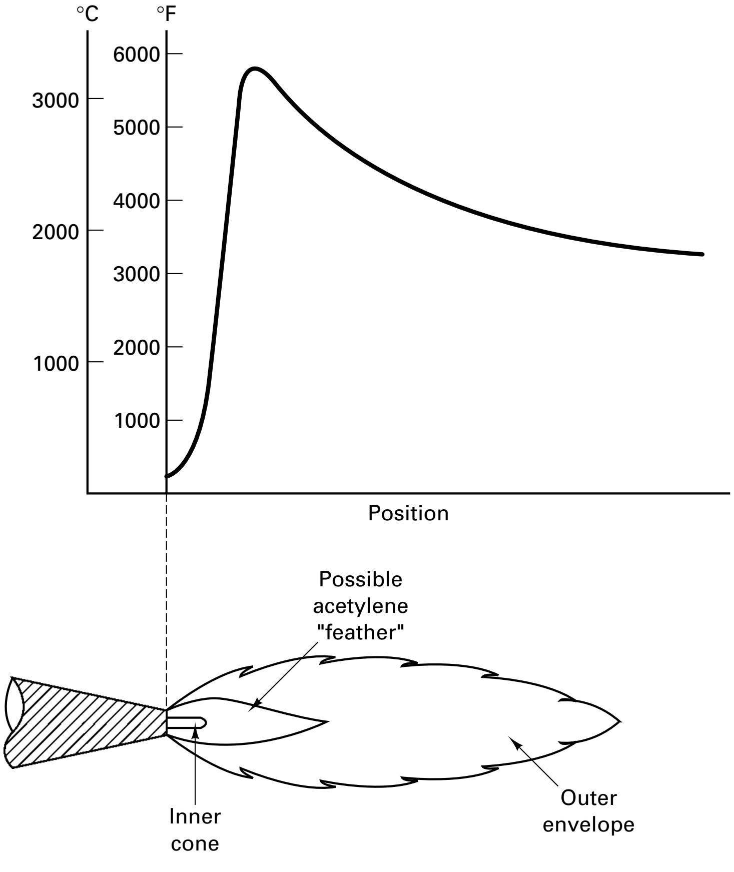

FIGURE 31-2 Typical oxyacetylene flame and the associated temperature distribution.

welding steel because the excess oxygen reacts with the carbon in the steel, lowering the carbon in the region around the weld.

Excess fuel, on the other hand, produces a *carburizing flame*. The excess fuel decomposes to carbon and hydrogen, and the flame temperature is not as great (about 3050°C or 5500°F). Flames with a slight excess of fuel are reducing flames. No carburization occurs, but the metal is well protected from oxidation. Flames of this type are used in welding Monel (a nickel–copper alloy), high-carbon steels, and some alloy steels, and for applying some types of hard-facing material.

For welding purposes, oxygen is usually supplied from pressurized tanks in a relatively pure form, but, in rare cases, air can also be used. The acetylene is usually obtained in portable storage tanks that hold up to 8.5 m^3 (300 ft^3) at 1.7 MPa (250 psi) pressure. Because acetylene is not safe when stored as a gas at pressures above 0.1 MPa (15 psi), it is usually dissolved in acetone. The storage cylinders are filled with a porous filler. Acetone is absorbed into the voids in the filler material and serves as a medium for dissolving the acetylene.

Alternative fuel gases include propane, propylene, and stabilized methyl acetylene propadiene, best known by the trade name of *MAPP* gas. While flame temperature is slightly lower, these gases can be safely stored in ordinary pressure tanks. Three to four times as much gas can be stored in a given volume, and cost per cubic foot can be less than acetylene. Butane, natural gas, and hydrogen have been used in combination with air or oxygen to weld the low-melting-temperature, nonferrous metals. They are generally not suited to the ferrous metals because the flame atmosphere is oxidizing and the heat output is too low.

The pressures used in gas-flame welding range from 0.006 to 0.1MPa (1 to 15 psi) and are controlled by pressure regulators on each tank. Because mixtures of acetylene and oxygen or air are highly explosive, precautions must be taken to avoid mixing the gases improperly or by accident. All acetylene fittings have left-hand threads, while those for oxygen are equipped with right-hand threads. This prevents improper connections.

The tip size, or orifice diameter of the torch, can be varied to control the shape of the inner cone and the flow rate of the gases. Larger tips permit greater flow of gases, resulting in greater heat input without the higher gas velocities that might blow the molten metal from the weld puddle. Larger torch tips are used for the welding of thicker metal.

USES, ADVANTAGES, AND LIMITATIONS

Almost all oxyfuel-gas welding is *fusion welding*. The metals to be joined are simply melted where a weld is desired and no pressure is required. Because a slight gap often exists between the pieces being joined, *filler metal* can be added in the form of a solid metal wire or rod. Welding rods come in standard sizes, with diameters from 1.5 to 9.5 mm ($^1/_{16}$ to $^3/_8$ in.) and lengths from 0.6 to 0.9 m (24 to 36 in.). They are available in standard grades that provide specified minimum tensile strengths or in compositions that match the base metal. Figure 31-3 shows a schematic of oxyfuel-gas welding using a consumable welding rod.

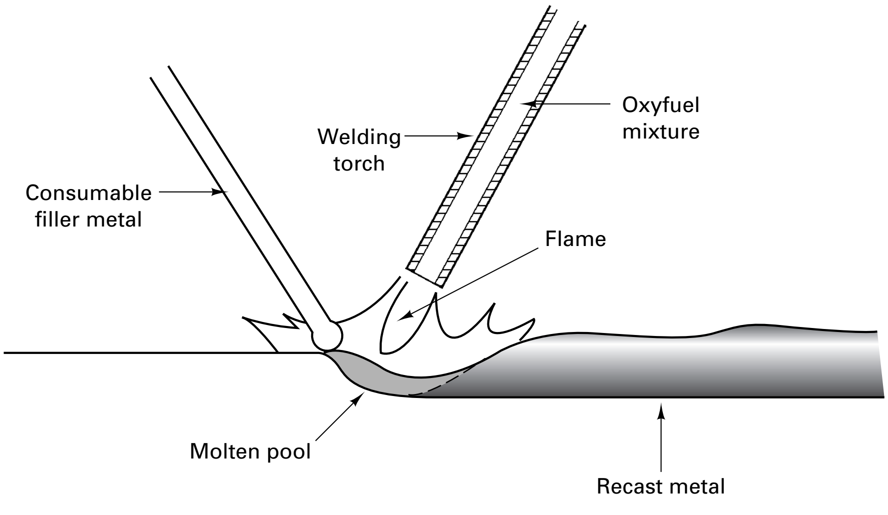

FIGURE 31-3 Oxyfuel-gas welding with a consumable welding rod.

TABLE 31-1 Process Summary: Oxyfuel-Gas Welding (OFW)

Heat source	Fuel gas—oxygen combustion
Protection	Gases produced by combustion
Electrode	None
Material joined	Best for steel and other ferrous metals
Rate of heat input	Low
Weld profile (Depth/Width)	$^1/_3$
Max. penetration	3 mm
Assets	Cheap, simple equipment, portable, versatile
Limitations	Large HAZ, slow

To promote the formation of a better bond, *fluxes* may be used to clean the surfaces and remove contaminating oxide. In addition, the gaseous shield produced by vaporizing flux can prevent further oxidation during the welding process, and the slag produced by solidifying flux can protect the weld pool as it cools. Flux can be added as a powder, the welding rod can be dipped in a flux paste, or the rods can be precoated.

The OFW processes can produce good-quality welds if proper caution is exercised. Welding can be performed in all positions, the temperature of the work can be easily controlled, and the puddle is visible to the welder. However, exposure of the heated and molten metal to the various gases in the flame and atmosphere makes it difficult to prevent contamination. Since the heat source is not concentrated, heating is rather slow. A large volume of metal is heated, and distortion is likely to occur. The thickness of the material being joined is usually less than 6.5 mm ($^1/_4$ in.). Thus, in production applications, the flame-welding processes have largely been replaced by arc welding. Nevertheless, flame welding is still quite common in field work, in maintenance and repairs, and in fabricating small quantities of specialized products.

Oxyfuel equipment is quite portable, relatively inexpensive, and extremely versatile.

A single set of equipment can be used for welding, brazing, and soldering, and as a heat source for bending, forming, straightening, and hardening. With the modifications to be discussed shortly, it can also perform flame cutting. Table 31-1 summarizes some of the key features of oxyfuel-gas welding. Table 31-2 shows its compatibility with some common engineering materials.

PRESSURE GAS WELDING

Pressure gas welding (PGW) is a process that uses equipment similar to the oxyfuel-gas process to produce butt joints between the ends of objects such as pipe and railroad rail. The ends are heated with a gas flame to a temperature below the melting point,

TABLE 31-2 Engineering Materials and Their Compatibility with Oxyfuel Welding

Material	Oxyfuel Welding Recommendation
Cast iron	Recommended with cast iron filler rods; braze welding recommended if there are no corrosion objections
Carbon and low-alloy steels	Recommended for low-carbon and low-alloy steels, using rods of the same material; more difficult for higher carbon
Stainless steel	Common for thinner material; more difficult for thicker
Aluminum and magnesium	Common for aluminum thinner than 1 in.; difficult for magnesium alloys
Copper and copper alloys	Common for most alloys; more difficult for some types of bronzes
Nickel and nickel alloys	Common for nickel, Monels, and Inconels
Titanium	Not recommended
Lead and zinc	Recommended
Thermoplastics, thermosets, and elastomers	Hot-gas welding used for thermoplastics, not used with thermosets and elastomers
Ceramics and glass	Seldom used with ceramics, but common with glass
Dissimilar metals	Difficult; best if melting points are within 50°F; concern for galvanic corrosion
Metals to nonmetals	Not recommended
Dissimilar nonmetals	Difficult

and the soft metal is then forced together under pressure. Pressure gas welding, therefore, is actually a form of solid-state welding where the gas flame simply softens the metal and coalescence is produced by pressure.

31.2 OXYGEN TORCH CUTTING

PROCESSES

Oxyfuel-gas cutting (OFC), commonly called flame cutting, is the most common *thermal cutting* process. In some cases the metal is merely melted by the flame of the oxyfuel-gas torch and is blown away to form a gap, or *kerf*, as illustrated in Figure 31-4. When ferrous metal is cut, however, the process becomes one where the iron actually burns (or oxidizes) at high temperatures according to one or more of the following reactions:

$$Fe + O \rightarrow FeO + \text{heat}$$

$$3Fe + 2O_2 \rightarrow Fe_3O_4 + \text{heat}$$

$$4Fe + 3O_2 \rightarrow 2Fe_2O_3 + \text{heat}$$

Because these reactions do not occur until the metal is above 815°C (1500°F), the oxyfuel flame is first used to raise the metal to the temperature where burning can be initiated. Then a stream of pure oxygen is added to the torch (or the oxygen content of the oxyfuel mixture is increased) to oxidize the iron. The liquid iron oxide and any unoxidized molten iron are then expelled from the joint by the kinetic energy of the oxygen-gas stream. Because of the low rate of heat input and the need for preheating ahead of the cut, oxyfuel cutting produces a relatively large heat-affected zone and associated distortion compared to competing techniques. Therefore, the process is best used where the edge finish or tolerance is not critical and the edge material will either be subsequently welded or removed by machining. Cutting speeds are relatively slow, but the low cost of both the required equipment and its operation make the process attractive for many applications.

Theoretically, the heat supplied by the oxidation will be sufficient to keep the cut progressing, but additional heat is often necessary to compensate for losses to the atmosphere and the surrounding metal. If the workpiece is already hot from other processing, such as solidification or hot working, no supplemental heating is required and a supply of oxygen through a small pipe is all that is needed to initiate and continue a cut. This is known as *oxygen lance cutting* (OLC). A workpiece temperature of about 1200°C (2200°F) is required to sustain continuous cutting.

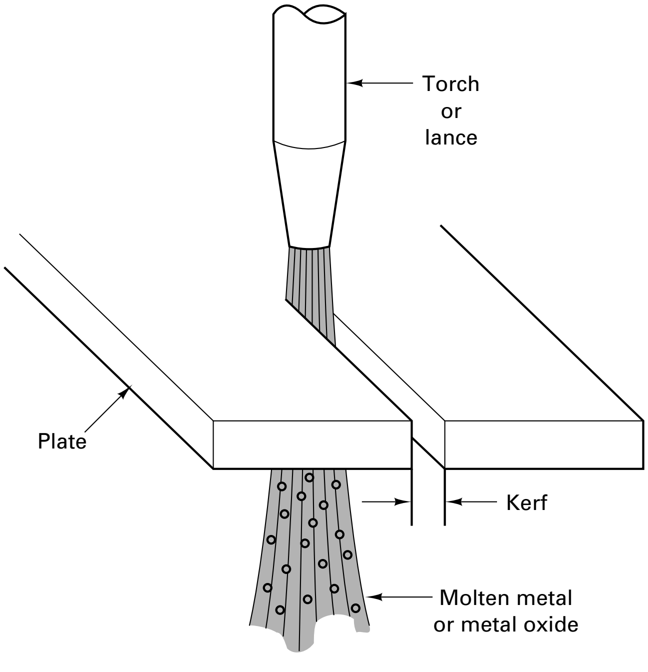

FIGURE 31-4 Flame cutting of a metal plate.

Oxyfuel-gas cutting works best on metals that oxidize readily but do not have high thermal conductivities. Carbon and low-alloy steels can be readily cut in thicknesses from 5 mm to in excess of 75 cm (30 in.). Stainless steels contain oxidation-resistant ingredients and are difficult to cut, as are aluminum and copper alloys.

FUEL GASES FOR OXYFUEL-GAS CUTTING

Acetylene is by far the most common fuel used in oxyfuel-gas cutting, and the process is often referred to as *oxyacetylene cutting* (OFC-A). Figure 31-5 shows a typical cutting torch. The tip contains a circular array of small holes through which the oxygen–acetylene mixture is supplied to form the heating flame. A larger hole in the center supplies a stream of oxygen and is controlled by a lever valve. The rapid flow of the cutting oxygen not only oxidizes the hot metal but also blows the formed oxides from the cut.

If the torch is adjusted and manipulated properly, it is possible to produce a relatively smooth cut. Cut quality, however, depends upon careful selection of the process variables, including preheat conditions, oxygen flow rate, and cutting speed. Oxygen purities over 99.5% are required for the most efficient cutting. If the purity drops to 98.5%, cutting speed will be reduced by 15%, oxygen consumption will increase by 25%, and the quality of the cut will diminish.

Cutting torches can be manipulated manually. However, when the process is applied to manufacturing, the desired path is usually controlled by mechanical or programmable means. Specialized equipment has been designed to produce straight cuts in flat stock and square-cut ends on pipe. The marriage of computer numerically controlled (CNC) machines and cutting torches has also proven to be quite popular. This approach, along with the use of robot-mounted torches, provides great flexibility along with good precision and control.

Fuel gases other than acetylene can also be used for oxyfuel-gas cutting, the most common being natural gas (OFC-N) and propane (OFC-P). While their flame temperatures are lower than that of acetylene, their use is generally a matter of economics and gas availability. For certain special work, hydrogen can also be used (OFC-H).

STACK CUTTING

When a modest number of duplicate parts are to be cut from thin sheet, but not enough to justify the cost of a blanking die, stack cutting may be the answer. The sheets should be flat, smooth, and free of scale, and they should be clamped together tightly so that there are no intervening gaps that could interrupt uniform oxidation or permit slag or

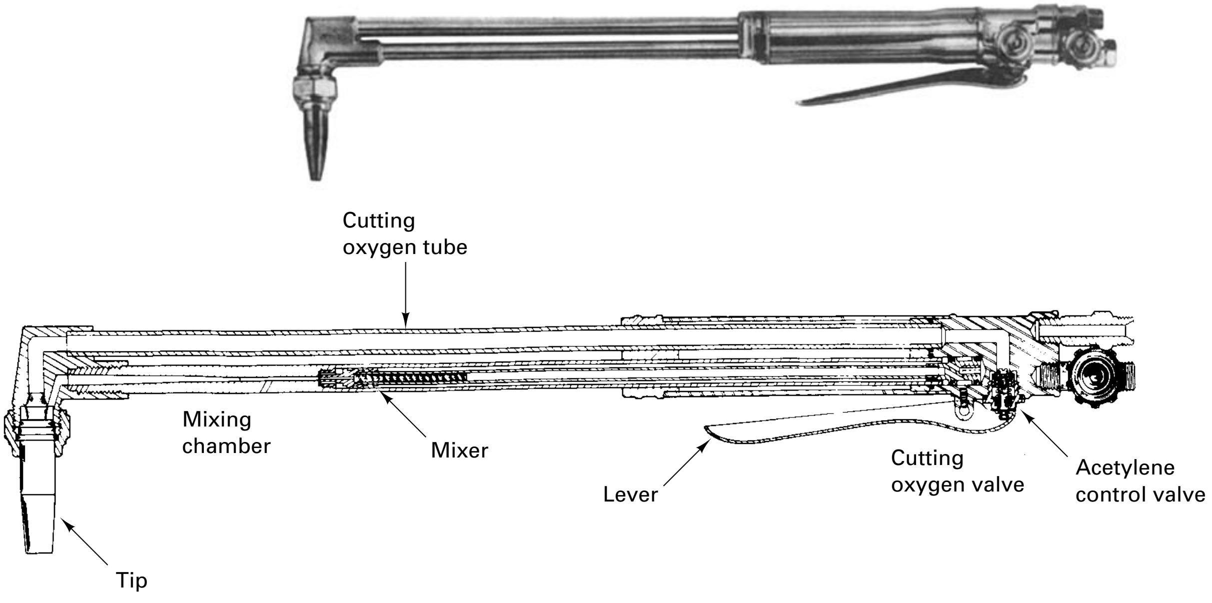

FIGURE 31-5 Oxyacetylene cutting torch and cross-sectional schematic. *(Courtesy of Victor Equipment Company, Denton, TX)*

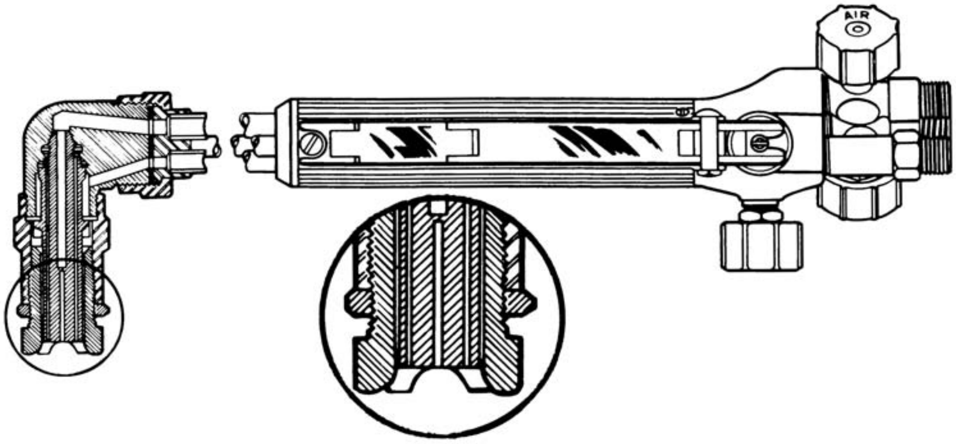

FIGURE 31-6 Underwater cutting torch. Note the extra set of gas openings in the nozzle to permit the flow of compressed air and the extra control valve. *(Courtesy of Bastian-Blessing Company, Chicago, IL)*

molten metal to be entrapped. Obviously, stack cutting will produce a less accurate cut than could be achieved by using a blanking die.

METAL POWDER CUTTING, CHEMICAL FLUX CUTTING, AND OTHER THERMAL METHODS

When cutting hard-to-cut materials, modified torch techniques may be required. Metal powder cutting (POC) injects iron or aluminum powder into the flame to raise its cutting temperature. Chemical flux cutting (FOC) adds a fine stream of special flux to the cutting oxygen to increase the fluidity of the high-melting-point oxides. Both of these methods, however, have largely been replaced by plasma arc cutting (PAC), which is discussed as an extension of plasma arc welding, to be presented later in this chapter. Laser- and electron-beam cutting will be presented with their welding parallels in a future chapter.

UNDERWATER TORCH CUTTING

The thermal cutting of materials underwater presents a special challenge. A specially designed torch, like the one shown in Figure 31-6, is used to cut steel. An auxiliary skirt surrounds the main tip, and an additional set of gas passages conducts a flow of compressed air that provides secondary oxygen for the oxyacetylene flame and expels water from the zone where the burning of metal occurs. The torch is either ignited in the usual manner before descent or by an electric spark device after being submerged. Acetylene gas is used for depths up to about 7.5 m (25 ft). For greater depths, hydrogen is used, since the environmental pressure is too great for the safe use of acetylene.

■ 31.3 FLAME STRAIGHTENING

Flame straightening uses controlled, localized *upsetting* as a means of straightening warped or buckled material. Figure 31-7 illustrates the theory of the process. If a straight piece of metal is heated in a localized area, such as the shaded area of the upper diagram, the metal on side *b* will be upset (i.e., plastically deformed) as it softens and tries to expand against the cooler restraining metal. When the upset portion cools, it will con-

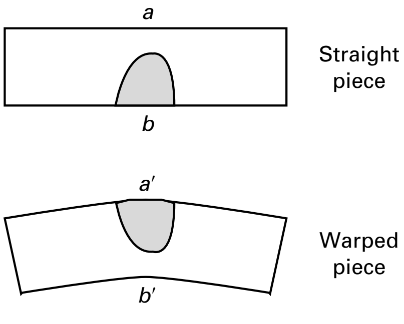

FIGURE 31-7 Schematic illustrating the theory of flame straightening.

tract, and the resulting piece will be shorter on side *b*, forcing it to bend to the shape in the lower diagram.

If the starting material is bent or warped, as in the lower segment of Figure 31-7, the upper surface can be heated. Upsetting and subsequent thermal contraction will shorten the upper surface at *a′*, bringing the plate back to a straight or flat configuration. This type of procedure can be used to restore structures that have been bent in an accident, such as automobile frames.

A similar process can be used to flatten metal plates that have become dished. Localized spots about 50 mm (2 in.) in diameter are quickly heated to the upsetting temperature while the surrounding metal remains cool. Cool water is then sprayed onto the plate, and the contraction of the upset spot brings the buckle into an improved degree of flatness. To remove large buckles, the process may have to be repeated at several spots within the buckled area.

Several cautions should be noted. When straightening steel, consideration should be given to the possible phase transformations that could occur during the heating and cooling. Since rapid cooling is used and martensite may form, a subsequent tempering operation may be required. In addition, one should also consider the residual stresses that are induced and their effect on subsequent cracking, stress–corrosion cracking, and other modes of failure. The effects of phase transformations and residual stresses have been discussed more fully in Chapter 31.

Also, flame straightening should not be attempted with thin material. For the process to work, the metal adjacent to the heated area must have sufficient rigidity to induce upsetting. If the material is too thin, localized heating and cooling will simply transfer the buckle from one area to another.

■ 31.4 ARC WELDING

With the development of commercial electricity in the late nineteenth century, it was soon recognized that an *arc* between two electrodes was a concentrated heat source that could produce temperatures approaching 4000°C (7000°F). As early as 1881, various attempts were made to use an arc as the heat source for fusion welding. A carbon rod was selected as one *electrode* and the metal workpiece became the other. Figure 31-8 depicts the basic electrical circuit. If needed, *filler metal* was provided by a metallic wire or rod that was independently fed into the arc. As the process developed, the filler metal replaced the carbon rod as the upper electrode. The metal wire not only carried the welding current but, as it melted in the arc, it also supplied the necessary filler.

The results of these early efforts were extremely uncertain. Because of the instability of the arc, a great amount of skill was required to maintain it, and contamination of the weld resulted from the exposure of hot metal to the atmosphere. There was little or no understanding of the metallurgical effects and requirements of arc welding. Consequently, while the great potential was recognized, very little use was made of the process until after World War I. Shielded metal electrodes were developed around 1920. These electrodes enhanced the stability of the arc by shielding it from the atmosphere and provided a fluxing action to the molten pool. The major problems of arc welding were overcome, and the process began to expand rapidly.

All *arc-welding* processes employ the basic circuit depicted in Figure 31-8. Welding currents vary from 1 to 4000 amps, with the range from 100 to 1000 being most typical.

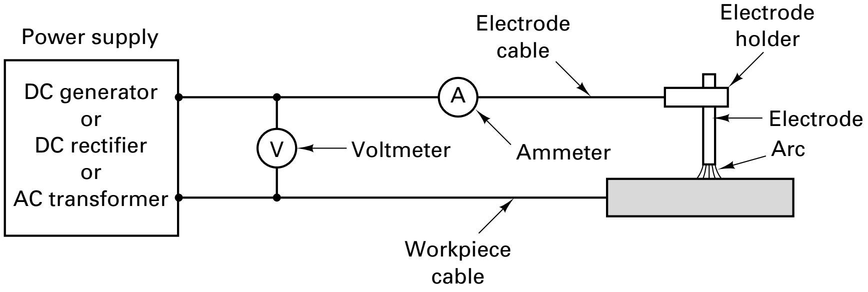

FIGURE 31-8 The basic electrical circuit for arc welding.

Voltages are generally in the range of 20 to 50 volts. If direct current is used and the electrode is made negative, the condition is known as straight polarity (SPDC) or *DCEN*, for direct-current electrode-negative. Electrons are attracted to the positive workpiece, while ionized atoms in the arc column are accelerated toward the negative electrode. Since the ions are far more massive than the electrons, the heat of the arc is more concentrated at the electrode. DCEN processes are characterized by fast melting of the electrode (high metal deposition rates) and a shallow molten pool on the workpiece (weld penetration). If the work is made negative and the electrode positive, the condition is known as reverse polarity (RPDC) or *DCEP*, for direct-current electrode-positive. The positive ions impinge on the workpiece, breaking up any oxide films and giving deeper penetration. The metal deposition rate is lower, however. Sinusoidal *alternating current* provides a 50–50 average of the above two modes and is a popular alternative to the dc conditions. *Variable polarity* power supplies also alternate between DCEP and DCEN conditions, but they use rectangular waveforms to vary the fraction of time in each mode as well as the frequency of switching. Weld characteristics can now be varied over a continuous range between DCEN and DCEP conditions.

In one group of arc-welding processes, the electrode is consumed (*consumable-electrode processes*) and thus supplies the metal needed to fill the joint. Consumable electrodes have a melting temperature below the temperature of the arc. Small droplets are melted from the end of the electrode and pass to the workpiece. The size of these droplets varies greatly, and the transfer mechanism depends on the type of electrode, welding current, and other process parameters. Figure 31-9 depicts metal transfer by the globular, spray, and short-circuit transfer modes. As the electrode melts, the arc length and the electrical resistance of the arc path will vary. To maintain a stable arc and satisfactory welding conditions, the electrode must be moved toward the work at a controlled rate. Manual arc welding is almost always performed with shielded (covered) electrodes. Continuous bare-metal wire can be used as the electrode in automatic or semiautomatic arc welding, but this is always in conjunction with some form of shielding and arc-stabilizing medium and automatic feed control devices that maintain the proper arc length.

The second group of arc-welding processes employs a tungsten electrode, which is not consumed by the arc, except by relatively slow vaporization. In these *nonconsumable-electrode processes*, a separate metal wire is required to supply the filler metal.

Because of the wide variety of processes available, arc welding has become a widely used means of joining material. Each process and application, however, requires the selection or specification of the welding voltage, welding current, arc polarity (straight polarity, reversed polarity, or alternating), arc length, welding speed (how fast the electrode is moved across the workpiece), arc atmosphere, electrode or filler material, and flux. Filler materials must be selected to match the base metal with respect to properties and/or alloy content (chemistry). For many of the processes, the quality of the weld also depends on the skill of the operator. Automation and robotics are reducing this dependence, but the selection and training of welding personnel are still of great importance.

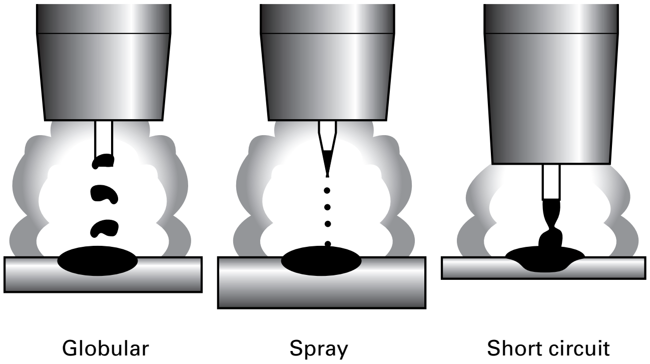

FIGURE 31-9 Three modes of metal transfer during arc welding. *(Courtesy of Republic Steel Corporation, Youngstown, OH)*

31.5 CONSUMABLE-ELECTRODE ARC WELDING

Four processes make up the bulk of consumable-electrode arc welding:

1. Shielded metal arc welding (SMAW)
2. Flux-cored arc welding (FCAW)
3. Gas metal arc welding (GMAW)
4. Submerged arc welding (SAW)

These processes all have a medium rate of heat input and produce a fusion zone whose depth is approximately equal to its width. Because the fusion zone is composed of metal from both of the pieces being joined, plus melted filler (i.e., electrode), the electrode must be of the same material as that being welded; the processes cannot be used to join dissimilar metals or ceramics.

SHIELDED METAL ARC WELDING

Shielded metal arc welding (SMAW), also called *stick welding* or covered-electrode welding, is among the most widely used welding processes because of its versatility and because it requires only low-cost equipment. The key to the process is a finite-length electrode that consists of metal wire, usually from 1.5 to 6.5 mm in diameter and 20 to 45 cm in length. Surrounding the wire is a bonded coating containing chemical components that add a number of desirable characteristics, including all or many of the following:

1. Vaporize to provide a protective atmosphere (a gas shield around the arc and pool of molten metal).
2. Provide ionizing elements to help stabilize the arc, reduce weld metal spatter, and increase efficiency of deposition.
3. Act as a *flux* to deoxidize and remove impurities from the molten metal.
4. Provide a protective *slag* coating to accumulate impurities, prevent oxidation, and slow the cooling of the weld metal.
5. Add alloying elements.
6. Add additional filler metal.
7. Affect arc *penetration* (the depth of melting in the workpiece).
8. Influence the shape of the weld bead.

The coated electrodes are classified by the tensile strength of the deposited weld metal, the welding position in which they may be used, the preferred type of current and polarity (if direct current), and the type of coating. A four- or five-digit system of designation has been adopted by the American Welding Society (AWS) and is presented in Figure 31-10. As an example, type E7016 is a low-alloy steel electrode that will provide a deposit with a minimum tensile strength of 70,000 psi (485 MPa) in the non-stress-relieved condition; it can be used in all positions, with either alternating or reverse-polarity direct current; and it has a low-hydrogen plus potassium coating. To assist in identification, all electrodes are marked with colors in accordance with a standard established by the National Electrical Manufacturers Association. Electrode selection consists of determining the electrode coating, coating thickness, electrode composition, and electrode diameter. The current type and polarity are matched to the electrode.

A variety of electrode coatings have been developed. The cellulose and titania (rutile) coatings contain: SiO_2; TiO_2; small amounts of FeO, MgO, and Na_2O; and volatile matter. Upon decomposition, the volatile matter may release hydrogen, which can dissolve in the weld metal and lead to embrittlement or cracking in the joint. Low-hydrogen electrodes are available with compositions designed to provide shielding without the emission of hydrogen. Since many of the electrode coatings can absorb moisture, and this is another source of undesirable hydrogen, the coated electrodes are often baked just prior to use.

To initiate a weld, the operator briefly touches the tip of the electrode to the workpiece and quickly raises it to a distance that will maintain a stable arc. The intense heat quickly melts the tip of the electrode wire, the coating, and portions of the adjacent base

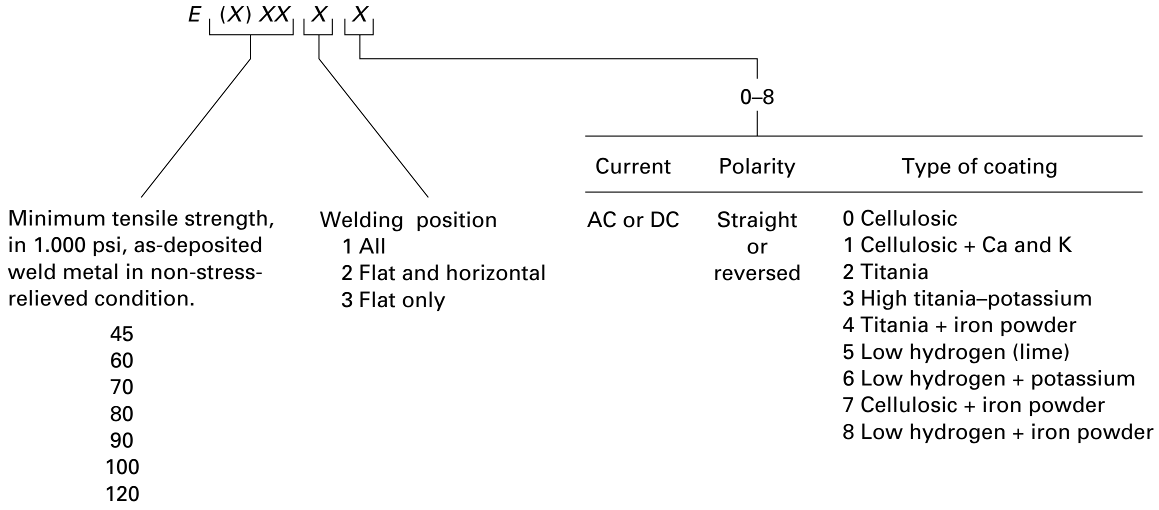

FIGURE 31-10 Designation system for arc-welding electrodes.

metal. As part of the electrode coating melts and vaporizes, it forms a protective atmosphere of CO, CO_2, and other gases that stabilizes the arc and protects the molten and hot metal from contamination. Other coating components surround the metal droplets with a layer of liquid flux and slag. The fluxing constituents unite with any impurities in the molten metal and float them to the surface to be entrapped in the slag coating that forms over the weld. The slag coating then protects the cooling metal from oxidation and slows down the cooling rate to prevent the formation of hard, brittle structures. The glassy slag is easily chipped from the weld when it has cooled. Figure 31-11 illustrates the shielded metal arc welding process, and Figure 31-12 provides a schematic of metal deposition from a shielded electrode.

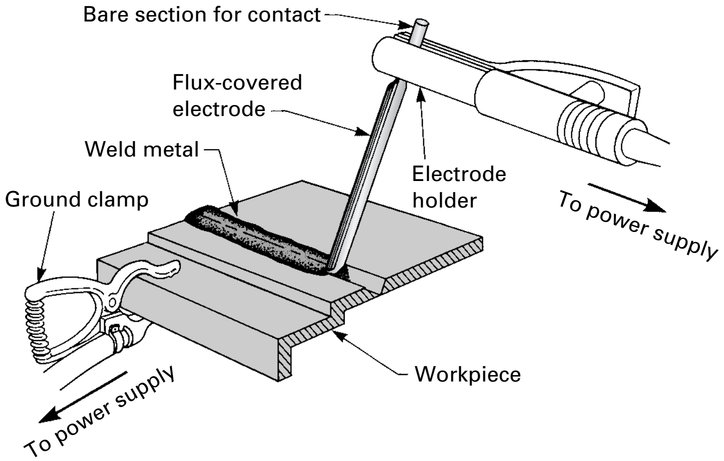

FIGURE 31-11 A shielded metal arc welding (SMAW) system.

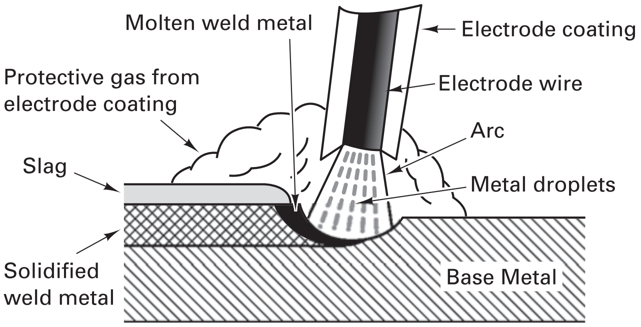

FIGURE 31-12 Schematic diagram of shielded metal arc welding (SMAW). *(Courtesy of American Iron and Steel Institute, Washington, DC.)*

Iron powder can be added to the electrode coating to significantly increase the amount of weld metal that can be deposited with a given size electrode wire and current. Alloy elements can also be incorporated into the coating to adjust the chemistry of the weld.

Special contact or drag electrodes utilize coatings that are designed to melt more slowly than the filler wire. If these electrodes are tracked along the surface of the work, the faster-melting center wire will be recessed by the proper length to maintain a stable arc.

Since electrical contact must be maintained with the center wire, SMAW electrodes are finite-length "sticks." Length is limited since the current must be supplied near the arc, or the electrode will tend to overheat (by electrical resistance heating) and ruin the coating. Overheating also restricts the weld currents to values below 300 amps (generally about 40 amps per millimeter of electrode diameter). As a result, the arc temperatures are somewhat low, and penetration is generally less than 5 mm ($^3/_{16}$ in.). Welding of material thicker than 5 mm will require multiple passes, and the slag coating must be removed between each pass.

The shielded metal arc process is best used for welding ferrous metals; carbon steels, alloy steels, stainless steels, and cast irons can all be welded. Welds can be made in all positions. DCEP conditions are used to obtain the deepest possible penetration, with alternate modes being employed when welding a thin sheet. The mode of metal transfer is either globular or short circuit.

Shielded metal arc welding is a simple, inexpensive, and versatile process, requiring only a power supply, power cables, an electrode holder, and a small variety of electrodes. The equipment is portable and can even be powered by gasoline or diesel generators. Therefore, it is a popular process in job shops and is used extensively in repair operations. The electrode provides and regulates its own flux, and there is less sensitivity to wind and drafts than in the gas-shielded processes. Welds can be made in all positions. Unfortunately, the process is discontinuous, produces shallow welds, and requires slag removal after each welding pass. Table 31-3 presents a process summary for shielded metal arc welding.

FLUX-CORED ARC WELDING

Flux-cored arc welding (FCAW) overcomes some of the limitations of the shielded metal arc process by moving the powdered flux to the interior of a continuous tubular electrode (Figure 31-13). When the arc is established, the vaporizing flux again produces a protective atmosphere and also forms a slag layer over the weld pool that will require subsequent removal. Alloy additions (metal powders) can be blended into the flux to create a wide variety of filler metal chemistries. Compared to the stick electrodes of the shielded metal arc process, the flux-cored electrode is both continuous and less bulky, since binders are no longer required to hold the flux in place.

The continuous electrode is fed automatically through a welding gun, with electrical contact being maintained through the bare-metal exterior of the wire at a position near the exit of the gun. Overheating of the electrode is no longer a problem, and welding

TABLE 31-3 Process Summary: Shielded Metal Arc Welding (SMAW)

Heat source	Electric arc
Protection	Slag from flux and gas from vaporized coating material
Electrode	Discontinuous, consumable
Material joined	Best for steel
Rate of heat input	Medium
Weld profile (D/W)	1
Current	<300 amps
Max. penetration	3–6 mm
Assets	Cheap, simple equipment
Limitations	Discontinuous, shallow welds; requires slag removal

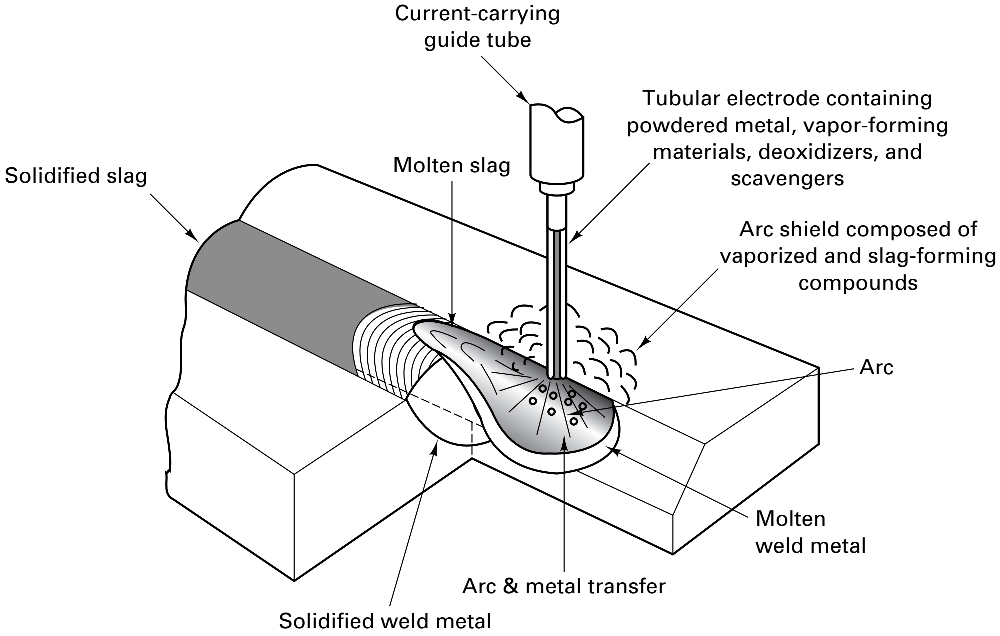

FIGURE 31-13 The flux-cored arc welding (FCAW) process. *(Courtesy of The American Welding Society, New York.)*

currents can be increased to about 500 A. The higher heat input increases penetration depth to about 1 cm ($^3/_8$ in.). The process is best used for welding steels, and welds can be made in all positions. Direct-current electrode-positive (DCEP) conditions are almost always used for the enhanced penetration. High deposition rates are possible, but the equipment cost is greater than that of SMAW because of the need for a controlled wire feeder and more costly power supply. Good ventilation is required to remove the fumes generated by the vaporizing flux.

In the basic flux-cored arc welding process, the shielding gas is provided by the vaporization of flux components. Better protection and cleaner welds can be produced by combining the flux with a flow of externally supplied shielding gas, such as CO_2.

Table 31-4 presents a process summary of flux-cored arc welding.

GAS METAL ARC WELDING

If the supplemental shielding gas flowing through the torch (described above) becomes the primary protection for the arc and molten metal, there is no longer a need for the volatilizing flux. The consumable electrode can now become a continuous, solid, uncoated metal wire or a continuous hollow tube with powdered alloy additions in the center, known as a metal-cored electrode. The resulting process, shown in Figure 31-14, was formerly called metal inert-gas, or MIG, welding and is now known as *gas metal arc welding (GMAW)*. The arc is still maintained between the workpiece and the automatically fed bare-wire electrode, which continues to provide the necessary filler metal.

TABLE 31-4 Process Summary: Flux-Cored Arc Welding (FCAW)

Heat source	Electric arc
Protection	Slag and gas from flux (optional secondary gas shield)
Electrode	Continuous, consumable
Material joined	Best for steel
Rate of heat input	Medium
Weld profile (D/W)	1
Current	<500 amps
Max. penetration	6–10 mm
Assets	Continuous electrode
Limitations	Requires slag removal

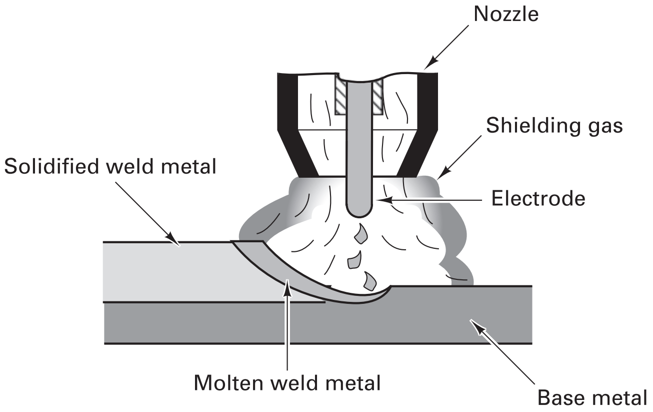

FIGURE 31-14 Schematic diagram of gas metal arc welding (GMAW). *(Courtesy of American Iron and Steel Institute, Washington, DC.)*

Electrode diameters range from 0.6 to 6.4 mm. The welding current, penetration depth, and process cost are all similar to the flux-cored process.

Because shielding is provided by the flow of gas, and fluxing and slag-forming agents are no longer required, the gas metal arc process can be applied to all metals. Argon, helium, and mixtures of the two are the primary shielding gases. When welding steel, some O_2 or CO_2 is usually added to improve the arc stability and reduce weld spatter. The cheaper CO_2 can also be used alone when welding steel, provided that a deoxidizing electrode wire is employed. Nitrogen and hydrogen may also be added to modify arc characteristics. Since these shielding gases only provide protection and do not remove existing contamination, starting cleanliness is critical to the production of a good weld.

The specific shielding gases can have considerable effect on the stability of the arc, the metal transfer from the electrode to the work, and also the heat transfer behavior, penetration, and tendency for undercutting (weld pool extending laterally beneath the surface of the base metal). Helium produces the hottest arc and deepest penetration. Argon is intermediate, and CO_2 yields the lowest arc temperatures and shallowest penetrations. Since argon is heavier than air, it tends to blanket the weld area, enabling the use of low gas flow rates. The lighter-than-air helium generally requires higher flow rates than either argon or carbon dioxide.

Electronic controls can be used to alter the welding current, enabling further control of the metal transfer mechanism, shown previously in Figure 31-9. *Short-circuit transfer* (GMAW-S) is promoted by the lowest currents and voltages (14 to 21 volts) and the use of CO_2 shield gas. The advancing electrode makes direct contact with the weld pool, and the short circuit causes a rapid rise in current. Big molten globs form on the tip of the electrode and then separate, forming a gap between the electrode and workpiece. This gap reinitiates a brief period of arcing, but the rate of electrode advancement exceeds the rate of melting in the arc, and another short circuit occurs. The power conditions oscillate between arcing and short circuiting at a rate of 20 to 200 cycles per second. Short-circuit transfer is preferred when joining thin materials and can be used in all welding positions, but it suffers from a high degree of spatter.

If the voltage and amperage are increased, the mode becomes one of *globular transfer*. The electrode melts from the heat of the arc, and metal drops form, with a diameter approximately equal to that of the electrode wire. Gravity and electromagnetic forces then transfer the drops to the workpiece at a rate of several per second. Since gravity plays a role in metal transfer, there is a definite limitation on the positions of welding. With even higher currents and voltages (25 to 32 volts and about 200 amps), argon gas shielding, and DCEP conditions, *spray transfer* (GMAW-ST) occurs. Small droplets emerge from a pointed electrode at a rate of hundreds per second. Because of their small size and the greater electromagnetic effects, the droplets are easily propelled across the arc in any direction, irrespective of the effects of gravity. Spray transfer is accompanied by deep penetration and low spatter. The biggest problem with out-of-position welding may be keeping the rather large molten weld pool in place until it solidifies.

Pulsed spray transfer (GMAW-P) was invented in the 1960s to overcome some of the limitations of conventional spray transfer. In this mode, a low welding current is first used to create a molten globule on the end of the filler wire. A burst of high current then "explodes" the globule and transfers the metal across the arc in the form of a spray. By alternating low and high currents at a rate of 60 to 600 times per second, the filler metal is transferred in a succession of rapid bursts, similar to the emissions of a rapidly squeezed aerosol atomizer. With the pulsed form of deposition, there is less heat input to the weld, and the weld temperatures are reduced. Thinner material can be welded, distortion is reduced, workpiece discoloration is minimized, heat-sensitive parts can be welded, high-conductivity metals can be joined, electrode life is extended, electrode cooling techniques may not be required, and fine microstructures are produced in the weld pool. Welds can be made in all positions, and the use of pulsed power lowers spattering and improves the safety of the process. The high speed of the process is attractive for productivity, and the energy or power required to produce a weld is lower than with other methods (reduced cost). Controls can be adjusted to alter the shape of the weld pool and vary the penetration.

In general, the gas metal arc process is fast and economical and currently accounts for over half of all weld metal deposition. There is no frequent change of electrodes as with the shielded metal arc process. No flux is required, and no slag forms over the weld. Thus, multiple-pass welds can be made without the need for intermediate cleaning. The process can be readily automated, and the lightweight, compact welding unit lends itself to robotic manipulation. A direct-current electrode-positive (DCEP) arc is generally used because of its deep penetration, spray transfer, and the ability to produce smooth welds with good profile. Process variables include type of current, current magnitude, shielding gas, electrode diameter, electrode composition, electrode stickout (extension beyond the gun), welding speed, welding voltage, and arc length. Table 31-5 provides a process summary for gas metal arc welding.

In a process modification known as advanced gas metal arc welding (AGMAW), a second power source is used to preheat the filler wire before it emerges from the welding torch. Less arc heating is needed to produce a weld, so less base metal is melted, producing less dilution of the filler metal and less penetration.

Another recent modification is the use of flat electrode wire, typically having a rectangular cross section of about 4 mm by 0.5 mm. By having a larger surface area participating in the arc, deposition rate is similar to a two-wire feed with only a single-wire delivery system. The arc is also asymmetric. Orienting the wire perpendicular to the weld seam produces a wide, shallow weld pool, suitable for bridging gaps and often eliminating the need to weave during deposition. A narrower, deeper weld pool results when the wire is parallel to the weld. Varying the angle between parallel and perpendicular generates a spectrum of weld-pool geometries.

SUBMERGED ARC WELDING

No shielding gas is used in the *submerged arc welding (SAW)* process, depicted in Figure 31-15. Instead, a thick layer of granular flux is deposited just ahead of a solid bare-wire consumable electrode, and the arc is maintained beneath the blanket of flux with only a few small flames being visible. A portion of the flux melts and acts to remove impurities from the rather large pool of molten metal, while the unmelted excess provides additional

TABLE 31-5 Process Summary: Gas Metal Arc Welding (GMAW)

Heat source	Electric arc

shielding. The molten flux solidifies into a glasslike covering over the weld. This layer, along with the flux that is not melted, provides good thermal insulation. The slow cooling of the weld metal helps to produce soft, ductile welds. Upon further cooling, the solidified flux cracks loose from the weld (due to the differential thermal contraction) and is easily removed. The unmelted granular flux is recovered by a vacuum system and reused.

Submerged arc welding is most suitable for making flat-butt or fillet welds in low-carbon steels (0.3% carbon). With some preheat and postheat precautions, medium-carbon and alloy steels and some cast irons, stainless steels, copper alloys, and nickel alloys can also be welded. The process is not recommended for high-carbon steels, tool steels, aluminum, magnesium, titanium, lead, or zinc. The reasons for this incompatibility are somewhat varied, including the unavailability of suitable fluxes, reactivity at high temperatures, and low sublimation temperatures.

Because the arc is totally submerged, high welding currents can be used (600 to 2000 A). High welding speeds, high deposition rates, deep penetration, and high cleanliness (due to the flux action) are all characteristic of submerged arc welding. A welding speed of 0.75 m/min in 2.5-cm-thick steel plate is typical. Single-pass welds can be made with penetrations up to 2.5 cm (1.0 in.), and greater thicknesses can be joined by multiple passes. Because the metal is deposited in fewer passes than with alternative processes, there is less possibility of entrapped slag or voids, and weld quality is further enhanced. For even higher deposition rates, multiple electrode wires can be employed.

Limitations to the process include the need for extensive flux handling, possible contamination of the flux by moisture (leading to porosity in the weld), the large volume of slag that must be removed, and shrinkage problems due to the large weld pool. The high heat inputs can produce large grain size structures, and the slow cooling rate

TABLE 31-6 Process Summary: Submerged Arc Welding (SAW)

Weld profile (D/W)	1
Current	<1000 amps
Max. penetration	25 mm
Assets	High-quality welds, high deposition rates
Limitations	Requires slag removal, difficult for overhead and out-of-position welding, joints often require backing plates

may enable segregation and possible hydrogen or hot cracking. Welding is restricted to the horizontal position, since the flux and slag are held in place by gravity. In addition, chemical control is quite important, since the electrode material often contributes over 70% of the molten weld region.

The electrodes are generally classified by composition and are available in diameters ranging from 1 to 10 mm (0.045 to $^3/_8$ in.). The larger electrodes can carry higher currents and enable more rapid deposition, but penetration is shallower. The welding of alloy steels can be performed in several ways: solid wire electrodes of the desired alloy, plain-carbon electrodes with the alloy additions being incorporated into the flux, or tubular metal electrodes with the alloy additions in the hollow core. Various fluxes are also available and are selected for compatibility with the weld metal. All are designed to have low melting temperatures, good fluidity, and brittleness after cooling.

In a modification of the submerged arc process known as *bulk welding*, iron powder is first deposited into the joint (ahead of the flux) as a means of increasing deposition rate. A single weld pass can then produce enough filler metal to be equivalent to seven or eight conventional submerged arc passes.

Table 31-6 provides a summary of the submerged arc welding process.

STUD WELDING

Stud welding (SW) is an arc-welding process used to attach studs, screws, pins, or other fasteners to a metal surface. A special gun is used, such as the one shown in Figure 31-16. The inserted stud acts as an electrode, and a DC arc is established between the end of

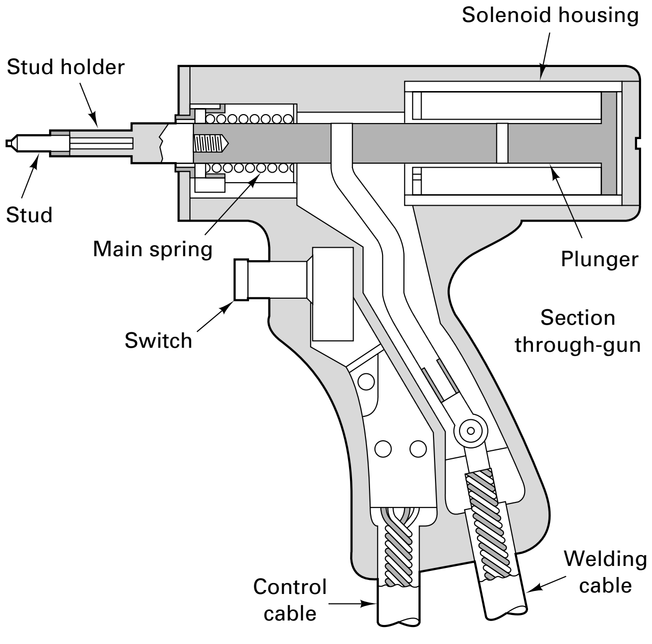

FIGURE 31-16 Diagram of a stud welding gun. *(Courtesy of American Machinist.)*

FIGURE 31-17 (Left) Types of studs used for stud welding. (Center) Stud and ceramic ferrule. (Right) Stud after welding and a section through a welded stud. *(Courtesy of Nelson Stud Welding Co, Elyria, OH)*

the stud and the workpiece. After a small amount of metal is melted, the two pieces are brought together under light pressure and allowed to solidify. Automatic equipment controls the arc, its duration, and the application of pressure to the stud.

Figure 31-17 shows some of the wide variety of studs that are specially made for this process. Many contain a recessed end that is filled with flux. A ceramic ferrule, such as the one shown in the center photo of Figure 31-17, may be placed over the end of the stud before it is positioned in the gun. During the arc, the ferrule serves to concentrate the heat and isolate the hot metal from the atmosphere. It also confines the molten or softened metal and shapes it around the base of the stud, as shown in the photo on the right of Figure 31-17. After the weld has cooled, the brittle ceramic is broken free and removed. Since burn-off or melting reduces the length of the stud, the original dimensions should be selected to compensate.

Stud welding requires almost no skill on the part of the operator. Once the stud and ferrule are placed in the gun and the gun positioned on the work, all the operator has to do is pull the trigger. The cycle is executed automatically and takes less than one second. Thus the process is well suited to manufacturing and can be used to eliminate the drilling and tapping of many special holes. Production-type stud welders can produce over 1000 welds per hour.

■ 31.6 NONCONSUMABLE-ELECTRODE ARC WELDING

GAS TUNGSTEN ARC WELDING

Gas tungsten arc welding (GTAW) was formerly known as tungsten inert-gas (TIG) welding, or Heliarc welding when helium was the shielding gas. A nonconsumable tungsten electrode provides the arc but not the filler metal. Inert gas (argon, helium, or a mixture of them) flows through the electrode holder to provide a protective shield around the electrode, the arc, the pool of molten metal, and the adjacent heated areas. (*Note:* CO_2 cannot be used in this process since it provides inadequate protection for the hot tungsten electrode.) While argon is the most widely used gas, and produces a smoother, more stable arc, helium may be added to increase the heat input (higher welding speeds and deeper penetration). Helium alone may be preferred for overhead welding since it is lighter than air and flows upward.

The composition, diameter, length, and tip geometry (balled, pointed, or truncated cone) of the tungsten or tungsten-alloy electrode are selected based on the material being welded, the thickness of the material, and the type of current being used. The

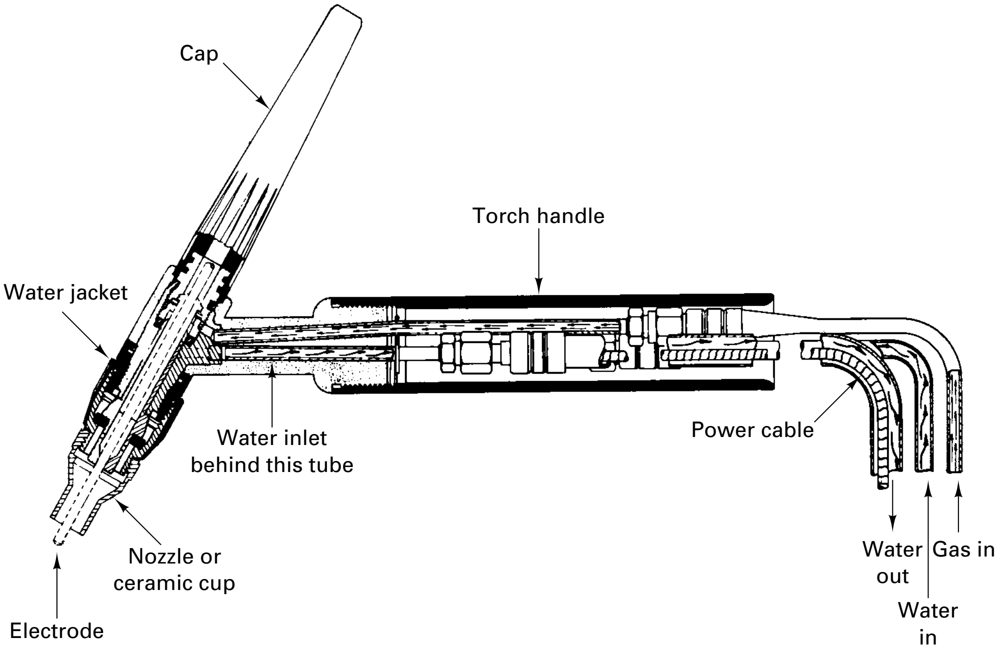

FIGURE 31-18 Welding torch used in nonconsumable-electrode, gas tungsten arc welding (GTAW), showing feed lines for power, cooling water, and inert-gas flow. *(Courtesy of Linde Division, Union Carbide Corporation, Houston, TX)*

tungsten is often alloyed with thorium oxide, zirconium oxide, cerium oxide, or lanthanum oxide to provide better current-carrying and electron-emission characteristics and longer electrode life. Since tungsten is not consumed at the temperatures of the arc, the arc length remains constant, and the arc is very stable and easy to maintain. Figure 31-18 shows a typical GTAW torch with cables and passages for gas flow, power, and cooling water.

In applications where there is a close fit between the pieces being joined, no filler metal may be needed. When filler metal is required, it is usually supplied as a separate rod, about a meter (3 ft) long and in various diameters, as illustrated in Figure 31-19. The filler metal is generally selected to match the chemistry and/or tensile strength of the metal being welded. When high deposition rates are desired, a separate resistance heating circuit can be provided to preheat the filler wire. As shown in Figure 31-20, the deposition rate of heated wire can be several times that of a cold wire. By oscillating the filler wire from side to side while making a weld pass, the deposition rate can be further increased. The hot-wire process is not practical when welding copper or aluminum, however, because it is difficult to preheat the low-resistivity filler wire.

With skilled operators, gas tungsten arc welding can produce high-quality welds that are very clean and scarcely visible. Since no flux is employed, no special cleaning or slag removal is required. However, the surfaces to be welded must be clean and free

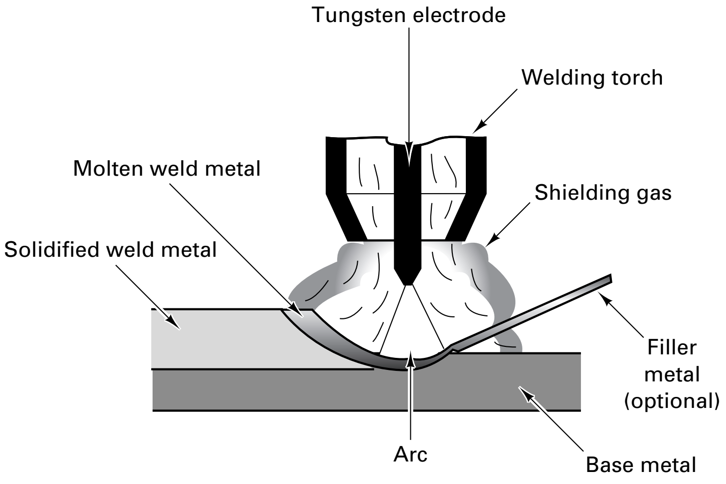

FIGURE 31-19 Diagram of gas tungsten arc welding (GTAW). *(Courtesy of American Iron and Steel Institute, Washington, DC.)*

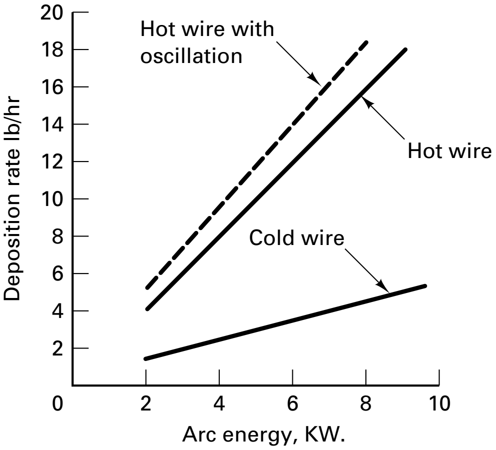

FIGURE 31-20 Comparison of the metal deposition rates in GTAW with cold, hot, and oscillating-hot filler wire. (*Courtesy of* Welding Journal.)

of oil, grease, paint, and rust, because the inert gas does not provide any cleaning or fluxing action. It is also important to control the arc length throughout the process. Since the arc is somewhat bell-shaped, decreasing the standoff distance will decrease the melt and heat-affected widths on the workpiece. However, if the hot tungsten electrode comes into contact with the workpiece or molten pool, it will contaminate the electrode.

All metals and alloys can be welded by this process, and the use of inert gas makes it particularly attractive for the reactive metals, such as aluminum, magnesium, and titanium, as well as the high-temperature refractory metals. Maximum penetration is obtained with direct-current electrode-negative (DCEN) conditions, although alternating current may be specified to break up surface oxides (as when welding aluminum). DCEP or reverse-polarity conditions are used only when welding thin pieces where shallow penetrations are desired. Weld currents should be kept low, since this mode tends to melt the tungsten electrode. Weld voltage is typically 20 to 40 volts, and weld current varies from less than 125 amps for DCEP to 1000 amps for DCEN. A high-frequency, high-voltage, alternating current is often superimposed on the regular AC or DC welding current to make it easier to start and maintain the arc. The pulsed arc gas tungsten arc welding (GTAW-P) modification offers all of the advantages previously cited for pulsed gas metal arc welding, including the ability to weld thinner materials due to the lower heat input and lower temperatures.

GTAW costs more than SMAW and is slower than GMAW. However, it produces a high-quality weld in a very wide range of thicknesses, positions, and geometries. The process has a medium rate of heat input, and the welds have a depth that is approximately equal to the width. The materials being welded are generally thinner than 6.5 mm ($^1/_4$ in.). Table 31-7 provides a process summary.

TABLE 31-7 Process Summary: Gas Tungsten Arc Welding (GTAW)

Heat source	Electric arc
Protection	Externally supplied shielding gas

Limitations	Slower than consumable electrode GMAW

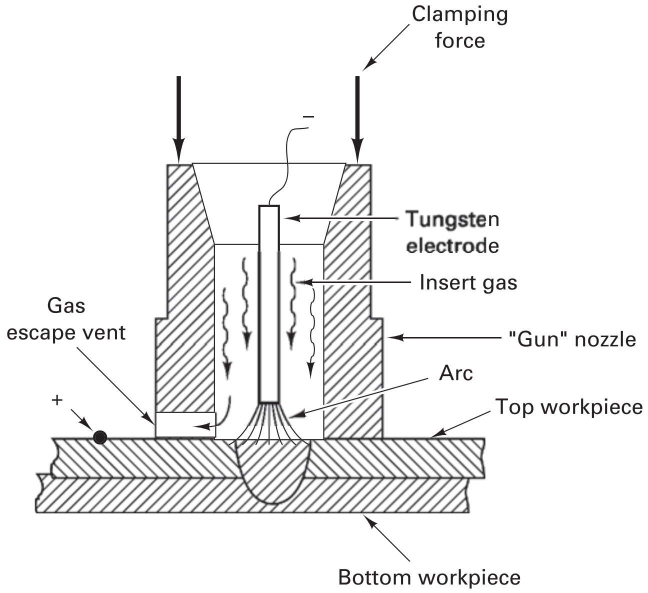

FIGURE 31-21 Process schematic of spot welding by the inert-gas-shielded tungsten arc process.

GAS TUNGSTEN ARC SPOT WELDING

A variation of gas tungsten arc welding can be used to produce *spot welds* between two pieces of metal where access is limited to one side of the joint or where thin sheet is being attached to heavier material. The basic procedure is illustrated in Figures 31-21 and 31-22. A modified tungsten inert-gas gun is used with a vented nozzle on the end. The nozzle is pressed firmly against the material, holding the pieces in reasonably good contact. (The workpieces must be sufficiently rigid to sustain the contact pressure.) Inert gas, usually argon or helium, flows through the nozzle to provide a shielding atmosphere. Automatic controls then advance the electrode to initiate the arc and retract it to the correct distance for stabilized arcing. The duration of arcing is timed automatically to produce an acceptable spot weld. The depth and size of the weld nugget are controlled by the amperage, time, and type of shielding gas.

In arc spot welding, the weld nugget begins to form at the surface where the gun makes contact. This is in contrast to the more standard resistance spot-welding methods, where the weld nugget forms at the interface between the two members. Each technique has its characteristic advantages and disadvantages.

FIGURE 31-22 Making a spot weld by the inert-gas-shielded tungsten arc process. *(Courtesy of Air Reduction Company Inc., New York, NY)*

PLASMA ARC WELDING

In *plasma arc welding (PAW)* the arc is maintained between a nonconsumable electrode and either the welding gun (*nontransferred arc*) or the workpiece (*transferred arc*), as illustrated in Figure 31-23. The nonconsumable tungsten electrode is set back within the "torch" in such a way as to force the arc to pass through or be contained within a small-diameter nozzle. An inert gas (usually argon) is forced through this constricted arc, where it is heated to a high temperature and forms a hot, fast-moving *plasma*. The emerging gas then transfers its heat to the workpiece and melts the metal. This flow is called the *orifice gas*. A second flow of inert gas surrounds the plasma column and provides shielding to the weld pool. When filler metal is needed, it is provided by an external feed.

Figure 31-24 presents a comparison of the nonconstricted arc of the GTAW process and the constricted arc of plasma arc welding, and shows the differences in temperature distribution. Plasma arc welding is characterized by a high rate of heat input and temperatures on the order of 16,500°C (30,000°F). This in turn offers fast welding speeds, narrow welds with deep penetration (a depth-to-width ratio of about 3), a narrow heat-affected zone, reduced distortion, and a process that is insensitive to variations in arc length since the plasma column is cylindrical. Welds can be made in all positions, and nearly all metals and alloys can be welded.

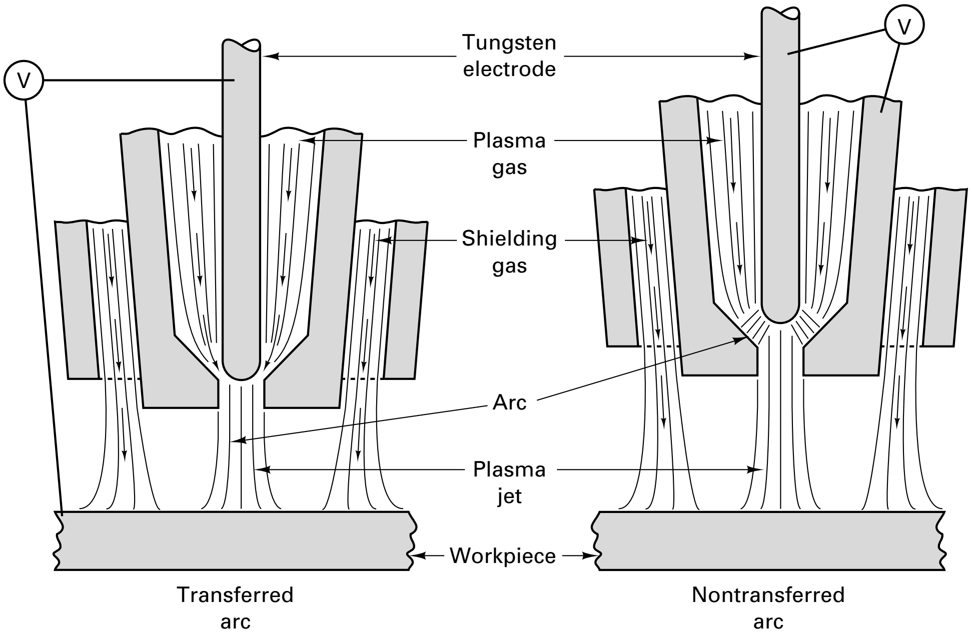

FIGURE 31-23 Two types of plasma arc torches. (Left) Transferred arc; (right) nontransferred arc.

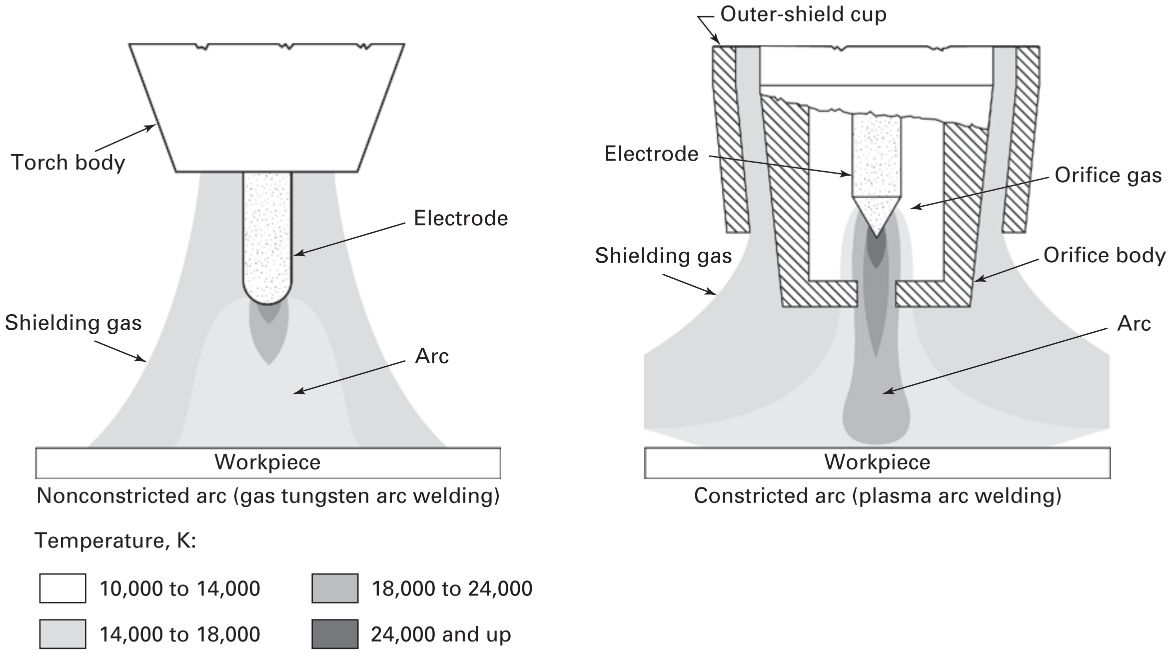

FIGURE 31-24 Comparison of the nonconstricted arc of gas tungsten arc welding and the constricted arc of the plasma arc process. Note the level and distribution of temperature. *(Courtesy ASM International, Materials Park, OH.)*

With a low-pressure plasma and currents between 20 and 100 amps, the metal simply melts and flows into the joint. At higher pressures and currents in excess of 100 amps, a "keyhole" effect occurs in which the plasma gas creates a hole completely through the sheet (up to 20 mm thick) that is surrounded by molten metal. As the torch is moved, liquid metal flows to fill the keyhole. If the gas pressure is increased even further, the molten metal is expelled from the region and the process becomes one of plasma cutting, which is discussed later in this chapter.

Many plasma torches employ a small, nontransferred arc within the torch to heat the orifice gas and ionize it. The ionized gas then forms a good conductive path for the main transferred arc. This dual-arc technique permits instant ignition of a low-current

TABLE 31-8 Process Summary: Plasma Arc Welding (PAW)

Heat source	Plasma arc
Protection	Externally supplied shielding gas
Electrode	Nonconsumable
Material joined	All common metals

Weld profile (D/W)	3
Current	<500 amps
Max. penetration	12–18 mm
Assets	Can have long arc length
Limitations	High initial equipment cost, large torches may limit accessibility

arc, which is more stable than that of an ordinary plasma torch. Separate DC power supplies are used for the pilot and main arcs. Microplasma, or needle arc, torches can operate with very low currents (0.1 to 20 A) and still produce stable arcs. They are quite useful for welding very thin sheet.

Table 31-8 provides a process summary for plasma arc welding.

31.7 WELDING EQUIPMENT

POWER SOURCES FOR ARC WELDING

Arc welding requires large electrical currents, often in the range of 100 to 1000 amps. The voltage is usually between 20 and 50 volts. Both DC and AC *power supplies* are available and generally employ the "drooping-voltage" characteristics shown in Figure 31-25. These characteristics are designed to minimize changes in welding current as the welding voltage fluctuates within anticipated limits.

In the past, most direct current units were gasoline- or diesel-powered motor-generator sets, and these are still used when welding is to be performed in remote locations. Most welding today, however, uses solid-state transformer-rectifier machines, such as the one shown in Figure 31-26. Operating on a three-phase electrical line, these machines can usually provide both AC and DC output.

If only AC welding is to be performed, relatively simple transformer-type power supplies can be used. These are usually single-phase devices with low power factors. When multiple machines are to be operated, as in a production shop, they are often connected to the various phases of a three-phase supply to help balance the load.

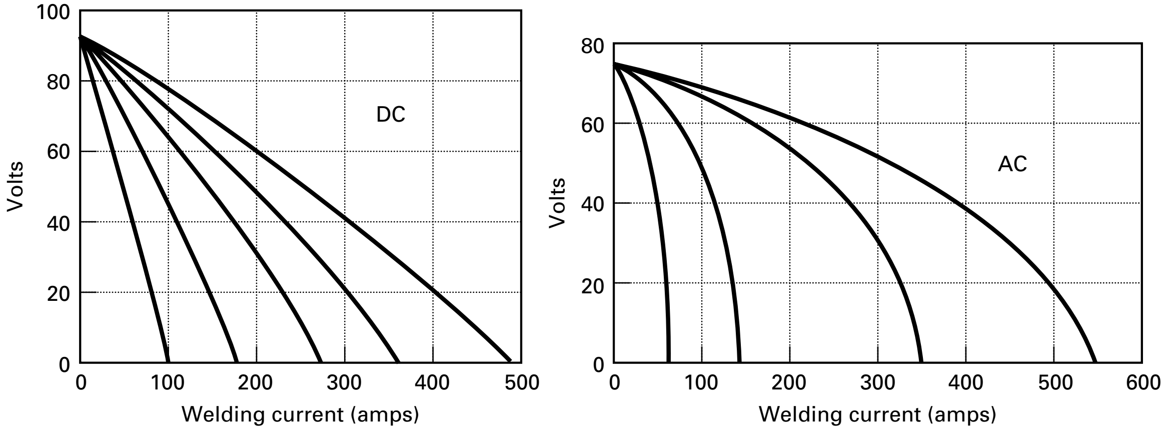

FIGURE 31-25 Drooping-voltage characteristics of typical arc-welding power supplies. (Left) Direct current; (right) alternating current.

FIGURE 31-26 Rectifier-type AC and DC welding power supply. *(Courtesy of Lincoln Electric Company, Cleveland, OH)*

Inverter-based power supplies, introduced in the 1980s, provide great flexibility. Through solid-state electronics, these AC machines can quickly modify the shape and frequency of the pulse waveform or momentarily change the power output. The square-wave technology currently being employed provides improved arc starts and more stable arcs. The percent of time in electrode negative or electrode positive can be adjusted, and output frequency can be varied from 20 to 250 Hz. Through feedback and logic control, the power supply can actually adjust to compensate for changes in a number of process variables.

JIGS, POSITIONERS, AND ROBOTS

Jigs or fixtures (also called *positioners*) are frequently used to hold the work in production welding. By positioning and manipulating the workpiece, the welding operations can often be performed in a more favorable orientation. Parts can also be mounted on numerically controlled (NC) tables that position them with respect to the welding tool.

Industrial robots have replaced humans for many welding applications. They can operate in hostile environments and are capable of producing high-quality welds in a repetitive mode.

31.8 ARC CUTTING

While oxygen torch cutting has been discussed earlier in this chapter, and laser cutting will be covered in a future chapter, there are a number of arc-cutting methods. Virtually all metals can be cut by some form of electric arc. In these processes the material is melted by the intense heat of the arc and then permitted, or forced, to flow away from the region of the slit or notch (*kerf*). Most of the techniques are simply adaptations of the arc-welding procedures discussed in this chapter. Each has its inherent characteristics and capabilities, including tolerance, thickness capability, kerf width, edge squareness, size of the heat-affected zone, and cost. Selection depends upon factors such as tolerance requirements, the subsequent processes that will be performed on the cut part, and the end use of the product.

CARBON ARC AND SHIELDED METAL ARC CUTTING

The carbon arc cutting (CAC) and shielded metal arc cutting (SMAC) methods use the arc from a carbon or shielded metal arc electrode to melt the metal, which is then removed from the cut by gravity or the force of the arc itself. These processes are generally limited to small shops, garages, and homes, where there is limited investment in equipment.

AIR CARBON ARC CUTTING

In air carbon arc cutting, the arc is again maintained between a carbon electrode and the workpiece, but high-velocity jets of air are directed at the molten metal from holes in the electrode holder. While there is some oxidation, the primary function of the air is to blow the molten material from the cut. Air carbon arc cutting is particularly effective for cutting cast iron and preparing steel plates for welding. Speeds up to 0.6 m/min are possible, but the process is quite noisy, and hot metal particles tend to be blown over a substantial area.

OXYGEN ARC CUTTING

In oxygen arc cutting (AOC), an electric arc and a stream of oxygen are combined to make the cut. The electrode is a coated ferrous-metal tube. The coated metal serves to establish a stable arc, while oxygen flows through the bore and is directed on the area of incandescence. With easily oxidized metals, such as steel, the arc preheats the base metal, which then reacts with oxygen, becomes liquefied, and is expelled by the oxygen stream.

GAS METAL ARC CUTTING

If the wire feed rate and other variables of gas metal arc welding (GMAW) are adjusted so that the electrode penetrates completely through the workpiece, cutting rather than welding will occur, and the process becomes gas metal arc cutting (GMAC). The wire feed rate controls the quality of the cut, and the voltage determines the width of the slit or kerf.

GAS TUNGSTEN ARC CUTTING

Gas tungsten arc cutting (GTAC) employs the same basic circuit and shielding gas as used in gas tungsten arc welding, with a high-velocity jet of gas added to expel the molten metal.

PLASMA ARC CUTTING

The torches used in plasma arc cutting (PAC) produce the highest temperatures available from any practical source. With the nontransferred type of torch, the arc column is completely within the nozzle, and a temperature of about 16,500°C (30,000°F) is obtained. With the transfer-type torch, the arc is maintained between the electrode and the workpiece, and temperatures can be as high as 33,000°C (60,000°F). Ionized gases flowing at these temperatures and near supersonic speeds are capable of cutting virtually any electrically conductive material simply by melting it and blowing it away from the cut.

Early efforts to employ this technique showed that the speed, versatility, and operating cost were far superior to those of the oxyfuel cutting methods. However, the early systems could not constrict the arc sufficiently to produce the quality of cut needed to meet the demands of manufacturing. Therefore, plasma arc cutting was generally limited to those materials that could not be cut by the oxidation type of cutting

FIGURE 31-27 Cutting sheet metal with a plasma torch. *(Courtesy of GTE Sylvania, Danvers, MA)*

techniques. In the 1970s radial impingement of water on the arc was found to produce the desired constriction. It provides an intense, highly focused source of heat, and water-injected torches can now cut virtually any metal in any position. Magnetic fields have also been used to constrict the arc and can produce high-quality cuts without the need for water impingement.

Compared to oxyfuel cutting, plasma cutting is more economical (cost per cut is a fraction of oxyfuel), more versatile (can cut all metals as easily as mild steel), and much faster (typically, five to eight times faster than oxyfuel). Cutting speeds up to 7.5 m/min have been obtained in 6-mm-thick aluminum and up to 2.5 m/min in 12.5-mm-thick steel. The combination of the extremely high temperatures and jetlike action of the plasma produces narrow kerfs and remarkably smooth surfaces, nearly as smooth as can be obtained by sawing. Plasma-cut surfaces are often within 2° of vertical, and surface oxidation is nearly eliminated by the cooling effect of the water spray. In addition, the heat-affected zone in the metal is only one-third to one-fourth as large as that produced by oxyfuel cutting, and a preheat cycle is not required in the cutting of steel. Heat-related distortion is extremely small.

Transferred-arc torches are usually used for cutting metals, while the nontransferred type are employed with the low-conductivity nonmetals. Ordinary air or inexpensive nitrogen can be used as the plasma gas for the cutting of all types of metal. Oxygen plasma systems were introduced in the 1980s and are used on carbon and low-alloy steel products with thicknesses ranging from 2 to 32 mm (up to $1^1/_4$ in.). When cutting thick sections (greater than 12 mm), an argon–hydrogen mixture may be preferred to provide a deeper-penetrating arc. A secondary flow of shielding gas (nitrogen, air, or carbon dioxide) may be used to help cool the torch, blow the molten metal away, shield the arc, and prevent oxidation of the cut surface. The arc-constricting water flow can also serve as a shielding medium.

During the 1990s *high-density*, or *precision plasma*, systems began to appear. Various designs are used to restrict the orifice (i.e., superconstrict the plasma), producing vertical edges (less than 1° taper), close tolerances ($^1/_3$ that of conventional), and dross-free plasma cutting of thin materials. The lower-amperage torches (10 to 100 amps) are limited to cutting carbon and low-alloy steels less than 16 mm ($^5/_8$ in.) thick and higher-performance metals (such as stainless and high-strength steels, nickel alloys, titanium, and aluminum) less than 12 mm ($^1/_2$ in.) thick. In addition, the cutting speeds are slower than conventional plasma cutting, but there is no reduction in the size of the heat-affected zone. *Pulsed plasma arc cutting*, another recent development, can reduce heat input to the workpiece while producing kerfs that are 50% narrower and cleaner edges on the cuts.

Combining a plasma torch with CNC manipulation can provide fast, clean, and accurate cutting, like that shown in Figure 31-27. In this process, the cutting table may be placed underwater as a means of reducing noise, air pollution, dust, and arc glare (dyes are placed in the water). Plasma arc torches can also be incorporated into punch presses to provide a manufacturing machine with outstanding flexibility in producing cut and punched products from a variety of materials.

Plasma arc cutting is also suitable for robot application. A single robot system can be used for both cutting and welding of intricate shapes and contours. Water constriction of the manipulated arc is a problem, however, making it important to select the right process parameters and type of gas for the particular application.

Table 31-9 compares the features of oxyfuel cutting, plasma arc cutting, and laser cutting.

31.9 METALLURGICAL AND HEAT EFFECTS IN THERMAL CUTTING

When used for cutting, the flame and arc processes expose materials to high localized temperatures and can produce harmful metallurgical effects. If the cut edges will be subsequently welded, or if they will be removed by machining, there is little cause for concern. When the edges are retained in the finished product, consideration should be given to the effects of cutting heat and their interaction with the applied loads. In some cases, additional steps may be required to avoid or overcome harmful consequences.

TABLE 31-9 Cutting Process Comparison: Oxyfuel, Plasma Arc, and Laser

Feature	Oxyfuel Cutting	Plasma Arc Cutting	Laser Cutting
Preferred materials	Carbon steel and titanium	All electrically conductive metals	Metal, plastic, wood, textiles
Quality of cut	Average	Similar to oxyfuel Almost as good as laser on thin material	Good quality—best for plate material less than $^{1}/_{2}$-inch thick
Thickness range			
1. Steel	3/16 inch to unlimited	26 ga. to 3 inch	Foil to 1 inch
2. Stainless	not used	26 ga. to 5 inch	20 ga. to $^{3}/_{4}$ inch
3. Aluminum	not used	22 ga. to 6 inch	20 ga. to $^{3}/_{4}$ inch
Cutting speed or time	Long preheat is required	Fast cutting	Slower than plasma, but faster than oxyfuel

For carbon steels with less than 0.25% carbon, thermal cutting does not produce serious metallurgical effects. However, in steels of higher carbon content, the metallurgical changes can be quite significant, and preheating and/or postheating may be required. For alloy steels, additional consideration should be given to the effects of the various alloy elements.

Because of the low rate of heat input, oxyacetylene cutting will produce a rather large *heat-affected zone*. The arc-cutting methods produce intermediate effects that are quite similar to those of arc welding. Plasma arc cutting is so rapid, and the heat is so localized, that the original properties of a metal are only modified within 1.5 mm of the cut.

All of the thermal cutting processes produce some *residual stresses*, with the cut surface generally in tension. Except in the case of thin sheet, warping should not occur. However, if subsequent machining removes only a portion of the cut surface, or does not penetrate to a sufficient depth, the resulting imbalance in residual stresses can induce distortion. It may be necessary to remove all cut surfaces to a substantial depth to ensure good dimensional stability.

Thermal cutting can also introduce geometrical features into the edge. All flame- or arc-cut edges are rough to varying degrees and thus contain notches that can act as stress raisers and reduce the endurance or fracture strength. If cut edges are to be subjected to high or repeated tensile stresses, the cut surfaces and the heat-affected zone should be removed by machining or at least subjected to a stress-relief heat treatment.

■ Review Questions

1. Why does an oxyfuel-gas welding torch usually have a flame with two distinct regions?
2. What is the location of the maximum temperature in an oxyacetylene flame?
3. What function or functions are performed by the outer zone of the welding flame?
4. What three types of flames can be produced by varying the oxygen–fuel ratio?
5. Which type of oxyfuel flame is most commonly used?
6. What are some of the attractive features of MAPP gas?
7. Why might a welder want to change the tip size (or orifice diameter) in an oxyacetylene torch?
8. What is filler metal, and why might it be needed to produce a joint?
9. What is the role of a welding flux?
10. Oxyfuel-gas welding has a low rate of heat input. What are some of the adverse features that result from the slow rate of heating?
11. What are some of the more attractive features of the oxyfuel-gas process?
12. How does pressure gas welding differ from the oxyfuel-gas process?
13. In what way does the torch cutting of ferrous metals differ from cutting nonoxidizing metals?
14. Why might it be possible to use only an oxygen lance to cut hot steel strands as they emerge from a continuous casting operation?
15. How does an oxyacetylene cutting torch differ from an oxyacetylene welding torch?
16. What are some of the ways in which cutting torches can be manipulated?
17. What modification must be incorporated into a cutting torch to permit it to cut metal underwater?
18. If a curved plate is to be straightened by flame straightening, should the heat be applied to the longer or shorter surface of the arc? Why?
19. Why does the flame-straightening process not work for thin sheets of metal?
20. What sorts of problems plagued early attempts to develop arc welding?
21. What are the three basic types of current and polarity that are used in arc welding?
22. What is the difference between a consumable and nonconsumable electrode? For which processes does a filler metal have to be added by a separate mechanism?
23. What are the three types of metal transfer that can occur during arc welding?
24. What are some of the process variables that must be specified when setting up an arc-welding process?
25. What are the four primary consumable electrode arc-welding processes?
26. What are some general properties of the consumable-electrode arc-welding processes?
27. What are some of the functions of the electrode coatings used in shielded metal arc welding?
28. How are welding electrodes commonly classified, and what information does the designation usually provide?
29. Why are shielded metal arc electrodes often baked just prior to welding?
30. What is the function of the slag coating that forms over a shielded metal arc weld?
31. What benefit can be obtained by placing iron powder in the coating of shielded metal arc electrodes that will be used to weld ferrous metals?
32. Why are shielded metal arc electrodes generally limited in length, forcing the process to be one of intermittent operation?
33. Why is the shielded metal arc-welding process limited to low welding currents and shallow penetration?
34. What are some of the attractive features of the shielded metal arc-welding process?
35. What is the advantage of placing the flux in the center of an electrode (flux-cored arc welding) as opposed to a coating on the outside (shielded metal arc welding)?
36. What feature enables the welding current in FCAW to be higher than in SMAW?
37. What are some of the advantages of gas metal arc welding compared to the shielded metal arc process?
38. Describe the relative performance of argon, helium, and carbon dioxide gases in creating a high-temperature arc and promoting weld penetration.
39. Which of the metal transfer mechanisms is most used in arc welding?
40. Describe the metal transfer that occurs during pulsed arc gas metal arc welding.
41. What are some of the benefits that can be obtained by the reduced heating of the pulsed arc process?
42. What are some of the primary process variables in the gas metal arc-welding process?
43. What benefits can be gained by using a rectangular cross-section electrode wire as opposed to a round one?
44. What are some of the functions of the flux in submerged arc welding?
45. What are some of the attractive features of submerged arc welding? Major limitations?
46. What is the primary goal or objective in bulk welding?
47. What is the primary objective of stud welding?
48. What is the function of the ceramic ferrule placed over the end of the stud in stud welding?
49. What is the current (or proper) designation for MIG welding? TIG welding? Heliarc welding?
50. What types of shielding gases are used in the gas tungsten arc process?
51. What can be done to increase the rate of filler metal deposition during gas tungsten arc welding?
52. What are some of the attractive features of gas tungsten arc welding?
53. How are the spot welds produced by gas tungsten arc spot welding different from those made by conventional resistance spot welding?
54. How is the heating of the workpiece during plasma arc welding different from the heating in other arc-welding techniques?
55. What are the two different gas flows in plasma arc welding?
56. What are some of the attractive features of plasma arc welding?
57. What is the primary difference between plasma arc welding and plasma arc cutting?
58. What are the attractive features or benefits of an inverter-based power supply?
59. What is the kerf in thermal cutting operations?
60. What is the purpose of the oxygen in oxygen arc cutting?

61. Why is plasma arc cutting an attractive way of cutting high-melting-point materials?
62. What techniques can be used to constrict the arc in plasma arc cutting, producing a narrower, more controlled cut?
63. Compared to oxyfuel cutting, what are some of the attractive features of the plasma technique?
64. Describe the relative size of the heat-affected zone for the various cutting processes: oxyfuel, arc, and plasma.
65. Why might the residual stresses induced during cutting operations be objectionable?
66. Why might it be wise to machine away the thermally cut edge and heat-affected zone of metal that will be used as a stressed machine part?

Chapter 31 CASE STUDY

Bicycle Frame Construction and Repair

As a new employee in a bicycle shop, you learn that customers will frequently seek advice regarding various types of bicycle repair. Bent or broken frames appear to be a common problem, and you learn that inexpensive bicycles generally have frames made from welded low-carbon steel tubing. This material can be heated to straighten and is easily repair welded using a wide variety of welding techniques. As you move to the more costly lightweight or high-performance models, you learn that repair is generally not quite as simple.

a. In one case, the frame of a high-quality, lightweight bicycle had been fabricated from aluminum-alloy tubing, with joints made by adhesive bonding of the tubes to connectors that incorporate either internal lugs or external sleeves. When the frame fractured near one of the joints, the owner contacted a local auto body shop and requested that a repair be made using conventional gas tungsten arc welding. The welder was familiar with the welding of aluminum, and the repair seemed to be of good quality. Shortly thereafter, however, the frame broke again. This time the fracture was adjacent to the repair weld and the characteristics of the break were different. While the first fracture was somewhat brittle in nature, the second appeared to be more ductile, with evidence of metal flow prior to fracture. Since the second fracture occurred in the tube material, not the weld itself, the welder felt that the failure was not related to the attempted repair and that the material in the tubing must be defective.
   1. If the material had been cold-drawn aluminum tubing (i.e., strain hardened), explain what may have occurred during the repair. What is the probable cause of the second fracture? Was the weld in any way defective? Was the second failure related to the welding repair?
   2. If the tubing had been strengthened by an age-hardening heat treatment, could the same results have occurred? Explain.
   3. Is there a better means of repairing the original fracture? What would have been your recommendation?

b. Titanium offers the strength of heat-treated steel at approximately half of the weight. Magnesium, while not as strong as steel or aluminum, is the lightest-weight engineering metal. Would these materials be appropriate for bicycle frame construction? If so, how would they be assembled?

c. If the bicycle frame deflects, motion of the cyclist and related energy are wasted. Therefore, a rigid frame is quite desirable. Beryllium is an extremely rigid, lightweight metal. Could it be used as a material for bicycle frames? How would you fabricate the tubing and assemble the frame?

d. Composite materials can be used to produce tailored sets of properties. Fiber-reinforced composites can have extremely high rigidity in the direction of fiber orientation, coupled with extremely light weight. If you were to assemble a composite frame using fiber-reinforced tubing, such as graphite fiber-reinforced epoxy, how would you join the assembly?

e. Premium-quality racing bikes (such as Tour De France models) have used one-piece carbon-fiber composite frames (i.e. no joints at all!). What is the benefit of such a design?

CHAPTER 32

RESISTANCE AND SOLID-STATE WELDING PROCESSES

32.1 INTRODUCTION

As indicated in the lists of Figures 30-1 and 30-2, there are a number of welding and cutting processes that utilize heat sources other than oxyfuel flames and electric arcs, and some use no heat source at all. We begin this chapter with a group of processes that use electrical resistance heating to form the joint. A second group of processes, known as solid-state welding processes, create joints without any melting of the workpiece or filler material.

32.2 THEORY OF RESISTANCE WELDING

In *resistance welding*, heat and pressure are combined to induce coalescence. *Electrodes* are placed in contact with the material, and electrical resistance heating is used to raise the temperature of the workpieces and the interface between them. The same electrodes that supply the current also apply the pressure, which is usually varied throughout the weld cycle. A certain amount of pressure is applied initially to hold the workpieces in contact and thereby control the electrical resistance at the interface. When the proper temperature has been attained, the pressure is increased to induce coalescence. Because pressure is utilized, coalescence occurs at a lower temperature than that required for oxyfuel gas or arc welding. In fact, melting of the base metal does not occur in many resistance-welding operations. Resistance-welding processes might well be considered as a form of solid-state welding, although they are not officially classified as such by the American Welding Society.

In some resistance-welding processes, additional pressure is applied immediately after coalescence to provide a certain amount of forging action. Accompanying the deformation is a certain amount of grain refinement. Additional heating can also be employed after welding to provide tempering and/or stress relief.

The required temperature can often be attained, and coalescence can be achieved, in a few seconds or less. Resistance welding, therefore, is a very rapid and economical process, extremely well suited to automated manufacturing. No filler metal is required, and the tight contact maintained between the workpieces excludes air and eliminates the need for fluxes or shielding gases.

HEATING

The heat for resistance welding is obtained by passing a large electrical current through the workpieces for a short period of time. The amount of heat input can be determined by the basic relationship:

$$H = I^2Rt$$

where:

H = total heat input in joules

I = current in amperes

R = electrical resistance of the circuit in ohms

t = length of time during which current is flowing in seconds

It is important to note that the workpieces actually form part of the electrical circuit, as illustrated in Figure 32-1, and that the total resistance between the electrodes consists of three distinct components:

1. The bulk resistance of the electrodes and workpieces—the upper electrode, upper workpiece, lower workpiece and lower electrode
2. The contact resistance between the electrodes and the workpieces—between the upper electrode and upper workpiece and the lower electrode and lower workpiece
3. The resistance between the surfaces to be joined, known as the *faying surfaces*

Since the maximum amount of heat is generated at the point of maximum resistance, it is desirable to have this be the location where the weld is to be made. Therefore, it is essential to keep components 1 and 2 as low as possible with respect to resistance 3. The bulk resistance of the electrodes is always quite low, and that of the workpieces is determined by the type and thickness of the metal being joined. Because of the large areas involved and the relatively high electrical conductivity of most metals, the workpiece resistances are usually much less than the contact or interface values. Resistance 2 (the resistance between the electrodes and workpieces) can be minimized by using electrode materials that are excellent electrical conductors and by controlling the size and shape of the electrodes and the applied pressure. Any change in the pressure between the electrodes and workpieces, however, also affects the contact between the faying surfaces. Therefore, only limited control of the electrode-to-work resistance can be obtained by pressure variation.

The final resistance, that between the faying surfaces, is a function of (1) the quality (surface finish or roughness) of the surfaces; (2) the presence of nonconductive scale, dirt, or other contaminants; (3) the pressure; and (4) the contact area. These factors must all be controlled if uniform resistance welds are to be produced.

As indicated in Figure 32-2, the objective of resistance welding is to bring both of the faying surfaces to the proper temperature, while simultaneously keeping the remaining material and the electrodes relatively cool. Water cooling is usually used to keep the electrode temperature low and thereby extend their useful life.

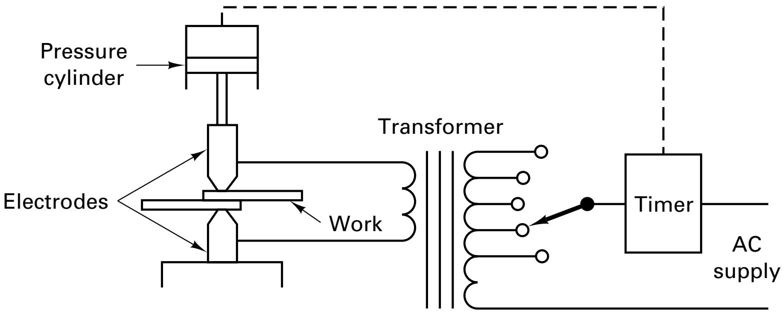

FIGURE 32-1 The basic resistance welding circuit.

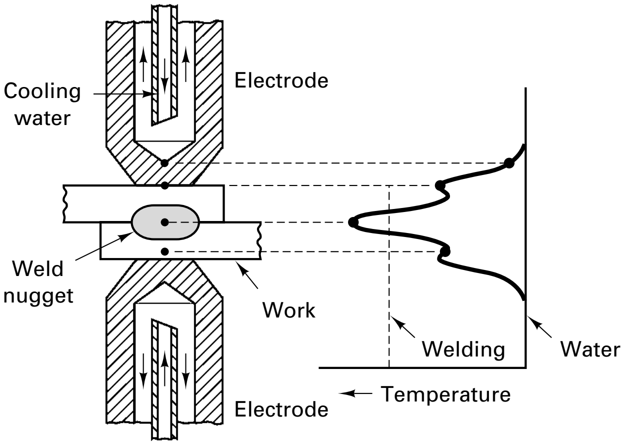

FIGURE 32-2 The desired temperature distribution across the electrodes and workpieces during resistance welding.

PRESSURE

Because the applied pressure promotes a forging action, resistance welds can be produced at lower temperatures than welds made by other processes. Controlling both the magnitude and timing of the pressure, however, is very important. If too little pressure is used, the contact resistance will be high and surface burning or pitting of the electrodes may result. If excessive pressure is applied, molten or softened metal may be expelled from between the faying surfaces or the electrodes may indent the softened workpiece. Ideally, moderate pressure should be applied to hold the workpieces in place and establish proper resistance at the interface prior to and during the passage of the welding current. The pressure should then be increased considerably just as the proper welding temperature is attained. This completes the coalescence and forges the weld to produce a fine-grained structure.

On small, foot-operated machines, only a single spring-controlled pressure is used. On larger, production-type welders, the pressure is generally applied through controllable air or hydraulic cylinders.

CURRENT AND CURRENT CONTROL

While surface conditions and pressure are important variables, the temperature achieved during resistance welding is primarily determined by the magnitude and duration of the welding current. The various resistances change as current flows and the material heats. The bulk resistances of metal increase as temperature rises, and the contact resistances decrease as the metal softens and pressure improves the contact. Since the best conditions are the initial ones, high currents and short time intervals are generally preferred. The weld location can attain the desired temperature while minimizing the amount of heat generated in or dissipated to the adjacent material.

In production-type welders, the magnitude, duration, and timing of both current and pressure can be programmed to follow specified cycles. Figure 32-3 shows a relatively simple cycle for a resistance weld that includes both forging and postheating operations.

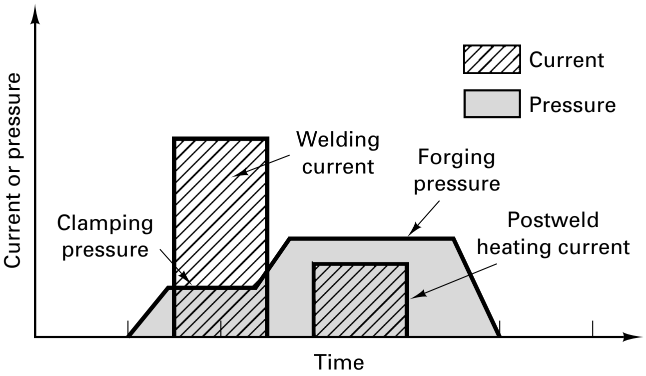

FIGURE 32-3 A typical current and pressure cycle for resistance welding. This cycle includes forging and postheating operations.

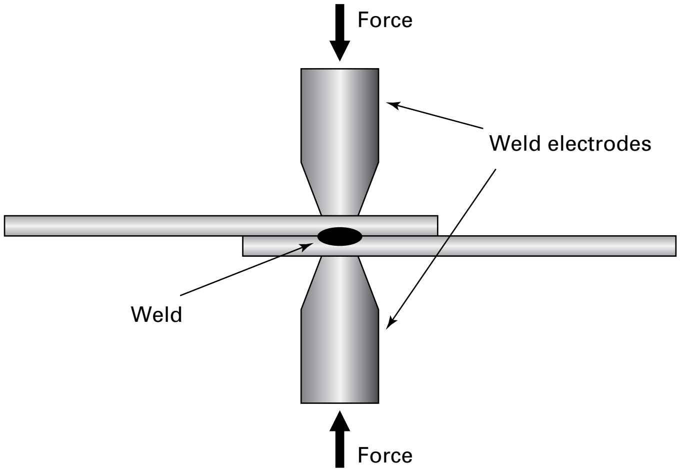

FIGURE 32-4 The arrangement of the electrodes and workpieces in resistance spot welding.

The quality of the final weld, therefore, often depends more on the development of a proper schedule and the subsequent setup, adjustment, and maintenance of equipment than it does on operator skill.

POWER SUPPLY

Since the overall resistance in the welding circuits can be quite low, high currents are generally required to produce a resistance weld. Power transformers convert the high-voltage, low-current line power to the high-current (up to 100,000 amps), low-voltage (0.5 to 10 volts) power required for welding. Smaller machines may utilize single-phase circuitry, but the larger units generally operate on three-phase power. Many resistance welders use DC welding current, obtained through solid-state rectification of the three-phase power. These machines reduce the current demand per phase, give a balanced load, and produce excellent welds.

32.3 RESISTANCE WELDING PROCESSES

RESISTANCE SPOT WELDING

Resistance spot welding (RSW) is the simplest and most widely used form of resistance welding, providing a fast, economical means of joining overlapped materials that will not require subsequent disassembly. Even with all of the advances in technology, resistance spot welding is still the dominant method for joining sheet material, and the average steel-bodied automobile contains between 2000 and 5000 spot welds. Figure 32-4 presents a schematic of the process. Overlapped metal sheets are positioned between water-cooled electrodes, which have reduced areas at the tips to produce welds that are usually from 1.5 to 13 mm ($^1/_{16}$ to $^1/_2$ in.) in diameter. The electrodes close on the work, and the controlled cycle of pressure and current is applied to produce a weld at the metal interface. The electrodes are then opened, and the work is removed.

A satisfactory spot weld, like the one shown in Figure 32-5, consists of a *nugget* of coalesced metal formed between the faying surfaces. There should be little indentation

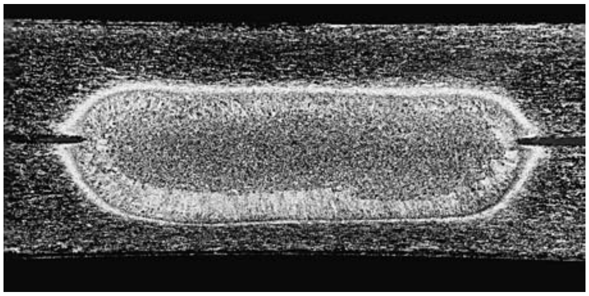

FIGURE 32-5 A spot-weld nugget between two sheets of 1.3-mm (0.05-in.) aluminum alloy. The nugget is not symmetrical because the radius of the upper electrode is greater than that of the lower electrode. *(Courtesy Lockheed Martin Corporation, Bethesda, MD.)*

FIGURE 32-6 Tear test of a satisfactory spot weld, showing how failure occurs outside of the weld.

of the metal under the electrodes. As shown in Figure 32-6, the strength of the weld should be such that in a tensile or tear test, the weld will remain intact while failure occurs in the heat-affected zone surrounding the nugget. Sound spot welds can be obtained with excellent consistency if proper current density and timing, electrode shape, electrode pressure, and surface conditions are maintained,

Spot-Welding Equipment. A variety of spot-welding equipment is available to meet the needs of production operations. For light-production work where complex current–pressure cycles are not required, a simple *rocker-arm machine* is often used. The lower electrode arm is stationary, while the upper electrode, mounted on a pivot arm, is brought down into contact with the work by means of a spring-loaded foot pedal. Rocker-arm machines are available with throat depths up to about 1.2 m (48 in.) and transformer capacities up to 50 kVa. They are used primarily on steel.

Larger spot welders, and those used at high production rates, are generally of the press type, as shown in Figure 32-7. On these machines, the movable electrode is controlled by an air or hydraulic cylinder, and complex pressure cycles can be programmed. Capacities up to 500 kVa with a 1.5-m (60-in.) throat depth are quite common. Special-purpose press-type welders can employ multiple welding heads to make up to 200 simultaneous spot welds in less than 60 seconds.

Quite often, the desired products are too large to be manipulated and positioned on a welding machine. Portable spot-welding guns have been instrumental in extending the process to such applications. The guns are connected to a stationary power supply and control unit by flexible air hoses, electrical cables, and water-cooling lines. They can be used in a manual fashion or installed on industrial robots where programmed positioning enables quality spot welds to be produced in a highly automated fashion. Robotic spot welding is currently the most common means of joining sheet metal components in the automotive industry.

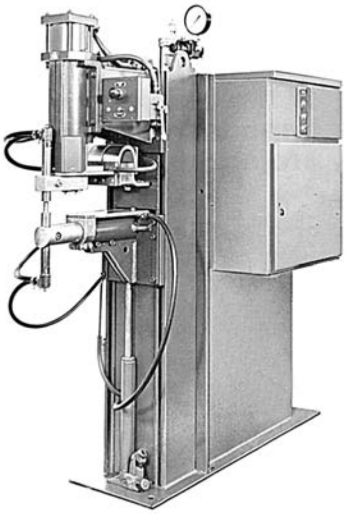

FIGURE 32-7 Single-phase, air-operated, press-type resistance welder with microprocessor control. *(Courtesy Sciaky Inc., Chicago, IL.)*

Electronic advances in the late 1980s enabled the welding transformer to be integrated into the welding gun. By transforming the power immediately adjacent to the area of use, the small integral transformer guns, or *transguns*, offer reduced power losses and enhanced process efficiency. However, if accurate positioning is required in an articulated system like an industrial robot, the added weight of the integral transformer may become a disadvantage. Servomotors have also been incorporated into a variety of spot-welding machines to control the electrode positioning, speed of closure, level of applied torque or pressure, and rate at which the load is applied.

Electrodes. Resistance spot-welding electrodes must conduct the welding current to the work, set the current density at the weld location, apply force, and help dissipate heat during the noncurrent portions of the welding cycle. Electrical and thermal conductivity properties are important considerations for electrode selection. Hot compressive strength must be sufficient to resist electrode deformation during the application of pressure. In addition, the electrode should not melt under welding conditions and should be of a composition that does not alloy with the material being welded—a

TABLE 32-1 Metal Combinations That Can Be Spot Welded

Metal	Aluminum	Brass	Copper	Galvanized Iron	Iron (Wrought)	Monel	Nichrome	Nickel	Nickel Silver	Steel	Tin Plate	Zinc

phenomenon that promotes sticking or galling and electrode wear. The Resistance Welder Manufacturers Association (RWMA) has standardized various electrode geometries and has approved a variety of electrode materials, including copper-base alloys, refractory metals, and refractory–metal composites.

Spot-Weldable Metals and Geometries. While steel is clearly the most common metal that is spot welded, one of the greatest advantages of the process is that virtually all of the commercial metals can be joined, and most of them can be joined to each other. In only a few cases do the welds tend to be brittle. Table 32-1 shows some of the many combinations of metals that can be successfully spot welded.

While spot welding is primarily used to join wrought sheet material, other forms of metal can also be welded. Sheets can be attached to rolled shapes and steel castings, as well as some types of nonferrous die castings. Most metals require no special preparation, except to be sure that the surface is free of corrosion and is not badly pitted. For best results, aluminum and magnesium should be cleaned immediately prior to welding by some form of mechanical or chemical technique. Metals that have high electrical conductivity require clean surfaces to ensure that the electrode-to-metal resistance is low enough for adequate temperature to be developed within the metal itself. Silver and copper are especially difficult to weld because of their high thermal conductivity. Higher welding currents coupled with water cooling of the surrounding material may be required if adequate welding temperatures are to be obtained.

When the two pieces being joined are of the same thickness, the practical limit for spot welding is about 3 mm ($^{1}/_{8}$ in.) for each sheet. Sheets of differing thickness can also be joined, and thin pieces can be attached to material that is considerably thicker than 3 mm. When metals of different thickness or different conductivity are to be welded, however, a larger electrode or one with higher conductivity is often used against the thicker or higher-resistance material to ensure that both workpieces will be brought to the desired temperature in a simultaneous fashion.

RESISTANCE SEAM WELDING

Resistance seam welds (RSEW) can be made by two distinctly different processes. In the first process, sheet metal segments are joined to produce gas- or liquid-tight vessels, such as gas tanks, mufflers, and simple heat exchangers. The weld is made between overlapping sheets of metal, and the seam is simply a series of overlapping spot welds, like

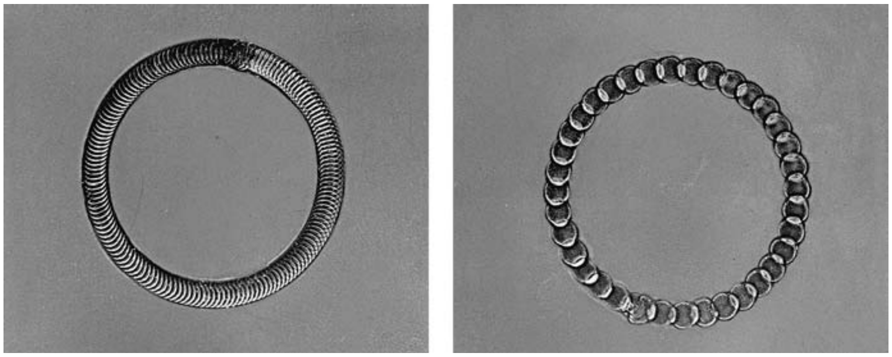

FIGURE 32-8 Seam welds made with overlapping spots of varied spacing. *(Courtesy Taylor-Winfield Corporation, Brookfield, OH.)*

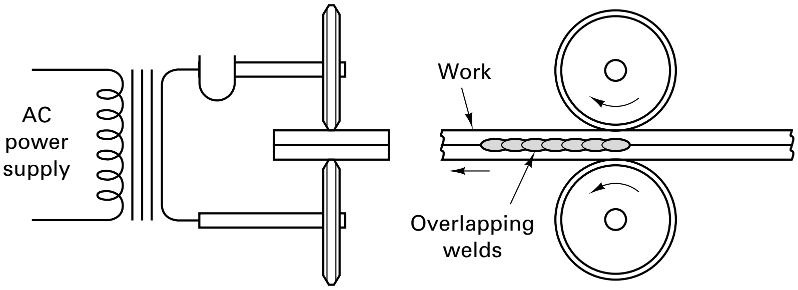

FIGURE 32-9 Schematic representation of the seam-welding process.

those shown in Figure 32-8. The basic equipment is the same as for spot welding, except that the electrodes now assume the form of rotating disks, like those shown schematically in Figure 32-9. As the metal passes between the electrodes, timed pulses of current form the overlapping welds. The timing of the welds and the movement of the work are controlled to ensure that the welds overlap and the workpieces do not get too hot. The welding current is usually a bit higher than in conventional spot welding (to compensate for the short circuit of the adjacent weld), and the workpiece is often cooled by a flow of air or water. In a variation of the process, a continuous current is passed through the rotating electrodes to produce a continuous seam. This form of seam welding is best suited for thin materials, but metals up to 6 mm ($^1/_4$ in.) can be joined. A typical welding speed is about 2 m/min for thin sheet.

The second type of resistance seam welding, known as *resistance butt welding*, is used to produce butt welds between thicker metal plates. The electrical resistance of the abutting metals is still used to generate heat, but high-frequency current (up to 450 kHz) is now employed to restrict the flow of current to the surfaces to be joined and their immediate surroundings. (*Note:* This is similar to the results obtained in the parallel process of high-frequency induction heating.) When the abutting surfaces attain the desired temperature, they are pressed together to form a weld.

Resistance butt welding is used extensively in the manufacture of pipes and tubes, as illustrated in Figure 32-10, but the process is also used to construct simple structural shapes from sections of plate. Material from 0.1 mm (0.004 in.) to more than 20 mm ($^3/_4$ in.) in thickness can be welded at speeds up to 80 m/min (250 fpm). The combination of high-frequency current and high welding speed produces a very narrow heat-affected zone. Almost any type or combination of metal can be welded, including difficult dissimilar metals and the high-conductivity metals, such as aluminum and copper.

PROJECTION WELDING

In a mass-production operation, conventional spot welding is plagued by two significant limitations. Because the small electrodes provide both the high currents and the required pressure, the electrodes generally require frequent attention to maintain their geometry. In addition, the process is designed to produce only one spot weld at a time. When increased strength is required, multiple welds are often needed, and this means

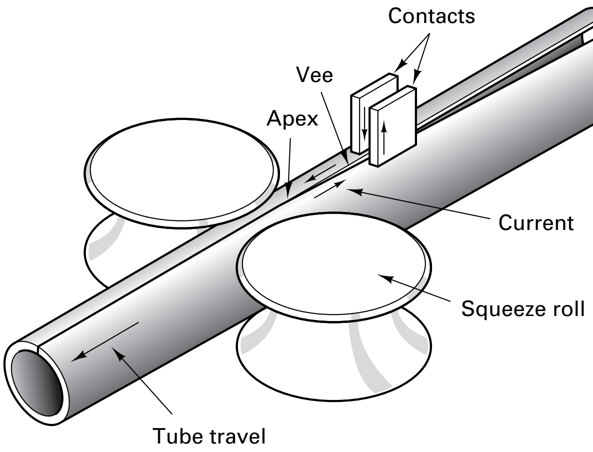

FIGURE 32-10 Using high-frequency AC current to produce a resistance seam weld in butt-welded tubing. Arrows from the contacts indicate the path of the high-frequency current.

multiple operations. *Projection welding* (RPW) provides a means of overcoming these limitations.

Figure 32-11 illustrates the principle of projection welding. A dimple is *embossed* into one of the workpieces at the location where a weld is desired. The two workpieces are then placed between large-area electrodes in a press machine, and pressure and current are applied as in spot welding. Since the current must flow through the points of contact (i.e., the dimples), the heating is concentrated where the weld is desired. As the metal heats and becomes plastic, the pressure causes the dimple to flatten and form a weld.

Because the projections are press formed into the sheet, they can often be produced during previous blanking and forming operations with virtually no additional cost. Moreover, the dimples or projections can be made in almost any shape—round, oval, or circular ring-shaped—to produce welds of shapes that optimize a given design. It is important, however, that the shape be such that the weld will form outward from the center of the projection. Since the heat tends to develop in the piece with the projections, it is best to incorporate them into the heavier of the two pieces to be joined or the metal with the higher conductivity.

Multiple dimples can be incorporated into a sheet, enabling multiple welds to be produced at one time. The number of projections is limited only by the ability of the machine to provide the required current and pressure and the need to uniformly distribute both. If more than three projections are to be made at one time, however, the height of all projections should be uniform to ensure uniform contact and heating.

An attractive feature of projection welding is the fact that it does not require special equipment. Conventional spot-welding machines can be converted to projection welding simply by changing the size and shape of the electrodes. In addition, projection welding leaves no indentation mark on the exterior surfaces, a definite advantage over spot welding when good surface appearance is required.

In a variation of the process, projection welding can also be used to attach bolts and nuts to other metal parts. Contact is made at a projection that has been machined or forged onto the bolt or nut. Current is applied, and the pieces are pressed together to form a weld.

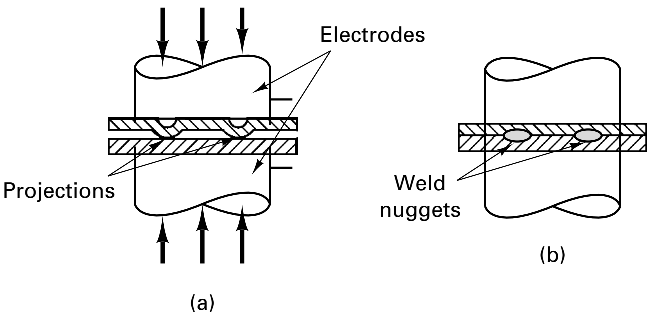

FIGURE 32-11 Principle of projection welding (a) prior to application of current and pressure and (b) after formation of the welds.

32.4 ADVANTAGES AND LIMITATIONS OF RESISTANCE WELDING

The resistance-welding processes have a number of distinct advantages that account for their wide use, particularly in mass-production operations:

1. They are very rapid.
2. The equipment can often be fully automated.
3. They conserve material, since no filler metal, shielding gases, or flux is required.
4. There is minimal distortion of the parts being joined.
5. Skilled operators are not required.
6. Dissimilar metals can be easily joined.
7. A high degree of reliability and reproducibility can be achieved.

The primary limitations of resistance welding include:

1. The equipment has a high initial cost.
2. There are limitations to the thickness of material that can be joined (generally less than 6 mm or $^1/_4$ inch) and the type of joints that can be made (mostly *lap joints*). Lap joints tend to add weight and material.
3. Access to both sides of the joint is usually required to apply the proper electrode force or pressure.
4. Skilled maintenance personnel are required to service the control equipment.
5. For some materials, the surfaces must receive special preparation prior to welding.

The resistance-welding processes are among the most common techniques for high-volume joining. The rapid heat inputs, short welding times, and rapid quenching by both the base metal and the electrodes can produce extremely high cooling rates in and around the weld. While these conditions can be quite attractive for most nonferrous metals, untempered martensite can form in steels containing more than 0.15% carbon. For these materials, some form of postweld heating is generally required to eliminate possible brittleness.

Table 32-2 provides a process summary for resistance welding.

32.5 SOLID-STATE WELDING PROCESSES

FORGE WELDING

Being the most ancient of the welding processes, *forge welding* (FOW) has both historical and practical value, as it helps us to understand how and why the modern welding practices were developed. The armor makers of ancient times occupied positions of prominence in their society, largely because of their ability to join pieces of metal into single, strong products. The village blacksmith was a more recent master of forge welding. With his hammer and anvil, coupled with skill and training, he could create a wide variety of useful shapes from metal.

TABLE 32-2 Process Summary: Resistance Welding (RW)

Heat source	Electrical resistance heating with high current
Protection	None; isolation of weld site is adequate
Material joined	All common metals (steel, aluminum, and copper)
Rate of heat input	High
Weld profile (D/W)	Does not apply
Maximum penetration	Does not apply
Assets	High speed; Small HAZ; no flux, filler metal, or shielding gas required; adaptable to mass production
Limitations	Equipment is more expensive than arc welding; welds are weaker than arc welds; requires access to both sides of a joint

Using a charcoal forge, the blacksmith heated the pieces to be welded to a practical forging temperature and then prepared the ends by hammering so that they could be properly fitted together. The ends were then reheated and dipped into a borax flux. Heating was continued until the blacksmith judged (by color) that the workpieces were at the proper temperature for welding. They were then withdrawn from the heat and either struck on the anvil or hit by the hammer to remove any loose scale or impurities. The ends to be joined were then overlapped on the anvil and hammered to the degree necessary to produce an acceptable weld.

As the two pieces reduce in thickness, they spread in width, resulting in the creation of new, fresh, uncontaminated metal surface. As these surfaces are being created, the hammer blows also provide the necessary pressure to produce instant coalescence. Thus, by the correct combination of heat and deformation, a competent blacksmith could produce joints that might be every bit as strong as the original metal. However, because of the crudeness of the heat source, the uncertainty of temperature, and the difficulty in maintaining metal cleanliness, a great amount of skill was required and the results were highly variable.

FORGE-SEAM WELDING

Although forge welding has largely been replaced by other joining methods, a large amount of *forge-seam welding* is still used in the manufacture of pipe. As previously presented in Chapter 17, a heated strip of steel is first formed into a cylinder, and the edges are simply pressed together in either a lap or a butt configuration. Welding is the result of pressure and deformation when the metal is pulled through a conical welding bell or passed between welding rolls.

COLD WELDING

Cold welding is a variation of forge welding that uses no heating but produces metallurgical bonds by means of room-temperature plastic deformation. The surfaces to be joined are first cleaned and placed in contact. They are then subjected to high localized pressure, sufficient to cause about 30 to 50% cold work. While some heating will occur due to the severe deformation, the primary factor in producing coalescence is the high pressure acting on newly formed surface material. The cold-welding process is generally confined to the joining of small parts made from soft, ductile metal, such as the electrical connections shown in Figure 32-12.

ROLL WELDING OR ROLL BONDING

In the *roll-welding* or *roll-bonding* (ROW) process, two or more sheets or plates of metal are joined by passing them simultaneously through a rolling mill. As the materials are reduced in thickness, the length and/or width must increase to compensate. The newly

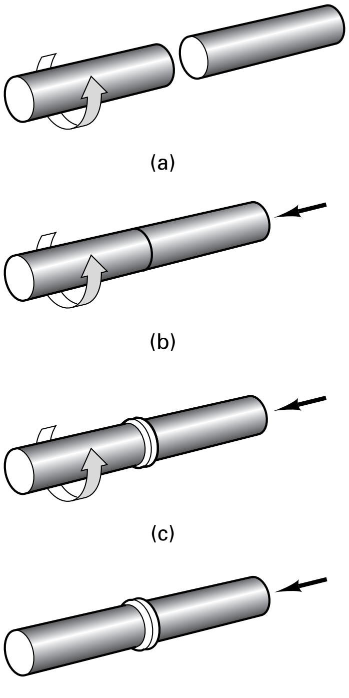

FIGURE 32-14 Sequence for making a friction weld. (a) Components with square surfaces are inserted into a machine where one part is rotated and the other is held stationary. (b) The components are pushed together with a low axial pressure to clean and prepare the surfaces. (c) The pressure is increased, causing an increase in temperature, softening, and possibly some melting. (d) Rotation is stopped and the pressure is increased rapidly, creating a forged joint with external flash.

created uncontaminated interfaces are pressed together by the rolls and coalescence is produced. Roll bonding can be performed either hot or cold and can be used to join either similar or dissimilar metals (such as the Alclad aluminums—a skin of high-corrosion-resistance aluminum over a core of high-strength aluminum—or conventional steel with a stainless steel cladding). The resulting bond can be quite strong, as evidenced by the roll-bonded "sandwich" material used in the production of various U.S. coins.

By precoating select portions of one interface surface with a material that prevents bonding, the roll-bonding process can be used to produce sheets that have both bonded and nonbonded areas. Subsequent heating in an oven or furnace can cause the no-bond coating to volatilize. The resulting pressure expands the no-bond regions, producing flow paths for gases or liquids. A common example of this technique is in the manufacture of refrigerator freezer panels, like those shown in Figure 32-13, where inexpensive sheet metal is used to produce structural panels that also serve to conduct the coolant.

FRICTION WELDING AND INERTIA WELDING

In *friction welding* (FRW) the heat required to produce the joint is generated by friction heating at the interface. The components to be joined are first prepared to have smooth, square-cut surfaces. As shown in Figure 32-14, one piece is then held stationary while the other is mounted in a motor-driven chuck or collet and rotated against the first piece at high speed. A low contact pressure may be applied initially to permit cleaning of the surfaces by a burnishing action. The pressure is then increased, and contact friction quickly generates enough heat to soften both components and raise the abutting surfaces to the welding temperature. As soon as this temperature is reached, rotation is stopped and the pressure is further increased to complete the weld. The softened metal is squeezed out to the edges of the joint, forming a *flash*, which can be removed by subsequent machining. Clean, uncontaminated material is left on the interface, and the force creates a "forged" structure in the joint. Friction welding has been used to join steel bars up to 20 cm (8 in.) in diameter and tubes of even larger diameter. The process is also ideal for welding dissimilar metals with very different melting temperatures and physical

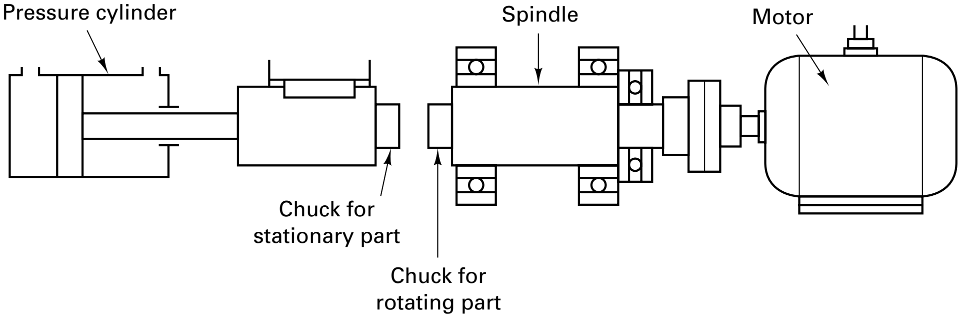

FIGURE 32-15 Schematic diagram of the equipment used for friction welding. *(Courtesy of* Materials Engineering.*)*

properties, such as copper to aluminum, titanium to copper, and nickel alloys to steel. Figure 32-15 shows a schematic of the equipment required for friction welding.

Inertia welding is a modification of friction welding where the moving piece is attached to a rotating flywheel (Figure 32-16). The flywheel is brought to a specified rotational speed, storing a predetermined amount of kinetic energy, and is then separated from the driving motor. The rotating and stationary components are then pressed together, and the kinetic energy of the flywheel is converted into frictional heat at the interface between the two pieces. The weld is formed when the flywheel stops its motion and the pieces remain pressed together. Since the conditions of inertia welding are easily duplicated, welds of extremely consistent quality can be produced and the process can be readily automated.

With inertia welding, the time required to form a weld can be very short, often on the order of several seconds. Because of the high rate of heat input and the limited time for heat to flow away from the joint, both the weld and heat-affected zones are usually very narrow. Oxides and other surface impurities tend to be displaced radially into the upset *flash*, which is generally removed after welding. Because virtually all of the energy is converted to heat, the process is very efficient. No material is melted, so joints can be formed with a wide variety of metals or combinations of metals, including some not normally considered compatible, such as aluminum to steel. Graphite-bearing cast irons, free-machining metals, and some bearing materials must be excluded, since the graphite, lead, or free-machining additive smears across the surface, reducing the friction heating and preventing good solid-state bonding. One, or preferably both, of the components must be sufficiently ductile (when hot) to permit deformation during the forging stage. Grain size tends to be refined during the hot deformation, so the strength of the weld is about the same as that of the base metal. In addition, the friction processes are environmentally attractive since no smoke, fumes, or gases are generated, and no fluxes are required.

Because of the rotational motion, both of the above processes require that one of the components have rotational symmetry. They are used primarily to join round bars or tubes of the same size or connect bars or tubes to flat surfaces. By using linear, orbital, or angular reciprocating motions, friction welding can be extend to noncircular shapes, such as square and rectangular bars. Figure 32-17 shows some typical friction-welded parts.

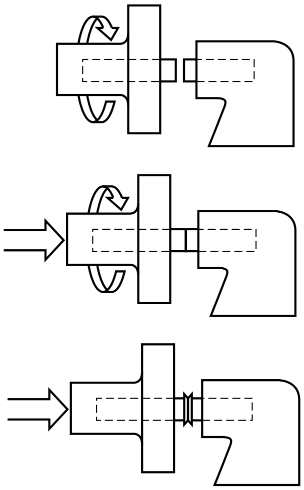

FIGURE 32-16 Schematic representation of the various steps in inertia welding. The rotating part is now attached to a large flywheel.

FRICTION-STIR WELDING

A relatively new process, first performed by the Welding Institute of Great Britain in 1991, *friction-stir welding* (FSW) has matured rapidly and currently offers significant benefits compared to conventional methods. As illustrated in Figure 32-18, a nonconsumable welding tool (containing a shoulder and protruding cylindrical or tapered probe or pin) is rotated at several hundred revolutions per minute. It is then lowered into the interface between pieces of rigidly clamped material, and frictional heat is generated along the top surface (under the rotating shoulder) and along the surfaces of the rotating probe. After a period of time for heating and softening, the tool is driven along the material interface. As the probe traverses, a plasticized region is continually created. This softened material is swept along the periphery of the pin, flows to the back of the advancing probe, and coalesces to form a solid-state bond. The most common application is the formation of butt welds, usually between plates of the lower-melting-point metals (both wrought and cast alloys) or thermoplastic polymers.

FIGURE 32-17 Some typical friction-welded parts. (Top) Impeller made by joining a chrome–moly steel shaft to a nickel–steel casting. (Center) Stud plate with two mild steel studs joined to a square plate. (Bottom) Tube component where a turned segment is joined to medium-carbon steel tubing. *(Courtesy of Newcor Bay City, Division of Newcor, Inc., Royal Oak, MI.)*

Weld quality is excellent. The extensive plastic deformation creates a refined grain structure with no entrapped oxides or gas porosity. As a result, the strength, ductility, fatigue life, and toughness of the resulting weld are all quite good. Welds in aircraft aluminum are 30 to 50% stronger than those formed by arc welding. Since no material is melted, both wrought and cast alloys can be joined, and they can be joined to each other. No filler material or shielding gas is required, and the process is environmentally friendly (no fumes, weld spatter, or arc glare). Because of the high energy efficiency, total heat input and associated distortion and shrinkage are all low. Joint preparation is minimal, and surface oxides need not be removed. Welding can be performed in any position and requires access to only one side of the plate. Gaps up to 10% of the material thickness can be accommodated with no reduction in weld quality or performance. Weld speed, however, is slower than in most fusion processes.

As shown in Figure 32-18, the key process variables include probe geometry (diameter, depth, and profile), shoulder diameter, rotation speed, downward force, travel speed, and possible tilt to the tool.

Friction-stir welding has been used to weld nearly all of the wrought aluminum alloys, including some that are classified as "unweldable" by fusion processes. Aluminum plates up to 65 mm ($2^{1}/_{2}$ in.) thick have been successfully welded from a single side, and aluminum up to 75 mm (3 in.) thick has been welded by a two-sided process. Copper, lead, magnesium, titanium, and zinc have all been successfully welded, along with thin steel plate and some combinations of dissimilar materials.

As an indication of process capability, the Eclipse 500, a six-passenger, short-hop air taxi, built by Eclipse Aviation of Albuquerque, New Mexico, contains over 135 meters (5300 inches) of friction-stir welds on the aluminum fuselage and wing panel assemblies, eliminating over 60% of the usual rivets. Various thermoplastics, including polyethylene, polypropylene, nylon, polycarbonate, and ABS, have also been successfully welded, with several exhibiting as-welded strengths exceeding 95% of the tensile strength of the base material.

In an extension known as *friction-stir processing*, the thermomechanical features of friction-stir are used for purposes other than creating a joint. By tracking the stir tool through the material with overlapping passes, ultrafine grain size ($<10\ \mu$m) can be produced that enables superplastic forming at comparatively high strain rates. While superplasticity is usually limited to thin sheets, thicker material can now be made superplastic, and by stirring only selected locations, large parts can be made from less expensive conventional materials, with enhanced formability in only the needed locations. In other applications, key surfaces of large castings can be enhanced by the passage of the probe. The cast structure, with possible microporosity and segregation, is replaced by a fine, homogeneous, wrought microstructure. Strength, ductility, corrosion resistance, and fatigue resistance are all improved. Fusion welds can be stirred to replace the cast structure with a fine, worked structure, removing any weld defects and enhancing properties. Reinforcement particles can be stirred into a material to create a

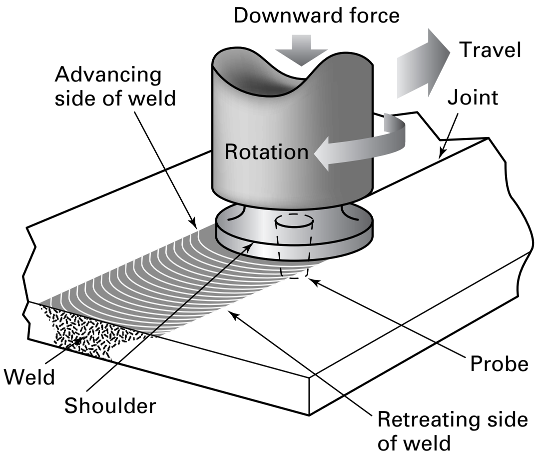

FIGURE 32-18 Schematic of the friction-stir welding process. The rotating probe generates frictional heat, while the shoulder provides additional friction heating and prevents expulsion of the softened material from the joint. (*Note*: To provide additional forging action and confine the softened material, the tool may be tilted so the trailing edge is lower than the leading segment.)

particle-reinforced composite surface on a standard alloy substrate. Powder products of unique composition can be brought to full density with attractive strength and ductility. In a modification known as friction-stir channeling, a slight upward helix is incorporated onto the surface of the rotating probe. As the probe rotates, material is displaced upward, creating a continuous subsurface channel, such as those used for conveying cooling water.

One of the photos in Figure 32-19 shows a friction-stir weld in aluminum plate, viewed from the top. The other shows the structural changes induced by a friction-stir pass through an aluminum-alloy casting. Note the significant refinement in structure. Table 32-3 summarizes some of the attractive features of the friction-stir process.

TABLE 32-3 Attractive Features of Friction-Stir Welding

Metallurgical benefits:

- Excellent weld quality
- Applicable to a wide range of materials, including some "nonweldable" by fusion methods
- Solid-state process
- Low distortion of the workpiece
- High joint strength
- No loss of alloy elements
- Fine microstructure
- No cracking

Environmental benefits:

- No shielding gas is required
- No surface cleaning is required
- No solvent degreasing is used
- No fumes, gases, or smoke is produced
- Postweld finishing is often unnecessary
- No arc glare or reflected laser beams

Energy benefits:

- Welds produced with far less energy than in other processes
- Enables weight reduction in aircraft, automobiles, and ships

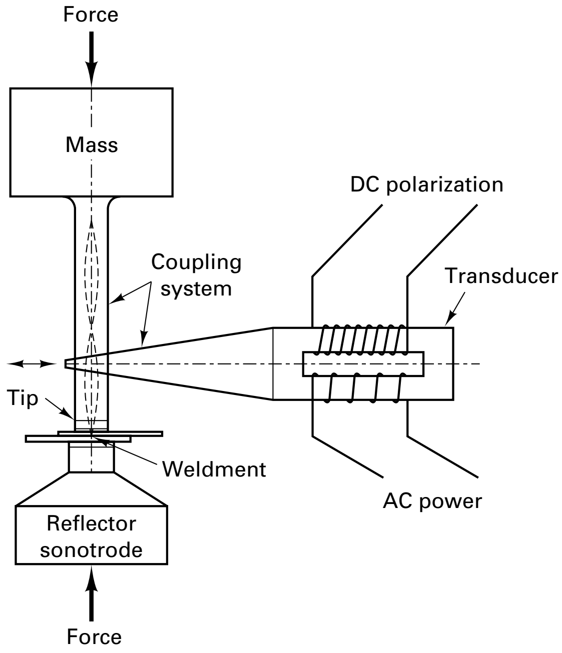

FIGURE 32-20 Diagram of the equipment used in ultrasonic welding.

ULTRASONIC WELDING

In *ultrasonic welding* (USW), coalescence is produced by the localized application of high-frequency (10,000 to 200,000 Hz) shear vibrations to surfaces that are held together under rather light normal pressure. Although there is some heating at the faying surfaces, the interface temperature rarely exceeds one-half of the melting point of the material (on an absolute-temperature scale). Instead, it appears that the rapid reversals of stress along the contact interface break up and disperse the oxide films and surface contaminants, allowing the clean metal surfaces to coalesce into a high-strength bond.

Figure 32-20 depicts the basic components of the ultrasonic welding process. The ultrasonic transducer is essentially the same as that employed in ultrasonic machining. It is coupled to a force-application system that contains a welding tip on one end, either stationary for spot welds or rotating for seams. The pieces to be welded are placed between this tip and a reflecting anvil, thereby concentrating the vibratory energy.

Ultrasonic welding is restricted to the lap joint welding of thin materials—sheet, foil, and wire—or the attaching of thin sheets to heavier structural members. The maximum thickness is about 2.5 mm (0.1 in.) for aluminum and 1.0 mm (0.04 in.) for harder metals. As indicated in Table 32-4, the process is particularly attractive because of the number of metals and combinations of dissimilar metals that can be joined. It is even possible to bond metals to nonmetals, such as aluminum to ceramics or glass. Because the temperatures are low and no arcing or current flow is involved, the process is often preferred for heat-sensitive electronic components. Intermetallic compounds seldom form, and there is no contamination of the weld or surrounding area. The equipment is simple and reliable, and only moderate skill is required of the operator. Surface preparation is less than for most competing processes (such as resistance welding), and less energy is needed to produce a weld. Typical applications include joining the dissimilar metals in bimetallics, making microcircuit electrical contacts, welding refractory or reactive metals, bonding ultra-thin metal, and encapsulating explosives or chemicals.

Ultrasonic welding has also been used to produce spot and seam welds on thin plastics and to seal foil or plastic envelopes and pouches. Compared to joining methods that employ solvents or adhesives, the ultrasonic method is considerably faster and results in products with cleaner surfaces.

DIFFUSION WELDING

Diffusion welding (DFW) or *diffusion bonding* occurs when properly prepared surfaces are maintained in contact under sufficient pressure and time at elevated temperature.

TABLE 32-4 Metal Combinations Weldable by Ultrasonic Welding

Metal	Aluminum	Copper	Germanium	Gold	Molybdenum	Nickel	Platinum	Silicon	Steel	Zirconium
Aluminum	x	x	x	x	x	x	x	x	x	x

Gold				x		x	x	x		
Molybdenum					x	x			x	x
Nickel						x	x		x	x
Platinum							x		x	
Silicon										
Steel									x	x
Zirconium										x

In contrast to the deformation-welding methods, plastic flow is limited and the principal bonding mechanism is atomic diffusion. A well-prepared interface can be viewed as a planar grain boundary with intervening voids and impurities. Under low pressure and elevated temperature, atomic diffusion will provide the necessary void shrinkage and grain boundary migration to form a metallurgical bond.

The quality of a diffusion weld depends on the surface condition of the materials, temperature, time at temperature, pressure, and the possible use of intermediate material layers, which can either promote diffusion or prevent the formation of undesirable intermetallic compounds. Some intermediate layers are designed to melt and form a temporary liquid that significantly accelerates the rate of atom movement.

Diffusion bonding is frequently used to join dissimilar metals and composite materials. Furnaces with inert or protective atmospheres can be used to produce high-quality joints with the reactive metals, such as titanium, beryllium, and zirconium, and the high-temperature refractory metals. Since the bonding process is quite slow, multiple parts are generally loaded into a furnace or the application is restricted to low-volume production.

EXPLOSIVE WELDING

Explosive welding (EXW) is used primarily to bond sheets of corrosion-resistant metal to heavier plates of base metal (a cladding operation), particularly when large areas are involved. As shown in Figure 32-21, the bottom sheet or plate is positioned on a rigid base or anvil, and the top sheet is inclined to it with a small open angle between the surfaces to be joined. An explosive material, usually in the form of a sheet, is placed on top of the

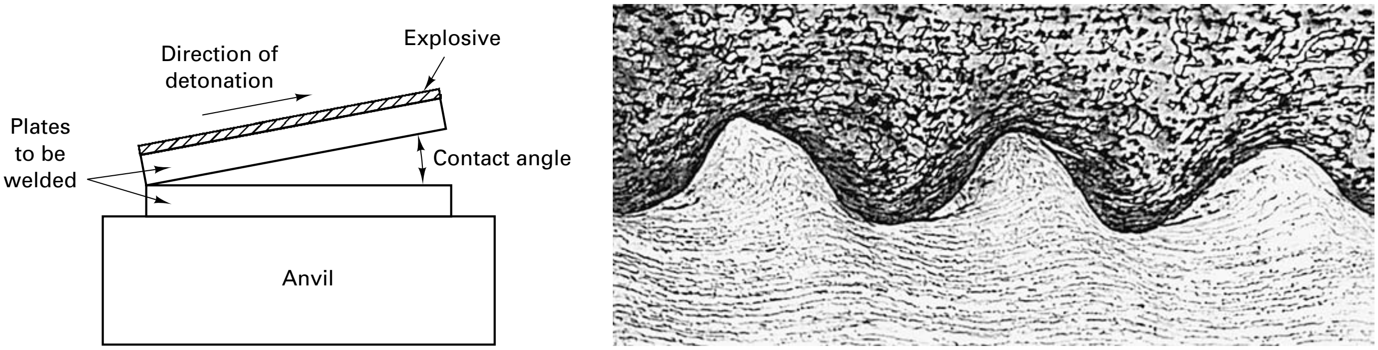

FIGURE 32-21 (Left) Schematic of the explosive welding process. (Right) Explosive weld between mild steel and stainless steel, showing the characteristic wavy interface.

two layers of metal and detonated in a progressive fashion, beginning where the surfaces touch. A compressive stress wave, on the order of thousands of megapascals (hundreds of thousands of pounds per square inch), sweeps across the surface of the plates. Surface films are liquefied or scarfed off the metals and are jetted out of the interface. The clean metal surfaces are then thrust together under high contact pressure. The result is a low-temperature weld with an interface configuration consisting of a series of interlocking ripples. Since the bond strength is quite high, explosively clad plates can be subjected to a wide variety of subsequent processing, including further reduction in thickness by rolling. Because it is a solid-state welding process, numerous combinations of dissimilar metals can be joined.

Review Questions

1. What are the two primary functions of the electrodes in resistance welding?
2. What are the two major roles of the applied pressure in resistance welding?
3. Why might resistance welding be considered as a form of solid-state welding?
4. Why is there no need for fluxes or shielding gases in resistance welding?
5. Based on the heat input equation, which term is most significant in providing heat—current, resistance, or time?
6. What are the three components that contribute to the total resistance between the electrodes?
7. What measures can be taken to reduce the resistance between the electrodes and the workpieces?
8. What are the possible consequences of too little pressure during the resistance-welding cycle? Too much pressure?
9. What is the ideal sequence for pressure application during resistance welding?
10. Why do the resistance-welding conditions become less favorable as the material heats and softens?
11. What magnitude of current may be used to produce resistance welds?
12. What is the simplest and most widely used form of resistance welding?
13. What is the typical size of a spot-weld nugget?
14. What are the two basic types of stationary spot-welding machines?
15. What is the major advantage of spot-welding guns?
16. What are some of the properties that must be possessed by resistance-welding electrodes?
17. What is the most common metal that is spot welded?
18. What is the practical limit of the thicknesses of material that can be readily spot welded?
19. What design features can be altered to permit the joining of different thicknesses or different conductivity metals?
20. What are the two methods used to produce resistance seam welds?
21. What two limitations of spot welding can be overcome by using the projection approach?
22. What limits the number of projection welds that can be formed in a single operation?
23. What are some of the attractive features of resistance welding when viewed from a manufacturing standpoint?
24. What are some of the primary limitations to the use of resistance welding?
25. What type of metallurgical problem might be encountered when spot welding medium- or high-carbon steels?
26. What were some of the limitations that made the forge welds of a blacksmith somewhat variable in terms of quality?
27. What features promote coalescence in cold welding?
28. Describe how the roll-bonding process can be used to fabricate products that contain pressure-tight, fluid-flow channels that once required the use of metal tubing.
29. How is inertia welding similar to friction welding? Different from friction welding?
30. How are surface impurities removed in the friction- and inertia-welding processes?
31. What are some of the geometric limitations of friction and inertia welding?
32. How does friction-stir welding differ from friction welding?
33. What are some of the attractive features of friction-stir welding?
34. What types of material or property modifications can be induced through friction-stir processing?
35. How do ultrasonic vibrations produce a weld?
36. What are some of the geometric limitations of ultrasonic welding?
37. What are some of the attractive features of ultrasonic welding?
38. What are the conditions necessary to produce high-quality diffusion welds?
39. How are surface contaminants removed during explosive welding?
40. If the interface of a weld is viewed in cross section, what is the distinctive geometric feature of an explosive weld?

Problems

1. Many advanced engineering products, as well as composite materials, require the joining of dissimilar materials. Select several of the processes discussed in this chapter and investigate the capability of the process to join dissimilar materials and the associated limitations.
2. Friction-stir processing is an interesting extension of friction-stir welding. Can you identify other examples of where a welding or joining process is currently being used for purposes other than those for which it was initially developed?

www.wiley.com/college/degarmo

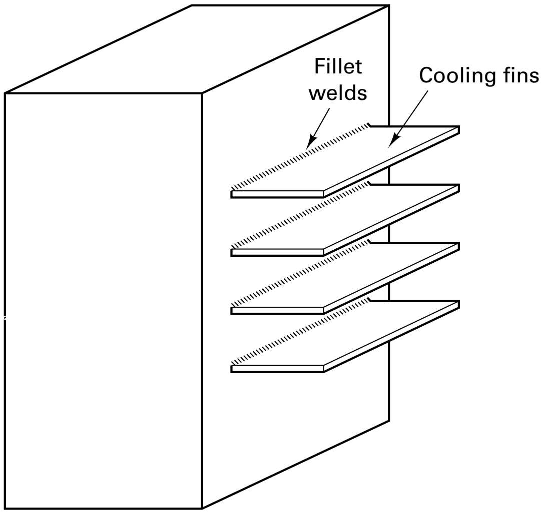
Chapter 32 CASE STUDY

Field Repair to a Power Transformer

Electric power transformers do not operate at 100% efficiency and generally incorporate some means of cooling in their design. Large transformers are often submerged in oil-filled reservoirs, where the volume of oil provides a noncorrosive heat sink. In addition, it is not uncommon for additional features, such as horizontal cooling fins, to be added to the design to aid in dissipating heat from the reservoir.

The figure shows the exterior of a large transformer that has been installed in a rural, somewhat remote location. The reservoir housing has been constructed by welding low-carbon steel plates 9 and 12 mm ($\frac{3}{8}$ and $\frac{1}{2}$ in.) thick. While the transformer was in use, a service vehicle accidentally backed into the cooling-fin assembly, producing cracks in several of the fillet areas and a resulting loss of oil. Overheating occurred, and a repair is now necessary. Because of the size of the transformer, some form of on-site repair is preferred. It is your job to determine the procedure and make the necessary arrangements.

1. Consider the full spectrum of welding processes and identify candidates that might be appropriate for this task.
2. For each of the candidate processes, identify its primary advantages and limitations.
3. Which of the candidate processes would you recommend? Why?
4. Describe the procedure that you would outline for such a repair. Are there any special concerns or precautions?



CHAPTER 33

OTHER WELDING PROCESSES, BRAZING AND SOLDERING

33.1 INTRODUCTION

We have already surveyed gas-flame and arc welding (Chapter 31), as well as resistance and solid-state joining processes (Chapter 32). Other processes within the realm of welding include some that are quite old (thermit welding) and others that are among the newest in manufacturing (laser and electron beam). These and several others will be presented here, along with a brief section devoted to the application of welding and welding-related processes to surfacing and thermal spray coating.

There are also many joining or assembly operations where welding may not be the best choice. Perhaps the heat of welding is objectionable, the materials possess poor weldability, welding is too expensive, or the joint involves thin or dissimilar materials. In such cases low-temperature joining methods may be preferred. These include brazing, soldering, adhesive bonding, and the use of mechanical fasteners. Brazing and soldering will be explored in this chapter, while adhesive bonding and mechanical fasteners are deferred to Chapter 34.

33.2 OTHER WELDING AND CUTTING PROCESSES

THERMIT WELDING

Thermit welding (TW) is an extremely old process in which superheated molten metal and slag are produced from an exothermic chemical reaction between a metal oxide and a metallic reducing agent. The name *thermit* usually refers to a mechanical mixture of about one part (by weight) finely divided aluminum and three parts iron oxide, plus possible alloy additions. When this mixture is ignited by a magnesium fuse (the ignition temperature is about 1150°C or 2100°F), it reacts according to the following chemical equation:

$$8Al + 3Fe_3O_4 \rightarrow 9Fe + 4Al_2O_3 + \text{heat}$$

The temperature rises to over 2750°C (5000°F) in about 30 seconds, superheating the molten iron, which then flows by gravity into a prepared joint, providing both heat and filler metal. Runners and risers must be provided, as in a casting, to channel the molten metal and compensate for solidification shrinkage.

Steels and cast irons can be welded using the process described above. Copper, brass, and bronze can be joined using a starting mixture of copper oxide and aluminum. Nickel, chromium, and manganese oxides have also been used in the thermit welding of more exotic metals.

Thermit welding has been replaced by alternative methods to a large degree. Nevertheless, it is still effective and can be used to produce economical, high-quality welds in thick sections of material, particularly in remote locations or where more sophisticated welding equipment is not available. One such application is the field repair of large steel castings that have broken or cracked.

ELECTROSLAG WELDING

Electroslag welding (ESW), depicted in Figure 33-1, is a very effective process for welding thick sections of steel plate. There is no arc involved (except to start the weld), so the process is entirely different from submerged arc welding, and the electrical resistance of the metal being welded plays no part in producing the heat. Instead, heat is derived from the passage of electrical current through a pool of electrically conductive liquid slag. Resistance heating raises the temperature of the slag to around 1750°C (3200°F). The molten slag then melts the edges of the pieces that are being joined, as well as continuously fed solid or flux-cored electrodes. Multiple electrodes are often used to provide an adequate supply of filler metal and maintain the molten pool. Under normal operating conditions, there is a 65-mm (2.5-in.)-deep layer of molten slag, which serves to protect and cleanse the underlying 12- to 20-mm ($^1/_2$ to $^3/_4$ in.)-deep pool of molten metal. These liquids are confined to the gap by means of sliding, water-cooled *molding plates* that are usually made of copper. As the weld metal solidifies at the bottom of the pool, the molding plates move upward at a rate that is typically between 12 and 40 mm/min ($^1/_2$ to $1^1/_2$ in./min).

Since a vertical joint provides the easiest geometry for maintaining a deep slag bath, the process is used most frequently in this configuration. Circumferential joints can also be produced in large pipe by using special curved slag-holder plates and rotating the pipe to maintain the welding area in a vertical position.

Because large amounts of weld metal and heat can be supplied, electroslag welding is the best of all the welding processes for making welds in thick plates. The thickness

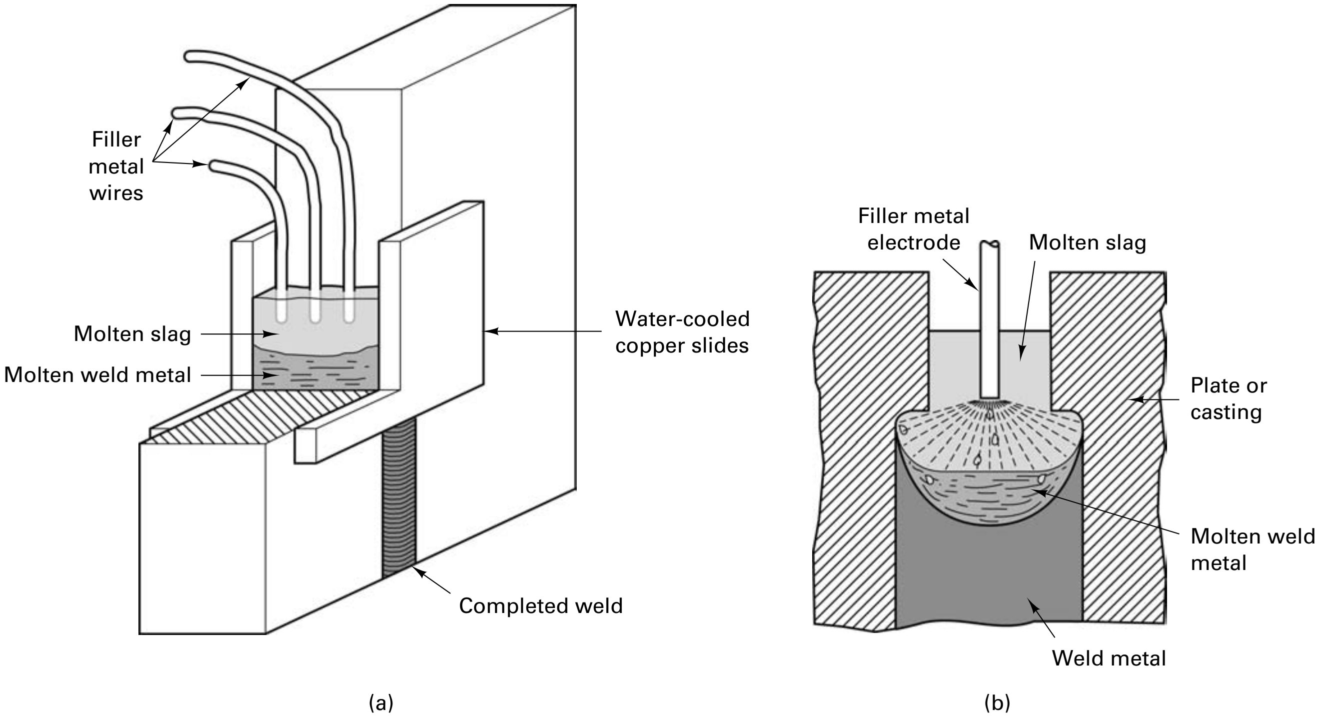


FIGURE 33-1 (a) Arrangement of equipment and workpieces for making a vertical weld by the electroslag process. (b) Cross section of an electroslag weld, looking through the water-cooled copper slide.

of the plates can vary from 12 to 900 mm ($^1/_2$ to 38 in.), and the length of the weld (amount of vertical travel) is almost unlimited. Edge preparation is minimal, requiring only squared edges separated by 25 to 35 mm. Applications have included building construction, shipbuilding, machine manufacture, heavy-pressure vessels, and the joining of large castings and forgings.

Solidification control is vitally important to obtaining a good electroslag weld, since slow cooling tends to produce a coarse grain structure. Cracking tendencies can be suppressed by adjusting the current, voltage, slag depth, number of electrodes, and electrode extension to produce a wide, shallow pool of molten metal. A large heat-affected zone and extensive grain growth are common features of the process. While these are undesirable metallurgical features, the long thermal cycle does serve to minimize residual stresses, distortion, and cracking in the heat-affected zone. Subsequent heat treatment of the welded structure may be necessary, however, if good fracture resistance is required.

ELECTRON-BEAM WELDING

In the *electron-beam welding* (EBW) process, the metal to be welded is heated by the impingement of a beam of high-velocity electrons. Originally developed for obtaining ultra-high-purity welds in reactive and refractory metals, the unique qualities of the process have led to a much wider range of applications.

Figure 33-2 presents the electron optical system. An electric current heats a tungsten filament to about 2200°C (4000°F), causing it to emit a stream of electrons by thermal emission. By means of a control grid, accelerating voltage, and focusing coils, these electrons are collected into a concentrated beam, accelerated, and directed to a focused

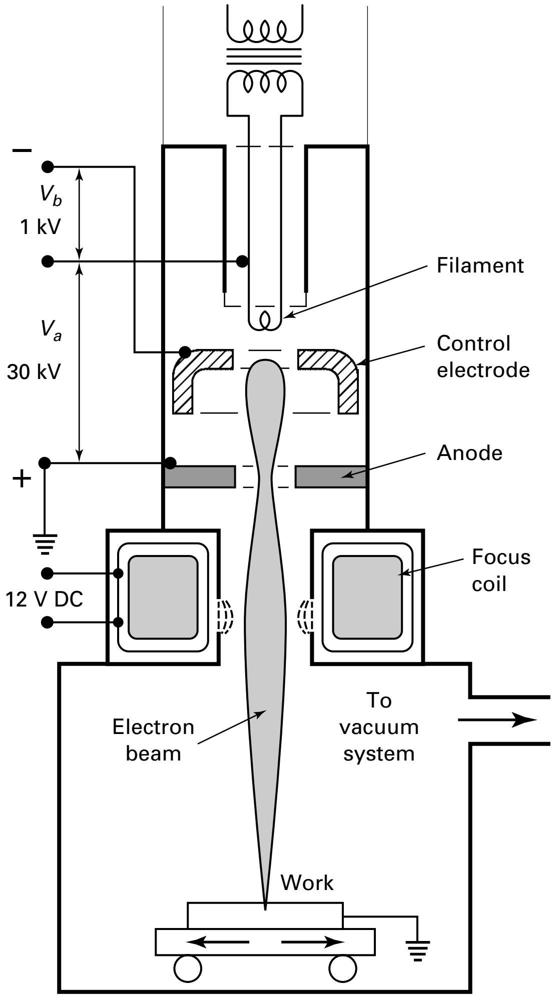

FIGURE 33-2 Schematic diagram of the electron-beam welding process.

spot between 0.8 and 3.2 mm. ($^1/_{32}$ to $^1/_8$ in.) in diameter. Since electrons accelerated at 150 kV achieve speeds nearly $^2/_3$ the speed of light, the electron beam is concentrated energy, capable of producing temperatures in excess of 1 million degrees Celsius when its kinetic energy is converted to heat. Since the beam is composed of charged particles, it can be positioned and moved by electromagnetic lenses. Unfortunately, the electrons cannot travel well through air. To be effective as a welding heat source, the beam must be generated and focused in a very high vacuum, typically at pressures of 0.01 Pa (1×10^{-4} mm Hg) or less.

In many operations, the workpiece must also be enclosed in the high-vacuum chamber, with provision for positioning and manipulation. The vacuum then ensures degasification and decontamination of the molten weld metal, and welds of very high quality are obtained. The size of the vacuum chamber, however, tends to impose serious limitations on the size of the workpiece that can be accommodated, and the need to break and reestablish the high vacuum as pieces are inserted and removed places a considerable restriction on productivity. As a consequence, electron-beam welding machines have been developed that operate at pressures considerably higher than those required for beam generation. Some permit the workpiece to remain outside the vacuum chamber, with the beam emerging through a small orifice in the vacuum chamber to strike an adjacent surface. High-capacity vacuum pumps are required to compensate for the leakage through the orifice. While these machines offer more production freedom, they do produce shallower, wider welds since the beam loses energy and diffuses as the pressure increases.

In general, two distinct ranges of accelerating voltage are employed in electron-beam welding. High-voltage equipment operates between 60 and 150 kV and produces a smaller spot size and greater penetration than does the lower-voltage type, which uses from 10 to 50 kV. Because of their high electron velocities, the high-voltage units emit considerable quantities of harmful X-rays and thus require expensive shielding and indirect viewing systems for observing the work. The X-rays produced by the low-voltage machines are sufficiently soft that the walls of the vacuum chamber absorb them, and the parts can be viewed directly through viewing ports.

Almost any metal can be welded by the electron-beam process, including those that are difficult to weld by other methods, such as zirconium, beryllium, and tungsten. Dissimilar metals, including those with extremely different melting points, can also be readily welded, since the intense beam will melt both metals simultaneously. Electron-beam welds typically exhibit a narrow profile and remarkable penetrations like those shown in Figure 33-3. The high power and heat concentrations can produce fusion zones with depth-to-width ratios up to 25:1. This is coupled with low total heat input, low distortion, and a very narrow heat-affected zone. Heat-sensitive materials can often be welded without damage to the base metal. Deep welds can be made in a single pass. High welding speeds are common; no shielding gas, flux, or filler metal is required; the process can be performed in all positions; and preheat or postheat is generally unnecessary.

TABLE 33-1 Process Summary: Electron-Beam Welding (EBW)

Heat source	High-energy electron beam
Protection	Vacuum
Electrode	None
Material joined	All common metals
Rate of heat input	High
Weld Profile (D/W)	20
Maximum penetration	175 mm (7 in.)
Assets	High precision; high quality; deep and narrow welds; small HAZ, low distortion; fast welding speed; beam is easily positioned and deflected; no filler metal, flux, or shielding gas required
Limitations	Beam and target must be within a vacuum; very expensive equipment; work piece size is limited by the vacuum chamber; significant edge preparation and alignment required; requires safety protection from X-ray and visible radiation

On the negative side, the equipment is quite expensive, and extensive joint preparation is required. Because of the deep and narrow weld profile, joints must be straight and precisely aligned over the entire length of the weld. Machining and fixturing tolerances are often quite demanding. The vacuum requirements tend to limit production rate, and the size of the vacuum chamber may restrict the size of the workpiece that can be welded.

The electron-beam process is best employed where welds of extremely high quality are required or where other processes will not produce the desired results. Electron-beam welds often exhibit joint strength 15 to 25% greater than arc welds in the same material. The unique capabilities have resulted in its routine use in a number of applications, particularly in the automotive and aerospace industries. Table 33-1 provides a process summary for electron-beam welding.

LASER-BEAM WELDING

Laser beams can be used as a heat source for welding, hole making, cutting, cladding, and heat treating a wide variety of engineering metals. When used for *laser-beam welding* (LBW), the beam of coherent light can be focused to a diameter of 0.1 to 1.0 mm, providing a power density in excess of 10^6 watts/mm^2. The high-intensity beam can be used to simply melt the material at the joint, but more often, it produces a very narrow column of vaporized metal (a "keyhole") with a surrounding liquid pool. As the beam traverses, the liquid flows into the joint to produce a weld with a depth-to-width ratio generally greater than 5:1. Because of the narrow weld-pool geometry, high travel speed of the beam (typically several meters per minute), and low total heat input, the molten metal solidifies quickly, producing a very thin heat-affected zone and little thermal distortion. Finishing costs are quite low. Since welds require only one-side access, many different joint configurations are possible.

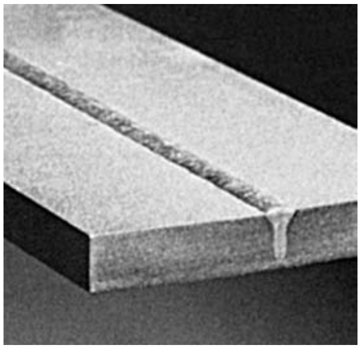

FIGURE 33-4 Laser butt weld of 3-mm (0.125-in.) stainless steel, made at 1.5 m/min with a 1250-watt laser. *(Courtesy of Coherent, Inc., Santa Clara, CA.)*

Laser-beam welding is most effective for simple fusion welds without filler metal (*autogenous welds*), but careful joint preparation is required to produce the narrow gap and necessary level of cleanliness. Filler metal can be added if the gap is excessive, and a low-velocity flow of inert gas (generally helium or argon) may be used to protect the weld pool from oxidation. Figure 33-4 shows a typical laser-beam weld, and Table 33-2 provides a process summary for laser-beam welding.

As shown in Figure 33-5, laser-beam welding and electron-beam welding both offer some of the highest power densities of the welding processes. The well-collimated beam of intense laser energy can produce deep penetration welds that are similar to electron-beam welds, but the laser-beam technique offers several distinct advantages:

1. The beam can be transmitted through air (i.e., a vacuum environment is not required). There is no physical contact between the welding equipment and the workpiece. The originating laser can be a considerable distance removed.

TABLE 33-2 Process Summary: Laser-Beam Welding (LBW)

Heat source	Laser light
Protection	None, or externally supplied gas
Electrode	None
Material joined	All common metals
Rate of heat input	High
Weld profile (D/W)	5
Maximum penetration	25 mm (1 in.)
Assets	High heat-transfer efficiency; can weld any location that is light-accessible; small HAZ; low distortion; can accurately focus the beam with light optics; high welding speed
Limitations	Possible problems with reflectivity of some metals; good positioning and fit-up required

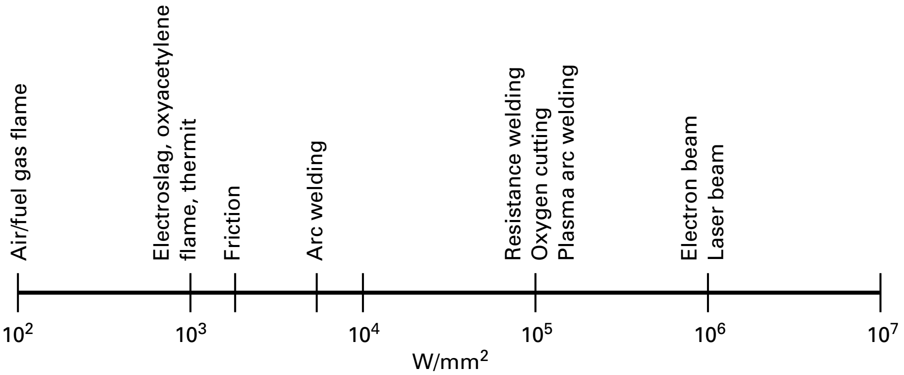

FIGURE 33-5 Comparison of the power densities of various welding processes. The high power densities of the electron-beam and laser-beam welding processes enable the production of deep, narrow welds with small heat-affected zones. Welds can be made quickly and at high travel speeds.

2. No harmful X-rays are generated.
3. The laser beam can be easily shaped, directed, and focused with both transmission and reflective optics (lenses and mirrors), and some beams can be transmitted through fiber-optic cables.
4. The only restriction on weld location is optical accessibility. Welds can be made in difficult-to-reach places, and materials can be joined within transparent containers, such as inside a vacuum tube.

A laser-welding system consists of an industrial laser, a means of guiding and focusing the beam, and a means of positioning and manipulating the parts to be welded. The traditional equipment for laser welding is a CO_2 laser with a power output range of 1.5 to 10 kW (or even higher). Because CO_2 lasers emit light with a far-infrared wavelength, they require mirror systems or special optical materials to focus and position the beam. They can be used to weld steel up to 25 mm (1 in.) thick at speeds ranging from 1 to 20 m/min. Nd:YAG (neodymium: yttrium–aluminum–garnet) lasers are more limited in power and capability but operate in a near-infrared wavelength that can utilize conventional glass lenses or delivery by flexible fiber-optic cable (as much as 3000 W of energy can be transmitted up to 150 m through a 0.6-mm-diameter fiber!).

The industrial lasers also lend themselves to automation and robotic manipulation. A single Nd:YAG laser with a fiber-optic system can distribute its beam to multiple workstations in either a simultaneous or time-sharing fashion, and the individual stations can be as much as 100 m (300 ft) from the laser. By using fiber-optic cables, laser energy can be piped directly to the end of a robot arm. This eliminates the need to mount and maneuver a heavy, bulky laser and, by reducing weight, enhances the speed and accuracy of both positioning and manipulation. Cutting, drilling, welding, and heat treating can all be performed with the same unit, and multiple axes of motion can provide a high degree of mobility and accessibility.

The equipment cost for a CO_2 or Nd:YAG laser-beam welding system is quite high, but this cost can be somewhat offset by the faster welding speeds, the ability to weld without filler metal, and low distortion, which enables a reduction in postweld straightening and machining. Caution should be used with such equipment, however, since reflected or scattered laser beams can be quite dangerous, even at great distances from the welding site. Eye protection is a must.

Because laser welds do not significantly reduce sheet metal formability, they have been used to produce tailored blanks for the production of sheet products. Different types of steel or different thicknesses can be joined to produce single-piece products with different properties at different locations. Laser welding has made great progress in the welding of aluminum alloys and has replaced gas tungsten arc welding or riveting in a number of applications.

With a sharply focused beam and short exposure times, laser welds can be very small and have a low total heat input, often on the order of 0.1 to 10 joules. These conditions are ideal for use in the electronics industry, and laser welding is frequently used to connect lead wires to small electronic components. Lap, butt, tee, and cross-wire configurations can all be used. It is even possible to weld wires without removing the polyurethane insulation. The laser simply evaporates the insulation and completes the weld with the internal wire.

Lasers have also been used in *hybrid processes* that combine laser welding with arc welding (GMAW, GTAW, or PAW), with both operating in one process zone and producing one weld pool. These hybrids combine the deep penetration, low distortion, and high-welding-speed features of laser welding with the wider pool, gap-bridging capability of arc welding. The resulting weld pool is wide and shallow at the surface, transitioning to deep and narrow. In addition to the unique and flexible weld-pool geometry, another benefit is the enhanced arc stabilization provided by the material that the laser evaporates. Laser power can be reduced from that required for lasers operating alone, and welds can be made faster than with just the arc-welding processes. The shielding gas from the arc-welding process protects the entire weld pool.

LASER-BEAM CUTTING

Cutting small holes, narrow slots, and closely spaced patterns in a variety of materials, or producing small quantities of complex-contoured sheet or plate, is another widely used application of industrial lasers. *Laser-beam cutting* (LBC) begins by “drilling” a hole through the material and then moving the beam along a programmed path. As shown in Figure 33-6, the intense heat from the laser is used to melt and/or evaporate the material being cut. A stream of *assist gas* blows the molten metal through the cut, cools the workpiece, minimizes the heat-affected zone, and may participate in a combustion reaction with the material being cut.

Oxygen is the usual gas for cutting mild steel. The laser heats the metal to a temperature where the iron and oxygen combine in an exothermic reaction. The molten iron and iron oxide have a low viscosity and are easily blown away by the flow of assist gas. In this exothermic cutting process, the assist gas actually contributes additional heat. High cutting speeds are possible, the speed being limited by the rate of material burning. Nitrogen is used with stainless steel and aluminum, and, because of its high reactivity, titanium requires an inert gas, such as argon. Inert gases or air are used when cutting nonmetallics. The latter processes are ones of endothermic cutting, since the gas actually absorbs energy as it is heated. Cutting speed is set by the rate at which the laser can melt and/or vaporize material. Exothermic cutting produces an oxidized edge, while endothermic cutting (or clean cutting) results in oxide-free surfaces.

Clean, accurate, square-edged cuts are characteristic of the laser cutting process, and the *kerf* (typically as small as 0.25 mm) and heat-affected zone are narrower than with any other thermal cutting process. No postcut finishing is required in many applications, even though the process does produce a thin recast surface. Figure 33-7 shows the edge of carbon steel that is 6 mm (0.25 in.) thick, laser cut at 1.8 m/min with a 1250-W laser.

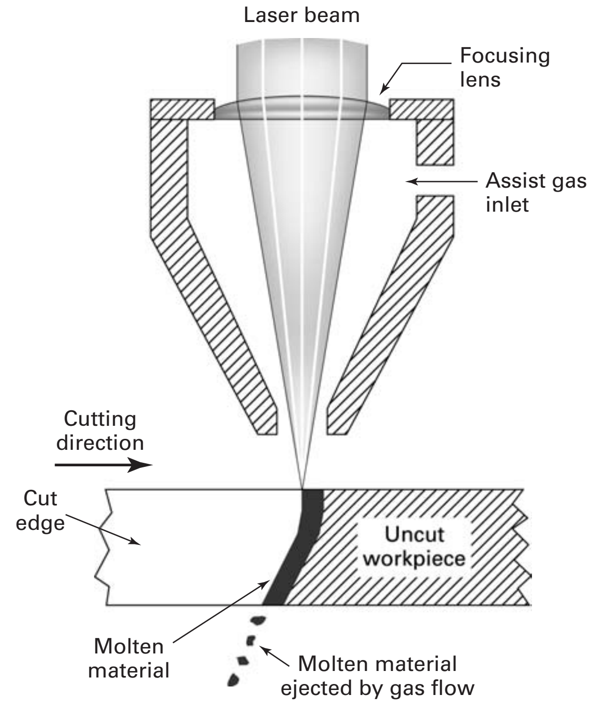

FIGURE 33-6 Schematic of laser-beam cutting. The laser provides the heat, and the flow of assist gas propels the molten droplets from the cut.

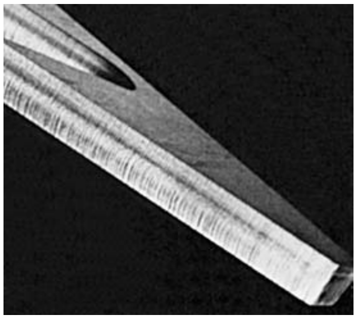

FIGURE 33-7 Surface of 6-mm-thick carbon steel cut with a 1250-watt laser at 1.8 m/min. *(Courtesy of Coherent, Inc., Santa Clara, CA.)*

CO_2 and YAG lasers have been used in both continuous and pulsed modes. While cutting speed depends on the material being cut and its thickness, it is greatest in the continuous mode that is preferred for straight and mildly contoured cuts. The pulsed mode is preferred for thin materials and enables tight corners and intricate details to be cut without excessive burning. Metal plates as well as a variety of nonmetals can be cut in thicknesses up to 30 mm ($1^1/_4$ in.). Cutting temperatures can be in excess of 11,000°C (20,000°F), and cutting speeds as high as 25 m/min have been observed with some nonmetals.

In addition to very common robotic applications, lasers have also been mounted on CNC-type machines or combined with traditional tools, such as punch presses, to produce extremely flexible hybrid equipment. Because no dedicated dies or tooling are required to produce a cut and there is no setup time, the laser is an economical alternative to blanking or nibbling for prototype or short-run products or for materials that are difficult to cut by conventional methods, such as plastics, wood, and composites.

Since lasers can cut a wide variety of metals and nonmetals, laser cutting has become a dominant process in the cutting of composite materials. The more uniform the thermal characteristics of the components, the better the cut and the less thermal damage to the material. Kevlar-reinforced epoxy cuts easiest and gives a narrow heat-affected zone. Glass-reinforced epoxy is more difficult because of the greater thermal differences, and graphite-reinforced epoxy is even worse because of the high dissociation temperature and thermal conductivity of the graphite. By the time the graphite has absorbed sufficient cutting heat, the epoxy matrix will have decomposed to a significant depth. The use of lasers for machining is discussed further in Chapter 27.

LASER SPOT WELDING

Lasers have also been used to produce spot welds in a manner that offers unique advantages when compared to the conventional resistance methods. A small clamping force is applied to ensure contact of the workpieces, and a fine-focused beam then scans the area of the weld. Welding is performed in the keyhole mode, where the laser produces a small hole through the molten puddle. As the beam is moved, molten metal flows into the hole and solidifies, forming a fusion-type nugget.

Laser spot welding can be performed with access to only one side of the joint. It is a noncontact process and produces no indentations. No electrodes are involved, so electrode wear is no longer a production problem. Weld quality is independent of material resistance, surface resistance, and electrode condition, and no water cooling is required. The total heat input is low, so the heat-affected zone is small. Speed of welding and strength of the resulting joint are comparable to resistance spot welds.

FLASH WELDING

Flash welding (FW) is a process used to produce butt welds between similar or dissimilar metals in solid or tubular form. The two pieces of metal are first secured in current-carrying grips and lightly touched together. An electric current may be passed through the joint to provide optional preheat, after which the pieces are withdrawn slightly. An intense flashing arc forms across the gap, which melts the material on both surfaces. The pieces are then forced together under high pressure (on the order of 70 MPa, or 10,000 psi), expelling the liquid and oxides, and upsetting the softened metal. The electric current is turned off, and the force is maintained until solidification is complete. If desired, the upset portion can then be removed by machining. Figure 33-8 shows a schematic of the flash-welding process, including both the equipment setup and the completed weld.

To produce a high-quality weld, it is important that the initial surfaces be flat and parallel so that the flashing is even across the area to be joined. The flashing action must be continued long enough to melt the interface and also soften the adjacent metal. Sufficient plastic deformation must occur during the upsetting to transfer the impurities and contaminants outward into the flash. The equipment required is generally large and expensive, but excellent welds can be made at high production rates.

Percussion welding (PEW) is a similar process, in which a rapid discharge of stored energy produces a brief period of arcing, which is followed by the rapid application of force to expel the molten metal and produce the joint. In percussion welding, the duration of the arc is on the order of 1 to 10 ms. The heat is intense but highly concentrated. Only a small amount of molten metal is produced, little or no upsetting occurs at the joint, and the heat-affected zone is quite small. Application is generally restricted to the butt welding of bar or tubing, where heat damage is a major concern.

Upset welding (UW) is also similar to flash welding, but there is no period of arcing. The equipment and geometries are similar, but the heating is achieved through electrical resistance. The parts are clamped in the machine, pressure is applied, and high current is passed through the joint. When the abutting surfaces have been heated to a suitable forging temperature, the current is stopped and an upsetting force is applied to produce coalescence. The initial conditions of interface flatness, finish, and alignment must create uniform contact if a good-quality weld is to be produced.

33.3 SURFACE MODIFICATION BY WELDING-RELATED PROCESSES

SURFACING (INCLUDING HARD FACING)

Surfacing or overlaying is the process of depositing a layer of weld metal on the surface or edge of a different-composition base material. The usual objectives are to obtain improved resistance to wear, abrasion, heat, or chemical attack, without having to make the entire piece from an expensive material, one that is difficult to fabricate, or one that would not possess the desired bulk properties. Since the deposited surfaces are generally harder than the base metal, the process is often called *hard facing*. This is not always true, however, for in some cases a softer metal (such as bronze) is applied to a harder base material.

Surfacing Materials. The materials most commonly used for surfacing include (1) carbon and low-alloy steels; (2) high-alloy steels and irons; (3) cobalt-based alloys; (4) nickel-based alloys, such as Monel, Nichrome, and Hastelloy; (5) copper-based alloys; (6) stainless steels; and (7) ceramic and refractory carbides, oxides, borides, silicides, and similar compounds.

Surfacing Methods and Applications. Since some of the base metal melts during the deposition, surfacing is actually a variation of fusion welding and can be performed by nearly all of the gas-flame or arc-welding techniques, including oxyfuel gas, shielded metal arc, gas metal arc, gas tungsten arc, submerged arc, and plasma arc. Arc welding is frequently used for the deposition of high-melting-point alloys. Submerged arc welding is used when large areas are to be surfaced or a large amount of surfacing material is to be applied. The plasma arc process further extends the process capabilities because of its extreme temperatures. To obtain true fusion of the surfacing material, a transferred arc is used and the surfacing material is injected in the form of a powder. If a nontransferred arc is used, only a mechanical bond is produced, and the process becomes a form of *metallizing*. Lasers can also be used in surfacing operations.

THERMAL SPRAY COATING OR METALLIZING

The *thermal spray* processes offer a means of applying a coating of high-performance material (metals, alloys, ceramics, intermetallics, cermets, carbides, or even plastics) to more economical and more easily fabricated base metals. A wire or rod of the coating material is fed into a gas flame or arc, where it melts and becomes atomized by a stream of gas, such as argon, nitrogen, combustion gases, or compressed air. The gas stream propels the 0.01- to 0.05-mm (0.0004- to 0.002-in.)-diameter particles toward the target surface, where they impact ("splat"), cool, and bond. Very little heat is transferred to the substrate, whose peak temperatures generally range from 100 to 250°C (200 to 500°F). As a result, thermal spraying does not induce undesirable metallurgical changes or excessive distortion, and coatings can be applied to thin or delicate targets or to heat-sensitive materials such as plastics. The applied coating can range in thickness from 0.1 to 12 mm (0.004 to 0.5 in.).

Several of the thermal spray processes use adaptations of oxyfuel welding equipment. Figure 33-9 shows a schematic of an oxyacetylene metal spraying gun designed to utilize a solid wire feed. The flame melts the wire and a flow of compressed air disintegrates the molten material and propels it to the workpiece. An alternative type of oxyfuel gun uses material in the form of powder, which is gravity or pressure fed into the flame, where it is melted and carried by the flame gas onto the target. The powder feed permits the deposition of material that would be difficult to fabricate into wire, such as cermets, oxides, and carbides. In addition, the droplet size is controlled by the powder, not by the factors that control atomization.

The lower temperatures and lower particle velocities of the oxyfuel deposition methods result in coatings with high porosity and low cohesive strength. An adaptation of the process known as high-velocity oxyfuel (HVOF) spraying propels the droplets with a supersonic stream of hot gas. Because the particles impact with high kinetic energies, the resulting coating is dense and well bonded.

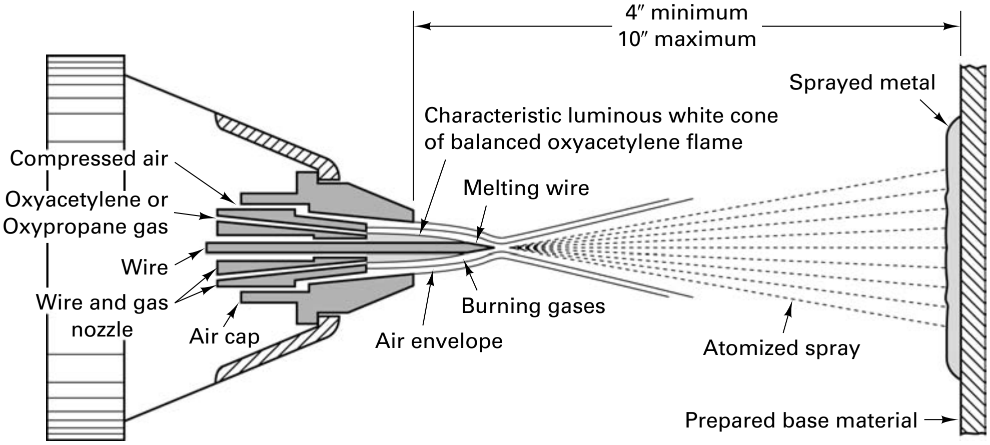

FIGURE 33-9 Schematic diagram of an oxyacetylene metal-spraying gun. *(Courtesy of Sulzer Metco, Winterthur, Switzerland.)*

The simplest of the electric arc methods is wire arc or electric arc spraying. Two oppositely charged electrode wires are fed through a gun, meeting at the tip, where they form an arc. A stream of atomizing gas flows through the gun, stripping off the molten metal to produce a high-velocity spray. Since all of the input energy is used to melt the metal, this process is extremely energy efficient.

Plasma spray metallizing, illustrated in Figure 33-10, is a more sophisticated technique. A plasma-forming gas serves as both the heat source and propelling agent for the coating material, which is usually fed in the form of powder. The molten particles attain high velocity and therefore produce a dense, strongly bonded coating. Since temperatures can reach 16,500°C (30,000°F), plasma spraying can be used to deposit materials with extremely high melting points. Metals, alloys, ceramics, carbides, cermets, intermetallics, and plastic-based powders have all been successfully deposited.

While thermal spraying or *metallizing* is similar to surfacing and is often applied for the same reasons, the coatings are usually thinner and the process is more suitable for irregular surfaces or heat-sensitive substrates. The deposition guns can be either handheld or machine-driven. A standoff distance of 0.15 to 0.25 m (6 to 10 in.) is usually maintained between the spray nozzle and the workpiece. Table 33-3 compares the features of five methods of thermal spray deposition.

Surface Preparation for Metallizing. Unlike surfacing, metallizing does not melt the base metal. Adhesion is entirely mechanical, so it is essential that the base metal be prepared in a way that promotes good mechanical interlocking. The target material must first be clean and free of dirt, moisture, oil, and other contaminants. The surface is then roughened by one of a variety of methods to create minute crevices that can anchor the solidifying particles. Grit blasting with a sharp, abrasive grit is the most common technique, and a surface roughness of 2.5 to 7.5 microns is adequate for most applications.

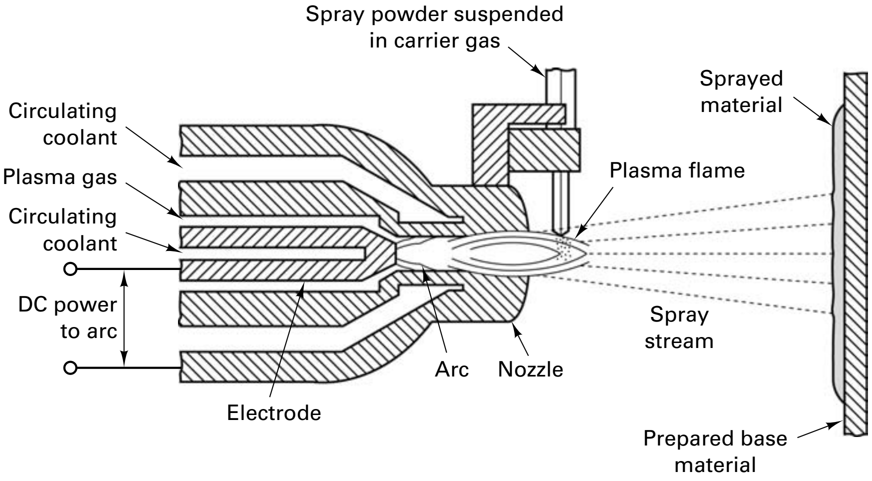

FIGURE 33-10 Diagram of a plasma-arc spray gun. *(Courtesy of Sulzer Metco, Winterthur, Switzerland.)*

TABLE 33-3 Comparison of Five Thermal Spray Deposition Techniques

Method	Heat		Deposited Materials	Particle Impact Velocity (m/sec)	Adhesion Strength	Maximum Spray Rate (kg/hr)
	Source	Temperature (°C)				
Flame spray						
Wire	Oxyfuel	3000	Metals	180	Medium	9
Powder	Oxyfuel	3000	Metals, ceramics, plastics	30	Low	7
High-velocity oxyfuel (HVOF)	Oxyfuel	3100	Metals, carbides	600–1000	Very high	14
Wire arc	DC arc	5500	Metals only	250	High	16
Plasma spray	DC arc	5500 to 16,500	All	250–1200	High to Very high	5-25

Characteristics and Applications of Sprayed Metals. During deposition, the atomized, molten, or semimolten particles mix with air and then cool rapidly upon impact with the base metal. The resultant coatings consist of bonded particles that span a range of size, shape, and degree of melting. Some particles become oxidized and interparticle voids can become entrapped. Compared to conventional wrought material, the coatings are harder, more porous (0.1 to 15% porosity), and more brittle. Thermal spray coatings add little, if any, additional strength to a part, since the strength of the porous coating is usually between one-third and one-half of its normal wrought strength. Applications, therefore, generally look to the coating to provide resistance to heat, wear, erosion, and/or corrosion, or to restore worn parts to original dimensions and specifications. Some typical applications include:

1. *Protective coatings.* Zinc and aluminum are sprayed on iron and steel to provide corrosion resistance—a process that may well extend the lifetime of bridges, buildings, and other infrastructure items. The interior surfaces of power boilers can be coated with high-chromium alloys to extend wall life by providing both heat-resistance and corrosion resistance.
2. *Building up worn surfaces.* Worn parts may be salvaged or their life extended by adding new metal to the depleted regions. The repair and restoration of aircraft engine components is probably the largest single use of thermal spraying.
3. *Hard surfacing.* Although metal spraying should not be compared to hard-facing deposits that are applied by welding techniques, it can be used when thin coatings are considered to be adequate. Typical applications might include automobile cylinder liners and piston rings; thread guides in textile plants; and critical parts within pumps, bearings, and seals.
4. *Applying coatings of expensive metals.* Metal spraying provides a simple method for applying thin coatings of noble metals to surfaces where conventional plating would not be economical.
5. *Electrical properties.* Because metal can be deposited on almost any surface, thermal spraying can be used to apply a conductive surface to an otherwise poor conductor or nonconductor. Copper, aluminum, or silver is frequently sprayed on glass or plastics for this purpose. Conversely, sprayed alumina (Al_2O_3) can be used to impart insulating or dielectric properties.
6. *Reflecting surfaces.* Aluminum, sprayed on the back of glass by a special fusion process, makes an excellent mirror.
7. *Decorative effects.* One of the earliest and still important uses of metal spraying was to obtain decorative effects. Because sprayed metal can be treated in a variety of ways, such as buffed, wire brushed, or left in the as-sprayed condition, it is frequently specified for finishing manufactured products and architectural materials.

8. *Tailored surface characteristics.* Porous coatings of cobalt or titanium alloys, or certain ceramic materials, have been applied to medical implants to help promote adhesion and in-growth of bone and tissue.

33.4 BRAZING

In brazing and soldering, the surfaces to be joined are first cleaned, the components assembled or fixtured, and a low-melting-point nonferrous metal is then melted, drawn into the space between the two solids by capillary action, and allowed to solidify. *Brazing* is the permanent joining of similar or dissimilar metals or ceramics (or composites based on those two materials) through the use of heat and a filler metal whose melting temperature (actually, liquidus temperature) is above 450°C (840°F)[1] but below the melting point (or solidus temperature) of the materials being joined. The brazing process is different from welding in a number of ways:

1. The *composition* (or chemistry) of the brazing alloy is significantly different from that of the base metal.
2. The *strength* of the brazing alloy is usually lower than that of the base metal.
3. The *melting point* of the brazing alloy is lower than that of the base metal, so none of the base metal is melted.
4. Bonding requires *capillary action* to distribute the filler metal between the closely fitting surfaces of the joint. The specific flow is dependent upon the viscosity of the liquid, the geometry of the joint, and surface wetting characteristics.

Because of these differences, the brazing process has several distinct advantages:

1. A wide range of metallic and nonmetallic materials can be brazed. The process is ideally suited for joining dissimilar materials, such as ferrous metal to nonferrous metal, cast metal to wrought metal, metals with widely different melting points, or even metal to ceramic.
2. Since less heating is required than for welding, the process can be performed quickly and economically.
3. The lower temperatures reduce problems associated with heat-affected zones (or other material property alteration), warping, and distortion. Thinner and more complex assemblies can be joined successfully. Thin sections can be joined to thick. Metal as thin as 0.01 mm (0.0004 in.) and as thick as 150 mm (6 in.) can be brazed.
4. Assembly tolerances are closer than for most welding processes, and joint appearance is usually quite neat.
5. Brazing is highly adaptable to automation and performs well when mass-producing complex or delicate assemblies. Complex products can also be brazed in several steps using filler metals with progressively lower melting temperatures.
6. A strong permanent joint is formed.

Successful brazing or soldering requires that the parts have relatively good fit-up (i.e., small joint clearances) to promote capillary flow of the filler metal. The parts must be thoroughly cleaned prior to joining, and many parts will require flux removal after joining. It is also important to remember that any subsequent heating of the assembly can cause inadvertent melting of the braze metal, thereby weakening or destroying the joint.

Another concern with brazed joints is their enhanced susceptibility to corrosion. Since the *filler metal* is of different composition from the materials being joined, the brazed joint is actually a localized galvanic corrosion cell. Corrosion problems can often be minimized, however, by proper selection of the filler metal.

NATURE AND STRENGTH OF BRAZED JOINTS

Brazing, like welding. forms a strong metallurgical bond at the interfaces. Clean surfaces, proper clearance, good wetting, and good fluidity will all enhance the bonding.

---

[1] This temperature is an arbitrary one, selected to distinguish brazing from soldering.

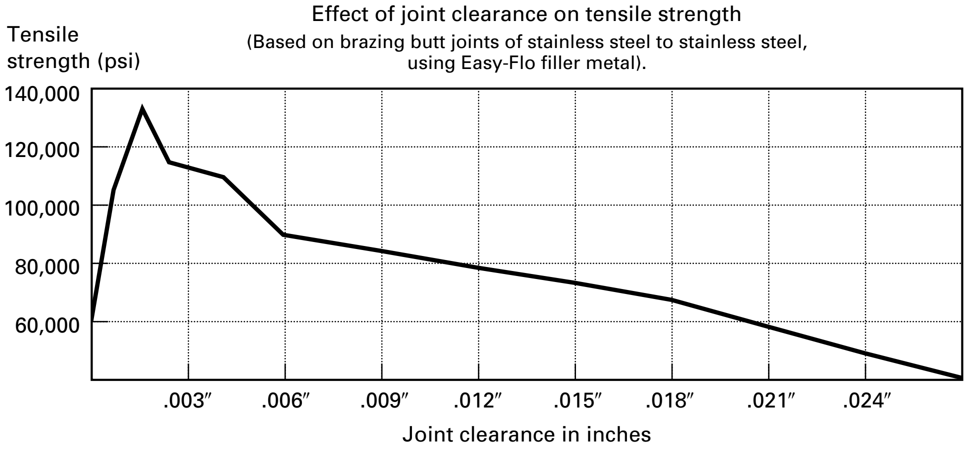

FIGURE 33-11 Typical variation of tensile strength with clearance in a butt-joint braze. *(Courtesy of Handy & Harman, Rye, NY.)*

The strength of the resulting joint can be quite high, certainly higher than the strength of the brazing alloy and often greater than the strength of the metal being brazed. Attainment of a high-strength joint, however, requires optimum processing and design.

Of all of the factors contributing to joint strength, *joint clearance* is the most important. If the joint is too tight, it may be difficult for the braze metal to flow into the gap (leaving unfilled voids), and flux may not be able to escape (remaining in locations that should be filled with braze material). There must be sufficient clearance for the braze metal to wet the joint and flow into it under the force of capillary action. As the gap is increased beyond an optimum value, however, the joint strength decreases rapidly, dropping off to the strength of the braze metal itself. If the gap becomes too great, the capillary forces may be unable to draw the material into the joint or hold it in place during solidification. Figure 33-11 shows the tensile strength of a butt-joint braze as a function of joint clearance.

Proper clearance can vary considerably, depending primarily on the type of braze metal being used. The ideal clearance is usually between 0.01 and 0.04 mm (0.0005 and 0.0015 in.), an “easy-slip” fit. A press fit can even be acceptable if fluxes are not used and surface roughness is sufficient to assure adequate flow of the filler metal into the joint. Clearances up to 0.075 mm (0.003 in.) can be accommodated with a more sluggish filler metal, such as nickel. When clearances range between 0.075 and 0.13 mm (0.003 and 0.005 in.), however, acceptable brazing becomes somewhat difficult, and joints with gaps in excess of 0.13 mm (0.005 in.) are almost impossible to braze. It should be noted that the specified gap should be maintained over the entire braze area—braze surfaces should be parallel.

It is also important to recognize that the dimensions cited above are the clearances that should exist *at the temperature of the brazing process*. Any effects of thermal expansion should be compensated when specifying the dimensions of the starting components. This is particularly significant when dissimilar materials are to be joined, for here the joint clearance will change as one material expands at a faster rate than the other. Consider a joint between brass and steel, like the one depicted in Figure 33-12. Brass expands more than steel when the temperature is increased. Therefore, if the insert tube is the brass component, the initial fit should be somewhat loose. The brass will expand more than the steel as the temperature is increased, and at the brazing temperature, the gap will assume the desired dimensions. Conversely, if a steel tube is to be inserted into a brass receiver, an initial force fit may be required since the interface will widen as the brass expands more than the steel. Problems can also occur when the reverse dimensional changes occur during cool-down. Significant residual stresses can form in the new joint, and tensile stresses can induce cracking.

Wettability is a strong function of the surface tensions between the braze metal and the base alloy. Generally, the wettability is good when the surfaces are clean and the two metals can form intermediate diffused alloys. Sometimes the wettability can be improved, as is done when steel is tin plated to accept a lead–tin solder, or plated with

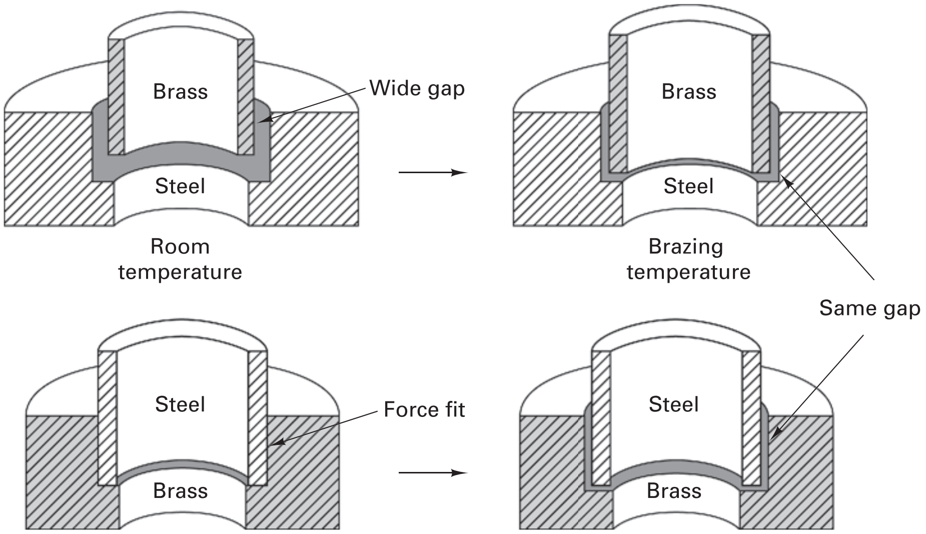

FIGURE 33-12 When brazing dissimilar metals, the initial joint clearance should be adjusted for the different thermal expansions (here brass expands more than steel). Proper brazing clearances should exist at the temperature where the filler metal flows.

nickel or copper to enhance brazing. *Fluidity* is a measure of the flow characteristics of the molten braze metal and is a function of the metal, its temperature, surface cleanliness, and clearance.

DESIGN OF BRAZED JOINTS

Because the strength of a braze filler metal is generally less than that of the metals being joined, a good joint design is required if one is to obtain adequate mechanical strength. The desired load-carrying ability is usually obtained by (1) ensuring proper joint clearance and (2) providing sufficient area for the bond. Figure 33-13 depicts the two most common types of brazed joints: *butt* and *lap*. Butt joints do not require additional thickness in the vicinity of the joint; they are most often used where the strength requirements are not that critical. The bonding area is limited to the cross-sectional area of the thinner or smaller member. In contrast, lap joints can provide bonding areas that are considerably larger than the butt configuration; they are often preferred when maximum strength is desired. If the joints are made very carefully, a lap of 1 to $1^1/_4$ times the material thickness can develop strength equal to that of the parent metal. For joints that are made by routine production, it is best to use a lap of 3 to 6 times the material thickness to ensure that failure will occur in the base metal, not in the brazed joint.

Variations of the two basic joint designs include the *butt-lap* and *scarf* configurations, shown in Figure 33-14. The butt-lap design is an attempt to combine the advantage of a uniform thickness with a large bonding area and companion high strength. Unfortunately, it also requires a higher degree of joint preparation. The scarf joint maintains uniform thickness and increases bonding area by tilting the butt joint interface. Careful joint preparation and component alignment is required to maintain the desired dimensions of joint clearance. Figure 33-14 shows relatively simple butt, lap, butt-lap, and scarf

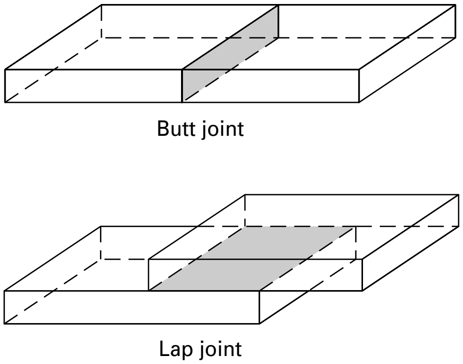

FIGURE 33-13 The two most common types of braze joints are butt and lap. Butt offers uniform thickness across the joint, whereas lap offers greater bonding area and higher strength.

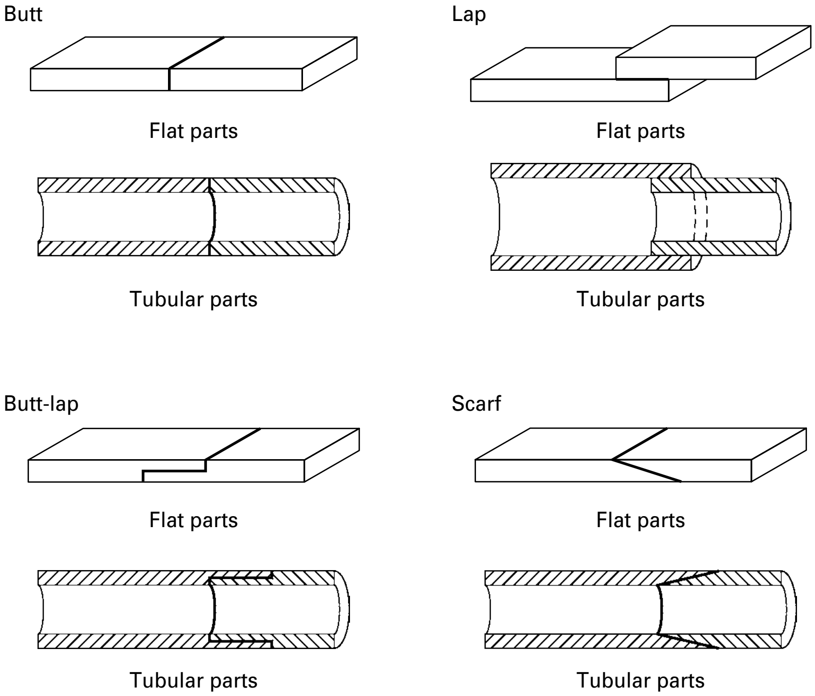

FIGURE 33-14 Variations of the butt and lap configurations include the butt-lap and scarf. The four types are shown for both flat and tubular parts.

joints for both flat and tubular parts. Figure 33-15 shows good brazing designs for a variety of joint configurations.

The materials being brazed also need to be considered when designing a brazed joint. Table 33-4 summarizes the compatibility of various engineering materials with the brazing process.

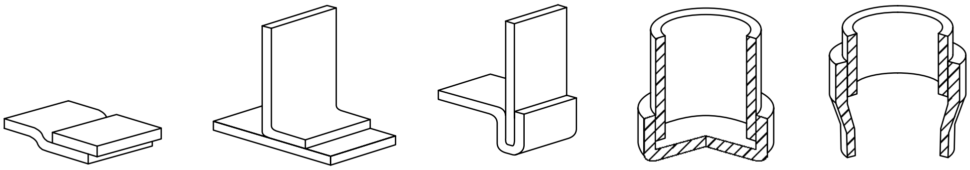

FIGURE 33-15 Some common joint designs for assembling parts by brazing.

TABLE 33-4 Compatibility of Various Engineering Materials with Brazing

Material	Brazing Recommendation
Cast iron	Somewhat difficult
Carbon and low-alloy steels	Recommended for low- and medium-carbon materials; difficult for high-carbon materials; seldom used for heat-treated alloy steels
Stainless steel	Recommended; silver and nickel brazing alloys are preferred
Aluminum and magnesium	Common for aluminum alloys and some alloys of magnesium
Copper and copper alloys	Recommended for copper and high-copper brasses; somewhat variable with bronzes
Nickel and nickel alloys	Recommended
Titanium	Difficult, not recommended
Lead and zinc	Not recommended
Thermoplastics, thermosets, and elastomers	Not recommended
Ceramics and glass	Not recommended
Dissimilar metals	Recommended, but may be difficult, depending on degree of dissimilarity
Metals to nonmetals	Not recommended
Dissimilar nonmetals	Not recommended

FILLER METALS

The filler metal used in brazing can be any metal that melts between 450°C (840°F) and the melting point of the material being joined. Actual selection, however, considers a variety of factors, including compatibility with the base materials, brazing-temperature restrictions, restrictions due to service or subsequent processing temperatures, the brazing process to be used, the joint design, anticipated service environment, desired appearance, desired mechanical properties (such as strength, ductility, and toughness), desired physical properties (such as electrical, magnetic, or thermal), and cost. In addition, the material must be capable of flowing through small capillaries, "wetting" the joint surfaces, and partially alloying with the base metals. The most commonly used brazing metals are copper and copper alloys, silver and silver alloys, and aluminum alloys. Many of the brazing alloys are based on eutectic reactions (see Chapter 4), where the material melts at a single temperature that is lower than the melting points of the individual metals in the alloy. Table 33-5 presents some common braze metal families, the metals they are used to join, and the typical brazing temperatures.

Copper and copper alloys are the most commonly used braze metals. Unalloyed copper is used primarily for brazing steel and other high-melting-point materials, such as high-speed steel and tungsten carbide. Its melting point is rather high (about 1100°C), and tight-fitting joints are required (gaps less than 0.075 mm). Copper–zinc alloys offer lower melting points and are used extensively for brazing steel, cast irons, and copper. Copper–phosphorus alloys are used for the fluxless brazing of copper since the phosphorus can reduce the copper oxide film. These alloys should not be used with ferrous or nickel-based materials, however, since they form brittle compounds with phosphorus and the resulting joints may be brittle. Manganese bronzes can also be used as filler metal in brazing operations.

Pure silver can be used for brazing titanium. *Silver solders* (alloys based on silver and copper) have brazing temperatures significantly below that of pure copper and are used in joining steels, copper, brass, and nickel. While silver and silver alloys are expensive, only a small amount is required to make a joint, so the cost per joint is still low.

Aluminum–silicon alloys, containing between 6 and 12% silicon, are used for brazing aluminum and other aluminum alloys. By using a braze metal that is similar to the base metal, the possibility of galvanic corrosion is reduced. These brazing alloys, however, have melting points of about 610°C (1130°F), and the melting temperature of commonly brazed aluminum alloys, such as 3003, is around 670°C (1290°F). Therefore, control of the brazing temperature is critical. In brazing aluminum, proper fluxing action, surface cleaning, and/or the use of a controlled atmosphere or vacuum environment is required to assure adequate flow of the braze metal.

Nickel- and cobalt-based alloys are attractive for joining assemblies that will be subjected to elevated-temperature service conditions and/or extremely corrosive environments. The service temperature for brazed assemblies can be as high as 1200°C (2200°F). Gold and palladium alloys offer outstanding oxidation and corrosion resistance, as well as good electrical and thermal conductivity. Magnesium alloys can be used to braze other types of magnesium.

TABLE 33-5 Some Common Braze Metal Families, Metals They Are Used to Join, and Typical Brazing Temperatures

Braze Metal Family	Materials Commonly Joined	Typical Brazing Temperature (°C)
Aluminum-silicon	Aluminum alloys	565–620
Copper and copper alloys	Various ferrous metals as well as copper and nickel alloys and stainless steel	925–1150
Copper-phosphorus	Copper and copper alloys	700–925
Silver alloys	Ferrous and nonferrous metals, except aluminum and magnesium	620–980
Precious metals (gold-based)	Iron, nickel, and cobalt alloys	900–1100
Magnesium	Magnesium alloys	595–620
Nickel alloys	Stainless steel, nickel, and cobalt alloys	925–1200

A variety of brazing alloys are currently available in the form of amorphous foils, formed by cooling metal at extremely rapid rates. These foils are extremely thin (0.04 mm or 0.0015 in. being typical) and exhibit excellent ductility and flexibility, even when they are made from alloys whose crystalline form is quite brittle. Shaped inserts can be cut or stamped from the foil and inserted into the joint region. Since the braze material is fully dense, no shrinkage or movement occurs during the brazing operation.

One amorphous alloy, composed of nickel, chromium, iron, and boron, is used to produce assemblies that can withstand high temperatures. During the brazing operation, the boron diffuses into the base metal, raising the melting point of the remaining filler. The brazed assembly can then be heated to temperatures above the melting point of the original braze alloy, and the brazed joint will not melt.

FLUXES

In a normal atmosphere, the heat required to melt the brazing alloy would also cause the formation of surface oxides that oppose the wetting of the surface and subsequent bonding. *Brazing fluxes*, therefore, play an important part in the process by (1) dissolving oxides that may have formed on the surfaces prior to heating, (2) preventing the formation of new oxides during heating, and (3) lowering the surface tension between the molten brazing metal and the surfaces to be joined, thereby promoting the flow of the molten material into the joint. Ideally, the flux will melt and become active at a temperature below the solidus of the filler metal yet remain active throughout the entire range of temperatures encountered while making the braze.

Surface cleanliness is one of the most significant factors affecting the quality and uniformity of brazed joints. Although fluxes can dissolve modest amounts of oxides, *they are not cleaners*. Before a flux is applied, dirt, grease, oil, rust, and heat-treat scale should be removed from the surfaces that are to be brazed. Cleaning operations can involve water- or solvent-based techniques; high-temperature burn-off of oils, greases, and fuel residues; acid pickling; grit blasting with selected media; other mechanical methods; or exposure to high-temperature reducing atmospheres. The less cleaning the flux has to do, the more effective it will be during the brazing operation. Because the presence of surface graphite impairs wetting, cast iron materials often require special treatment. Graphite removal by chemical etching may be required before cast iron can be brazed.

Brazing fluxes usually take the form of chemical compounds in which the most common ingredients are borates, fused borax, fluoroborates, fluorides, chlorides, acids, alkalies, wetting agents, and water. The particular flux should be selected for compatibility with the base metal being brazed and the particular process being used. Paste fluxes are utilized for furnace, induction, and dip brazing, and they are usually applied by brushing. Either paste or powdered fluxes can be used with the torch-brazing process, where application is usually achieved by dipping the heated end of the filler wire into the flux material.

APPLYING THE BRAZE METAL

The brazing filler metal can be applied to joints in several ways. The oldest method (and still a common technique when torch brazing) uses brazing metal in the form of a rod or wire. The joint area is first heated to a temperature high enough to melt the braze alloy and ensure that it remains molten while flowing into the joint. The torch is then used to melt the braze metal, and capillary action draws it into the prepared gap.

The above method of braze metal application requires considerable labor, and care must be taken to ensure that the filler metal has flowed into the inner portions of the joint. To avoid these difficulties, the braze metal is often inserted into the joint prior to heating, usually in the form of wires, foils, shims, powders, or preformed rings, washers, disks, or slugs. Rings or shims can also be fitted into internal grooves in the joint before the parts are assembled.

When using preloaded joints, care must be exercised to ensure that the filler metal is not drawn away from the intended surface by the capillary action of another surface of contact. Capillary action will always pull the molten braze metal into the smallest clearance, regardless of whether that was the intended location. In addition, the flow of filler metal must not be cut off by inadequate clearances or the presence of entrapped or escaping air. Fillets and grooves within the joint can also act as reservoirs and trap the filler metal.

Yet another approach is to precoat one or both of the surfaces to be joined with the brazing alloy. Simply placing the materials in contact and heating forms the desired bond. By having the braze material already in place over the full area of contact, the joining operation does not have to rely on capillary action and metal flow. More complex assemblies can be produced than with conventional methods, and the thickness of the braze material is precisely controlled to provide maximum strength to the joint.

All of the components must maintain fixed positions during the brazing operation, and some form of restraint or fixturing is often required. Alignment and clearances can often be maintained by tack welding, riveting, staking, expanding or flaring, swaging, knurling, or dimpling. Shims, wires, ribbons, and screens can also be employed to assist in locating pieces or maintaining fit. For more complex components, special brazing *jigs and fixtures* are often used to hold the components during the heating. When these are used, however, it is necessary to provide springs that will compensate for thermal expansion, particularly when two or more dissimilar metals are being joined.

HEATING METHODS USED IN BRAZING

Since molten metal tends to flow toward the location of highest temperature, it is important that the heat sources used in brazing control both the temperature and the uniformity of that temperature throughout the joint. In specifying the heating method, a number of factors should be considered, including the size and shape of the parts being brazed, the type of material being joined, and the desired quantity and rate of production.

A common source of heat for brazing is a gas-flame torch. In the *torch-brazing* procedure, oxyacetylene, oxy-hydrogen, or other gas-flame combinations can be used. Most repair brazing is done in this manner because of its flexibility and simplicity, but the process is also widely used in production applications where specially shaped torches speed the heating and reduce the amount of skill required. Local heating permits the retention of most of the original material strength and enables large components to be joined with little or no distortion. The major drawbacks are the difficulty in controlling the temperature and maintaining uniformity of heating, as well as meeting the cost of skilled labor. A protective flux is usually required, and the flux residue must be removed after brazing.

If the flux and filler metal can be preloaded into the joints and the part can endure uniform heating, a number of assemblies can be brazed simultaneously in controlled-atmosphere or vacuum furnaces, a process known as *furnace brazing*. If the components are not likely to maintain their alignment, brazing jigs or fixtures must be used. Fortunately, for most assemblies that are to be furnace brazed, a light press fit is usually sufficient to maintain alignment. Figure 33-16 shows some typical furnace-brazed assemblies.

Because excellent control of the furnace temperature is possible and no skilled labor is required, furnace brazing is particularly well suited for mass-production operations, with either batch- or continuous-type furnaces being used. Furnace brazing heats the entire assembly in a uniform manner and therefore produces less warpage and distortion than processes that employ localized heating. Extremely complex assemblies can be produced, with multiple joints being formed in a single heating.

A variety of furnace atmospheres can be utilized to reduce oxide films and prevent both the base and filler metals from oxidizing during the brazing operation. A chemical flux may no longer be needed, and the parts emerge clean and free of contaminants. When reactive materials are to be joined or the joint must meet the highest of standards, a vacuum furnace may be preferred.

A third type of heating is *salt-bath brazing*, where the parts are preheated and then dipped in a bath of molten salt that is maintained at a temperature slightly above the melting point of the brazing metal. This process offers three distinct advantages:

1. The salt bath acts as the brazing flux, preventing oxidation and enhancing wettability.
2. The work heats very rapidly because it is in complete contact with the heating medium.

FIGURE 33-16 Typical furnace-brazed assemblies. *(Courtesy of Pacific Metals Company, a division of Reliance Steel & Aluminum, Los Angeles, CA.)*

3. Temperature can be accurately controlled, so thin pieces can be attached to thicker pieces without danger of overheating. This last feature makes the process well suited for brazing aluminum, where precise temperature control is often required.

In salt-bath brazing, the parts must be held in jigs or fixtures (or be prefastened in some manner), and the brazing metal must be preloaded into the joints. To assure that the bath remains at the desired temperature during the immersion process, its volume must be substantially larger than that of the assemblies to be brazed.

In *dip brazing* the assemblies are immersed in a bath of molten brazing metal. The bath thus provides both the heat and the metal for the joint. Since the braze metal will usually coat the entire workpiece, it is a somewhat wasteful process and is usually employed only for small products.

Induction brazing utilizes high-frequency induction currents as the source of heat and is therefore limited to the joining of electrically conductive materials. A variety of high-frequency AC power supplies is available in large and small capacities. These are coupled to a simple heating coil designed to fit around the joint. The heating coils are generally formed from copper tubing and typically carry a supply of cooling water. Although the filler metal can be added to the joint manually after it is heated, the usual practice is to use preloaded joints to speed the operation and produce more uniform bonds. Induction brazing offers the following advantages, which account for its extensive use:

1. The complete heating cycle is very rapid, usually only a few seconds in duration.
2. The operation can be made semiautomatic so that only semiskilled labor is required.
3. Heating can be confined to the specific area of the joint through use of specially designed coils, frequency control, and short heating times. This minimizes softening and distortion and reduces problems associated with scale and discoloration.
4. Uniform results are easily obtained.
5. By making new and relatively simple heating coils, a wide variety of work can be brazed with a single power supply.

Resistance brazing can be used to produce relatively simple joints in metals with high electrical conductivity. The parts to be joined are pressed between two electrodes and a current is passed through. Unlike resistance welding, the carbon or graphite electrodes provide most of the resistance in resistance brazing, and the heating of the joint is primarily by conduction from the hot electrodes.

Infrared heat lamps, lasers, and electron beams can also be used to provide the heat required for brazing. Recent studies have also shown microwave energy to be an efficient heat source. Silicon carbide plates are positioned around the joint and are heated by the microwaves. Heat is then transferred to the joint by radiation.

FLUX REMOVAL AND OTHER POSTBRAZE OPERATIONS

Since most brazing fluxes are corrosive, the flux residue should be removed from the work as soon as brazing is completed. Rapid and complete flux removal is particularly important in the case of aluminum, where chlorides can be particularly detrimental. Fortunately, many brazing fluxes are water soluble, and an immersion in a hot-water tank for a few minutes will often provide satisfactory results. Blasting with grit or sand is another effective method of flux removal, but this procedure may not be attractive if a good surface finish is to be maintained. Fortunately, such drastic treatment is seldom necessary.

Other postbraze operations may include heat treating, cleaning, and inspection. A visual examination is probably the simplest of the inspection techniques and is most effective when both sides of a brazed joint are accessible for examination. A proof test can be performed by subjecting the joint to loads in excess of those expected during service. Leak tests or pressure tests can assure gas- or liquid-tightness. Cracks and other flaws can be detected by dye penetrant, magnetic particle, ultrasonic, or radiographic examination. Destructive forms of evaluation include peel tests, tension or shear tests, and metallographic examination.

FLUXLESS BRAZING

Since the application and removal of brazing flux involves significant costs, particularly where complex joints and assemblies are involved, a large amount of work has been devoted to the development of procedures where a flux is not required. Controlled furnace atmospheres can make a flux unnecessary by reducing existing oxides and preventing the formation of new ones. Vacuum furnaces can also be used to create and preserve clean brazing surfaces. Special brazing metals have been developed with alloy additions, such as phosphorus, that can also fulfill the role of a flux.

BRAZE WELDING

Braze welding differs from straight brazing in that capillary action is not required to distribute the filler metal. Here the molten filler is simply deposited by gravity, as in oxyacetylene gas welding. Because relatively low temperatures are required and warping is minimized, braze welding is very effective for the repair of steel products and ferrous castings. It is also attractive for joining cast irons since the low heat does not alter the graphite shape, and the process does not require good wetting characteristics. Strength is determined by the braze metal being used and the amount applied. Considerable buildup may be required if full strength is to be restored to the repaired part.

Braze welding is almost always done with an oxyacetylene torch. The surfaces are first "tinned" with a thin coating of the brazing metal, and the remainder of the filler metal is then added. Figure 33-17 shows a schematic of braze welding.

■ 33.5 SOLDERING

Soldering is a brazing-type operation where the filler metal has a melting temperature (or liquidus temperature if the alloy has a freezing range) below 450°C (840°F). It is typically used for joining thin metals, connecting electronic components, joining metals while avoiding

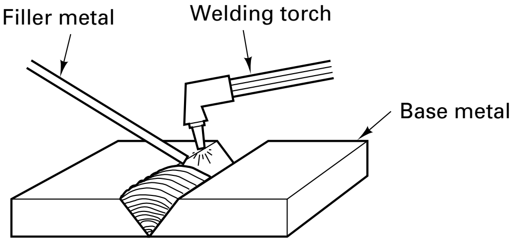

FIGURE 33-17 Schematic of the braze-welding process.

exposure to high elevated temperatures, and filling surface flaws and defects. The process generally involves six important steps: (1) design of an acceptable joint; (2) selection of the correct solder for the job; (3) selection of the proper type of flux; (4) cleaning of the surfaces to be joined; (5) application of flux, solder, and sufficient heat to allow the molten solder to fill the joint by capillary action and solidify; and (6) removal of the flux residue.

DESIGN AND STRENGTH OF SOLDERED JOINTS

Soldering can be used to join a wide variety of sizes, shapes, and thicknesses; it is employed extensively to provide electrical coupling or gas- or liquid-tight seals. While the low joining temperatures are attractive for heat-sensitive materials, soldered joints seldom develop shear strengths in excess of 1.75 MPa (250 psi). Consequently, if appreciable strength is required, soldered joints should be avoided, the contact area should be large, or some form of mechanical joint, such as a rolled-seam lock, should be made prior to soldering. Butt joints should never be used, and designs where peeling action is possible should be avoided. Figure 33-18 shows some of the more common solder joint designs, including lap, flanged butt, and interlock.

As with brazing, there is an optimal clearance for best performance. For typical solder joints, a clearance of 0.025 to 0.13 mm (0.001 to 0.005 in.) provides for capillary flow of the solder, expulsion of the flux, and reasonable joint strength. In addition, the parts should be held firmly so that no movement can occur until the solder has cooled to well below the solidification temperature. Otherwise, the resulting joint may contain cracks and have very little strength.

METALS TO BE JOINED

Table 33-6 summarizes the compatibility of soldering with a variety of engineering materials. Copper, silver, gold, and tin-plated steels are all easily soldered. Aluminum has a strong, adherent oxide that makes soldering difficult. Special fluxes and modified techniques may be required, but adequate joints are indeed possible, as shown by the large number of soldered aluminum radiators currently in automotive use.

SOLDER METALS

Soldering alloys, the filler metals for soldering, are generally combinations of low-melting-temperature metals, such as lead, tin, bismuth, indium, cadmium, silver, gold, and germanium. Because of their low cost, acceptable mechanical and physical properties, and many years of use, the most common solders are alloys of lead and tin with the addition of small amounts of antimony, usually less than 0.5%. The three most common alloys contain 60, 50, and 40% tin, and all melt below 240°C (465°F). Because tin is expensive, those alloys having higher proportions of tin are used only where their higher fluidity, higher strength, and lower melting temperature are desired. For wiped joints and for filling dents and seams, where the primary desire is appearance and little strength is required, solders containing only 10 to 20% tin are preferred. Joints made with the 5%

TABLE 33-6 Compatibility of Various Engineering Materials with Soldering

Material	Soldering Recommendation
Cast iron	Seldom used since graphite and silicon inhibit bonding
Carbon and low-alloy steels	Difficult for low-carbon materials; seldom used for high-carbon materials
Stainless steel	Common for 300 series; difficult for 400 series
Aluminum and magnesium	Seldom used; however, special solders are available
Copper and copper alloys	Recommended for copper, brass, and bronze
Nickel and nickel alloys	Commonly performed using high-tin solders
Titanium	Seldom used
Lead and zinc	Recommended, but must use low-melting-temperature solders
Thermoplastics, thermosets, and elastomers	Not recommended
Ceramics and glass	Not recommended
Dissimilar metals	Recommended, but with consideration for galvanic corrosion
Metals to nonmetals	Not recommended
Dissimilar nometals	Not recommended

tin alloy require higher temperatures to produce but will withstand service temperatures as high as 150°C (300°F).

Other soldering alloys may be specified for special purposes or where environmental or health concerns dictate the use of lead-free joints. Lead and lead compounds can be quite toxic. Since 1988, the use of lead-containing solders in drinking water lines has been prohibited in the United States, and concern has been expressed regarding other applications and industries. Japan and the European Union have banned the use of lead-containing solders in electronic equipment. If substitute solders are to be acceptable, however, they should not only be harmless to the environment, but should also exhibit desirable characteristics in the areas of melting temperature, wettability, electrical and thermal conductivity, thermal-expansion coefficient, mechanical strength, ductility, creep resistance, thermal fatigue resistance, corrosion resistance, manufacturability, and cost. At present, none of the *lead-free solders* meet all of these requirements, and most are deficient in more than one area. Compatible fluxes must also be identified, and assembly methods may need to be modified.

Most of the alternative solders have been proposed from other eutectic alloy systems. Tin–antimony and tin–copper alloys are useful in electrical applications and have good strength and creep resistance but high melting points. Bismuth alloys have very low melting points and good fluidity but suffer from poor wettability. Indium alloys offer low melting points, ductility that is retained even at cryogenic temperatures, and rapid creep that allows joints between dissimilar metals to adjust to changes in temperature without generating internal stresses. Tin–indium alloys have been used to join metal to glass and glass to glass. They have very low melting points and good wettability, but they are expensive and can be somewhat brittle. Aluminum is often soldered with tin–zinc, cadmium–zinc, or aluminum–zinc alloys. Tin–silver and tin–gold offer possibilities when a somewhat higher melting point is desired (typically above 205°C, or 400°F) coupled with good mechanical strength and creep resistance, but both systems are limited by the high cost of their components. Lead–silver and cadmium–silver alloys can also be used for higher-temperature service. The three-component tin–silver–copper system has received considerable attention for electronics applications.

Like the filler metal used in brazing and braze welding, solders are available as wire and paste, as well as in a variety of standard and special preshaped forms. Table 33-7 presents some of the more common solder alloys with their melting properties and typical applications.

SOLDERING FLUXES

As in brazing, soldering requires that the metal surfaces be clean and free of oxide so that the solder can wet the surfaces and be drawn into the joint to produce an effective bond. Soldering fluxes are used to remove surface oxides and prevent oxide formation

TABLE 33-7 Some Common Solders and Their Properties

Composition (wt %)	Freezing Temperature (°C)			
	Liquidus	Solidus	Range	Applications
Lead-tin solders

during the soldering process, but it is essential that dirt, oil, and grease be removed before the flux is applied. This precleaning or surface preparation can be performed by a variety of chemical or mechanical means, including solvent or alkaline degreasers, acid immersion (pickling), grit blasting, sanding, wire brushing, and other mechanical abrasion techniques.

Soldering fluxes are generally classified as *corrosive* or *noncorrosive*. The most common noncorrosive flux is *rosin* (the residue after distilling turpentine) dissolved in alcohol. Rosin fluxes are suitable for making joints to copper and brass, and to tin-, cadmium-, and silver-plated surfaces, provided that the surfaces have been adequately cleaned prior to soldering. Aniline phosphate is a more active noncorrosive flux, but it has limited use because it emits toxic gases when heated. The wide variety of corrosive fluxes provide enhanced cleaning action but require complete removal after the soldering operation to prevent corrosion problems during service.

THE SOLDERING OPERATION

Soldering requires a source of sufficient heat and a means of transferring it to the metals being joined. Any method of heating that is suitable for brazing can be used for soldering, but furnace and salt-bath heating are seldom used. Most hand soldering is still done with soldering irons or small oxyfuel or air-fuel (acetylene, propane, butane, or MAPP) torches. Induction heating is used when large numbers of identical parts are to be soldered. For low-melting-point solders, infrared heat sources can also be employed. The joints can be preloaded with solder, or the filler metal can be supplied from a wire. The particular method of heating usually dictates which procedure is used.

Wave soldering, depicted in Figure 33-19, is a process used to solder wire ends, such as the multiple connectors that protrude through holes in electronic circuit boards. Molten solder is pumped upward through a submerged nozzle to create a wave or crest in a pool of molten metal. The circuit boards are then passed across this wave at a height where each of the pins sees contact with the molten metal. Wetting and capillary action pulls solder into each joint, and numerous connections are made as each board passes across the wave.

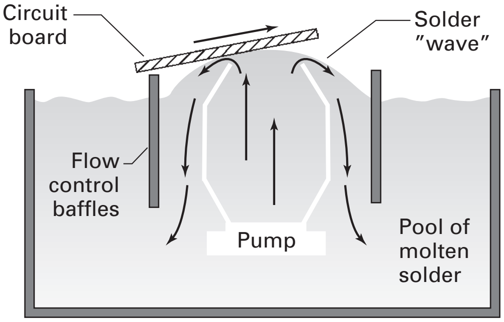

FIGURE 33-19 Schematic of wave soldering.

In the *vapor-phase soldering* process, a product with prepositioned solder is passed through a chamber containing hot, saturated vapor. The vapor condenses on the cooler product, transferring its heat of vaporization. This results in rapid and uniform heating, with excellent temperature control and the possibility of an oxygen-free environment. The soldering temperature is limited only by the boiling point of the fluid, with current materials operating in the range of 100° to 265°C (212°to 510°F). While the process can be used to cure epoxies and stress relieve metals, its primary application is the soldering of surface-mounted components to substrate materials. Because of the precise temperature control, multipass soldering is possible, using up to three different solder compositions with three different melting temperatures. Because the solder is prepositioned, this process is also known as *vapor-phase reflow soldering*.

Dip soldering, where the entire piece is immersed in molten metal, has been used to produce automobile radiators and "tinned" coatings.

FLUX REMOVAL

After soldering, the flux residues should be removed from the finished joints, either to prevent corrosion or for the sake of appearance. Flux removal is rarely difficult, provided that the type of solvent in the flux is known. Water-soluble fluxes can be removed with hot water and a brush. Alcohol will remove most rosin fluxes. However, when the flux contains some form of grease, as in most paste fluxes, a grease solvent must be used, followed by a hot-water rinse. In the past, solvents containing chlorofluorocarbons (CFCs) were the cleaners of choice, but since they have been implicated in the depletion of atmospheric ozone, an alternative means of flux removal should be employed or the process converted to fluxless soldering.

FLUXLESS SOLDERING

Several *fluxless-soldering* techniques have been developed using controlled atmospheres (such as hydrogen plasma), thermomechanical surface activation (such as plasma gas impingement), or protective coatings that prevent oxide formation and enhance wetting. Additional successes have been reported with both laser and ultrasonic soldering.

Review Questions

1. In what ways is a thermit weld similar to the production of a casting?
2. What is the source of the welding heat in thermit welding?
3. For what types of applications might thermit welding be attractive?
4. What is the source of the welding heat in electroslag welding?
5. What are some of the various functions of the slag in electroslag welding?
6. Electroslag welding would be most attractive for the joining of what types of geometries and thicknesses?
7. Why is a high vacuum required in the electron-beam chamber of an electron-beam welding machine?
8. What types of production limitations are imposed by the high-vacuum requirements of electron-beam welding? What compromises are made when welding is performed on pieces outside the vacuum chamber?
9. What are the major assets and negative features of high-voltage electron-beam welding equipment?
10. What are some of the attractive features of electron-beam welding? Negative features?
11. What is unique about the fusion zone geometry of electron-beam welds?
12. What are some of the ways in which laser-beam welding is more attractive than electron-beam welding?
13. Which type of laser light can be transmitted through fiber-optic cable?
14. Why is laser-beam welding an attractive process for producing tailored blanks for sheet metal forming? For use on small electronic components?
15. What are the attractive properties of hybrid processes that combine laser and arc welding?
16. What is the function of the *assist gas* in laser-beam cutting?
17. How do the cut edges differ with endothermic laser cutting and exothermic laser cutting?
18. What features have made lasers a common means of cutting composite materials?
19. What are some of the attractive features of laser spot welding?
20. In the flash-welding process, why is it important to have a sufficient duration of arcing and sufficient amount of upsetting?
21. What are some common objectives of surfacing operations?
22. What types of materials are applied by surfacing methods?
23. What are some of the primary methods by which surfacing materials can be deposited onto a metal substrate?
24. What are some of the techniques that can be used to apply a thermal spray coating?
25. How is thermal spraying similar to surfacing? How is it different?
26. Why is surface preparation such a critical feature of metallizing?
27. What are some of the more common applications of sprayed coatings?
28. Provide a reasonable definition of brazing.
29. What are some key differences between brazing and fusion welding?
30. Why is brazing an attractive process for joining dissimilar materials?
31. What advantages can be gained by the lower temperatures of the brazing process?
32. Why do brazed joints have an enhanced susceptibility to corrosion?
33. What is the most important factor contributing to the strength of a brazed joint?
34. How does capillary action relate to joint clearance?
35. Why is it necessary to adjust the initial room-temperature clearance of a joint between two significantly different metals?
36. What is wettability? Fluidity? How does each relate to brazing?
37. What are the two most common types of brazed joints and the attractive features of each?
38. What are some important considerations when selecting a brazing alloy?
39. What are some of the most commonly used brazing metals?
40. What special measures should be taken when brazing aluminum?
41. What are the three primary functions of a brazing flux?
42. Why is it important to preclean brazing surfaces before applying the flux?
43. In what ways might braze metal be preloaded into joints?
44. What is the purpose of brazing jigs and fixtures?
45. What is the primary attraction of furnace-brazing operations?
46. Why might reducing atmospheres or a vacuum be employed during furnace-brazing operations?
47. Why is dip brazing usually restricted to use with small parts?
48. What are some of the attractive features of induction brazing?
49. Why is flux removal a necessary part of many brazing operations?
50. What benefits can be achieved through fluxless brazing?
51. How does braze welding differ from traditional brazing?
52. What is the primary difference between brazing and soldering?
53. Why is soldering unattractive if a high-strength joint is desired?
54. For many years, the most common solders were alloys of what two base metals?
55. What is driving the conversion to lead-free solders?
56. What are some of the difficulties encountered when attempting a conversion to lead-free solder?
57. What are the two basic families of soldering flux?
58. What are some of the more common heat sources for producing a soldered joint?

Problems

1. A common problem with brazed or soldered joints is galvanic corrosion, since the joint usually involves dissimilar metals in direct metal-to-metal electrical contact.
   a. For each of the various solder or braze joints described below, determine which material will act as the corroding anode.
      (1) Two pieces of low-carbon steel being brazed with a copper-base brazing alloy
      (2) A copper wire being soldered to a steel sheet using lead–tin solder
      (3) Pieces of tungsten carbide being brazed into recesses in a carbon-steel plate
   b. How do the various lead-free solders compare to the conventional lead–tin solders with regard to their potential for galvanic corrosion?
   c. If galvanic corrosion becomes a significant and chronic problem in a brazed assembly, what changes might you suggest that could possibly reduce or eliminate the problem?

CHAPTER 34

ADHESIVE BONDING, MECHANICAL FASTENING, AND JOINING OF NONMETALS

34.1 ADHESIVE BONDING

The *ideal adhesive* bonds to any material, needs no surface preparation, cures rapidly, and maintains a high bond strength under all operating conditions. It also doesn't exist. However, tremendous advances have been made in the development of adhesives that are stronger, easier to use, less costly, and more reliable than many of the alternative methods of joining. From early applications, such as plywood, the use of structural adhesives has grown rapidly. Adhesives are everywhere—in construction, packaging, furniture, appliances, electronics, bookbinding, product assembly, and even medical and dental applications. They are used to bond metals, ceramics, glass, plastics, rubbers, composite materials, woods, and even a variety of roofing materials. Even such quality- and durability-conscious fields as the automotive and aircraft industries now make extensive use of adhesive bonding. Adhesives in the automotive industry have advanced from the attaching of interior and exterior trim to the joining of major components, such as door, hood, and trunk assemblies, and the installation of the nonmoving front and rear windows. Adhesive bonding has become the preferred means of assembly for polymeric body panels made from sheet-molding compounds and reaction-injection-molded (RIM) materials. Moreover, since adhesive bonding has the ability to bond such a wide variety of materials, its use has grown significantly with the ever-expanding applications of plastics and composites.

ADHESIVE MATERIALS AND THEIR PROPERTIES

In *adhesive bonding*, a nonmetallic material (the *adhesive*) is used to fill the gap and create a joint between two surfaces. The actual adhesives span a wide range of material types and forms, including *thermoplastic* resins, *thermosetting* resins, artificial *elastomers*, and even some ceramics. They can be applied as drops, beads, pellets, tapes, or coatings (films) and are available in the form of liquids, pastes, gels, and solids. *Curing* can be induced by the use of heat, radiation or light (photoinitiation), moisture, activators, catalysts, multiple-component reactions, or combinations thereof. Applications can be full load bearing (structural adhesives), light-duty holding or fixturing, or simply sealing (the forming of liquid- or gas-tight joints). With such a wide range of possibilities, the selection of the best adhesive for the task at hand can often be quite challenging.

The *structural adhesives* are selected for their ability to effectively transmit load across the joint; they include epoxies, cyanoacrylates, anaerobics, acrylics, urethanes, silicones, high-temperature adhesives, and hot melts. Both strength and rigidity may be important, and the bond must be able to be stressed to a high percentage of its maximum load for extended periods of time without failure.

1. *Epoxies*. The thermosetting epoxies are the oldest, most common, and most diverse of the adhesive systems; they can be used to join most engineering materials, including metal, glass, and ceramic. They are strong, versatile adhesives that can be designed to offer high adhesion, good tensile and shear strength, toughness, high rigidity, creep resistance, easy curing with little shrinkage, good chemical resistance, and tolerance to elevated temperatures. Various epoxies can be used over a temperature range from −50° to +250°C (−60° to +500°F). After curing at room temperature, shear strengths can be as high as 35 to 70 MPa (5000 to 10,000 psi).

   Single-component epoxies use heat as the curing agent. Most epoxies, however, are two-component blends involving a resin and a curing agent, plus possible additives such as accelerators, plasticizers, and fillers that serve to enhance cure rate, flexibility, peel resistance, impact resistance, or other characteristics. Heat may again be required to drive or accelerate the cure.

   Low peel strength and poor flexibility limit epoxy adhesives, and the bond strength can be sensitive to moisture and surface contamination. Epoxies are often brittle at low temperatures, and the rate of curing is comparatively slow. Sufficient strength for structural applications is generally achieved in 8 to 12 hours, with full strength often requiring two to seven days.

2. *Cyanoacrylates*. These are liquid monomers that polymerize when spread into a thin film between two surfaces. Trace amounts of moisture on the surfaces promote curing at amazing speeds, often in as little as two seconds. Thus, the cyanoacrylates offer a one-component adhesive system that cures at room temperature with no external impetus. Commonly known as *superglues*, this family of adhesives is now available in the form of liquids and gels of varying viscosity, toughened versions designed to overcome brittleness, and even nonfrosting varieties.

   The cyanoacrylates provide excellent tensile strength, fast curing, and good shelf life, and they adhere well to most commercial plastics, metals, and rubbers. They are limited by their high cost, poor peel strength, and brittleness. Bond properties are poor at elevated temperatures, and effective curing requires good component fit (gaps must be smaller than 0.25 mm, or 0.010 in.).

3. *Anaerobics*. These one-component, thermosetting, polyester acrylics remain liquid when exposed to air. When confined to small spaces and shut off from oxygen, as in a joint to be bonded or along the threads of an inserted fastener, the polymer becomes unstable. In the presence of iron or copper, it polymerizes into a bonding-type resin, without the need for elevated temperature. Curing can occur across gaps as large as 1 mm, or 0.04 in. Additives can reduce odor, flammability, and toxicity and can speed the curing operation. Slow-curing anaerobics require 6 to 24 hours to attain useful strength. With selected additives and heat, however, curing can be reduced to as little as five minutes.

   The anaerobics are extremely versatile and can bond almost anything, including oily surfaces. The joints resist vibrations and offer good sealing to moisture and other environmental influences. Unfortunately, they are somewhat brittle and are limited to service temperatures below 150°C (300°F).

4. *Acrylics*. The acrylic-based adhesives offer good strength, toughness, and versatility, and they are able to bond a variety of materials, including plastics, metals, ceramics, and composites, even oily or dirty surfaces. Most involve application systems where a catalyst primer (curing agent) is applied to one of the surfaces to be joined and the adhesive is applied to the other. The pretreated parts can be stored separately for weeks without damage. Upon assembly, the components react to produce a strong bond at room temperature. Heat can often accelerate the curing, and at least one va-

riety cures with ultraviolet (UV) light. In comparison to other varieties of adhesives, the acrylics offer strengths comparable to the epoxies, flexible bonds, good resistance to water and humidity, and the added advantages of room-temperature curing and a no-mix application system. Major limitations include poor strength at high temperatures, flammability, and an unpleasant odor when still uncured.

5. *Urethanes*. Urethane adhesives are a large and diverse family of polymers that are generally targeted for applications that involve temperatures below 65°C (150°F) and components that require great flexibility. Both one-part thermoplastic and two-part thermosetting systems are available. Urethanes cure quickly to handling strength but are slow to reach the full-cure condition. Two minutes to handling with 24 hours to complete cure is common at room temperature.

   Compared to other structural adhesives, the urethanes offer good flexibility and toughness, even at low operating temperatures. They are somewhat sensitive to moisture, degrade in many chemical environments, and can involve toxic components or curing products.

6. *Silicones*. The silicone thermosets cure from the moisture in the air or adsorbed moisture from the surfaces being joined. They form low-strength structural joints and are usually selected when considerable expansion and contraction are expected in the joint; flexibility is required (as in sheet metal parts); or good gasket, gap-filling, or sealing properties are necessary. Metals, glass, paper, plastics, and rubbers can all be joined. The adhesives are relatively expensive, and curing is slow, but the bonds that are produced can resist moisture, hot water, oxidation, and weathering, and they retain their flexibility at low temperature.

7. *High-temperature adhesives*. When strength must be retained at temperatures in excess of 300°C (500°F), high-temperature structural adhesives should be specified. These include epoxy phenolics, modified silicones or phenolics, polyamides, and some ceramics. High cost and long cure times are the major limitations for these adhesives, which see primary application in the aerospace industry.

8. *Hot melts*. Hot-melt adhesives can be used to bond dissimilar substrates, such as plastics, rubber, metals, ceramics, glass, wood, and fibrous materials like paper, fabric, and leather. They can produce permanent or temporary bonds, seal gaps, and plug holes. While generally not considered to be true structural adhesives, the hot melts are being used increasingly to transmit loads, especially in composite-material assemblies. The joints can withstand exposure to vibration, shock, humidity, and numerous chemicals, and they offer the added features of sound deadening and vibration damping.

   Most hot-melt adhesives are thermoplastic resins that are solid at room temperature but melt abruptly when heated into the range of 100° to 150°C (200° to 300°F). They are usually applied as heated liquids (between 160° and 180°C) and form a bond as the molten adhesive cools and resolidifies. Another method of application is to position the adhesive in the joint prior to operations, such as the paint-bake process in automobile manufacture. During the baking, the adhesive melts, flows into seams and crevices, and seals against the entry of corrosive moisture. These adhesives contain no solvents and do not need time to cure or dry. Hot melts achieve over 80% of their bond strength within seconds of solidification, but they do soften and creep when subsequently exposed to elevated temperatures and can become brittle when cold.

Additives also play a large part in the success of industrial adhesives. They can impart or enhance properties like toughness, joint durability, moisture resistance, adhesion, and flame retardance. Rheological additives and plasticizers control viscosity and flow. Adhesives must penetrate the surfaces to be bonded but should not flow in an uncontrollable fashion. Fillers and extenders provide bulk and reduce cost.

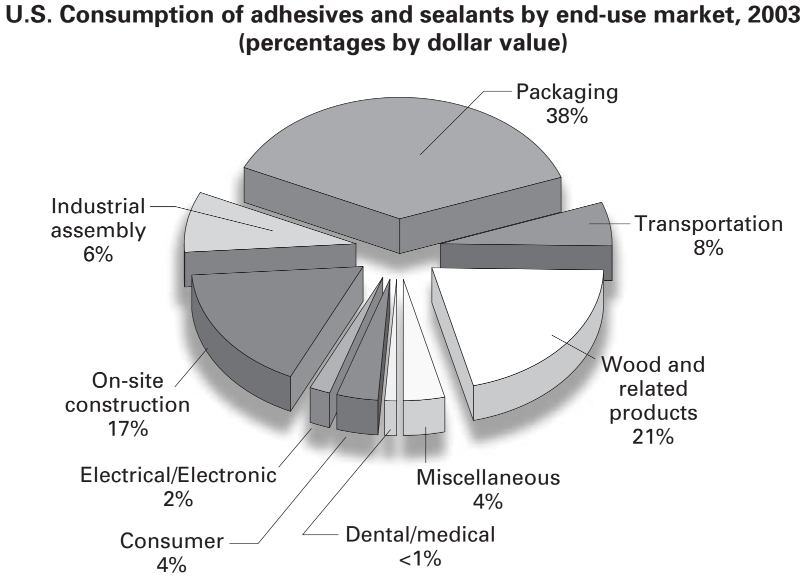

FIGURE 34-2 Distribution of adhesives and sealants by end-use areas. *(Reprinted with permission from* The Rauch Guide to the US Adhesives & Sealants Industry, *Fifth Edition, 2006, Grey House Publishing, Millerton, NY).*

Figure 34-1 shows the distribution of various types of adhesive and sealant products for a recent year, and Figure 34-2 classifies adhesives by end-use markets. Table 34-1 lists some popular structural adhesives, along with their service and curing temperatures and expected strengths. Table 34-2 presents the advantages and disadvantages of various curing processes.

NONSTRUCTURAL AND SPECIAL ADHESIVES

There are a number of other types of adhesives whose limited load-bearing capabilities place them in a nonstructural classification. Nevertheless, they still play roles in manufacturing through a variety of uses, such as labeling and packaging. The hot-melt adhesives are often placed in this category but can be used for applications in both classifications. *Evaporative adhesives* use an organic solvent or water base, coupled with vinyls, acrylics, phenolics, polyurethanes, or various types of rubbers. Some common evaporative adhesives are rubber cements and floor waxes. *Pressure-sensitive adhesives* are usually based on various rubbers, compounded with additives to bond at room

TABLE 34-1 Some Common Structural Adhesives, Their Cure Temperatures, Maximum Service Temperatures, and Strengths under Various Types of Loadings

Adhesive Type	Cure Temperature (°F)	Service Temperature (°F)	Lap Shear Strength (psi at °F)[a]	Peel Strength at Room Temperature (lb/in.)
Butyral-phenolic	275 to 350	−60 to 175	1000 at 175 2500 at RT	10
Epoxy				
Room-temperature cure	60 to 90	−60 to 180	1500 at 180 2500 at RT	4
Elevated-temperature cure	200 to 350	−60 to 350	1500 at 350 2500 at RT	5
Epoxy-nylon	250 to 350	−420 to 180	2000 at 180 6000 at RT	70
Epoxy-phenolic	250 to 350	−420 to 500	1000 at 175 2500 at RT	10
Neoprene-phenolic	275 to 350	−60 to 180	1000 at 180 2000 at RT	15
Nitrile-phenolic	275 to 350	−60 to 250	2000 at 250 4000 at RT	60
Polyimide	550 to 650	−420 to 1000	1000 at 1000 2500 at RT	3
Urethane	75 to 250	−420 to 175	1000 at 175 2500 at RT	50

[a] RT, room temperature.

TABLE 34-2 Advantages and Disadvantages of Various Structural Adhesive Curing Processes

Curing Process	Advantages	Disadvantages
Mixing reactive components	Good shelf life, unlimited depth of cure, accelerated with heat	High processing costs, mix ratio critical to performance
Anaerobic cure	Single-component adhesive, good shelf life	Poor depth of cure, require primer on many surfaces, sensitive to surface contaminants
Heat cure	Unlimited depth of cure, heat can aid adhesion	Expenses for oven energy cost, heat can adversely affect some substrates
Moisture cure	Room-temperature process, one component, no curing equipment required	Long cure cycles (12–72 hr), minimum % humidity required, limited depth of cure
Light cure	Rapid cure, cure on demand	Expenses for UV light source, limited depth of cure, most allow light to reach bond
Surface-initiated cure	Rapid cure	Poor depth of cure

temperature with a brief application of pressure. No cure is involved, and the tacky adhesive-coated surfaces require no activation by water, solvents, or heat. Peel-and-stick labels, cellophane tape, and Post-it notes are examples of this group of adhesives. *Delayed-tack adhesives* are similar to the pressure-sensitive systems but are nontacky until activated by exposure to heat. Once heated, they remain tacky for several minutes to a few days to permit use or assembly.

While most adhesives are electrical and thermal insulators, *conductive adhesives* can be produced by incorporating selected fillers, such as silver, copper, or aluminum, in the form of flakes or powder. Certain ceramic oxide fillers can be used to provide thermal conductivity coupled with electrical insulation.

Still another group of commercial adhesives are those designed to cure by exposure to radiation, such as visible, infrared, or ultraviolet light; microwaves; or electron beams. These *radiation-curing adhesives* offer rapid conversion from liquid to solid at room temperature and a curing mechanism that occurs throughout, rather than progressing from exposed surfaces (as with the competing low-temperature air or moisture cures). Current applications include a wide variety of dental amalgams that can fill cavities or seal surfaces while matching the color of the remaining tooth. In the manufacturing realm, heat-sensitive materials can be effectively bonded, and the rapid cure time significantly reduces the need for fixturing.

DESIGN CONSIDERATIONS

The structural adhesives have been used for a wide range of applications in fields as diverse as automotive, aerospace, appliances, biomedical, electronics, construction, machinery, and sporting goods. Proper selection and use, however, requires consideration of a number of factors, including the following:

1. What materials are being joined? What are their surface finishes, hardnesses, and porosities? Will the thermal expansions or contractions be different?
2. How will the joined assembly be used? What type of joint is proposed, what will be the bond area, and what will be the applied stresses? How much strength is required? Will there be mechanical vibration, acoustical vibration, or impacts?
3. What temperatures might be required to affect the cure, and what temperatures might be encountered during service? Consideration should be given to the highest temperature, lowest temperature, rates of temperature change, frequency of change, duration of exposure to extremes, properties required at the various conditions, and differential expansions or contractions.
4. Will there be subsequent exposure to solvents, water or humidity, fuels or oils, light, ultraviolet radiation, acid solutions, or general weathering?
5. What is the desired level of flexibility or stiffness? How much toughness is required?
6. Over what length of time is stability desired? What portion of this time will be under load?
7. Is appearance important?
8. How will the adhesive be applied? What equipment, labor, and skill are required?
9. Are there restrictions relating to storage or shelf life? Cure time? Disposal or recyclability?
10. What will it cost?

Because there is such a large difference in bonding area, adhesive-bonded joints are often classified as either continuous surface or core-to-face. In *continuous-surface bonds*, both of the adhering surfaces are relatively large and are of the same size and shape. *Core-to-face bonds* have one *adherend* area that is very small compared to the other, like when the edges of lightweight honeycomb core structures are bonded to the face sheets (see Figure 15-19).

A major design consideration for both types is the nature of the stresses that the joint will experience. As shown in Figure 34-3, applied stresses can subject the joint to *tension*, *compression*, *shear*, *cleavage*, and *peel*. Most of the structural adhesives are significantly weaker in peel and cleavage than they are in shear or tension. Therefore, adhesively bonded joints should be designed so as much of the stress as possible is in shear, tension, or compression, where all of the bonded area shares equally in bearing the load. The shear strengths of structural adhesives range from 14 to 40 MPa (2000 to 6000 psi) at room temperature, while the tensile strengths are only 4 to 8 MPa (600 to 1200 psi). The best adhesive-bonded joints, therefore, will be those that are designed to utilize the superior shear strengths. Creep, vibration and associated fatigue, thermal shock, and mechanical shocks can all induce additional stresses. When vibration or shock loading is expected, the elastomeric adhesives are quite attractive, since they can provide valuable damping.

Figure 34-4 shows some commonly used joint designs and indicates their relative effectiveness. The butt joint is unsatisfactory because it offers only a minimum of bond surface area and little resistance to cleavage. Useful strength is generally obtained by

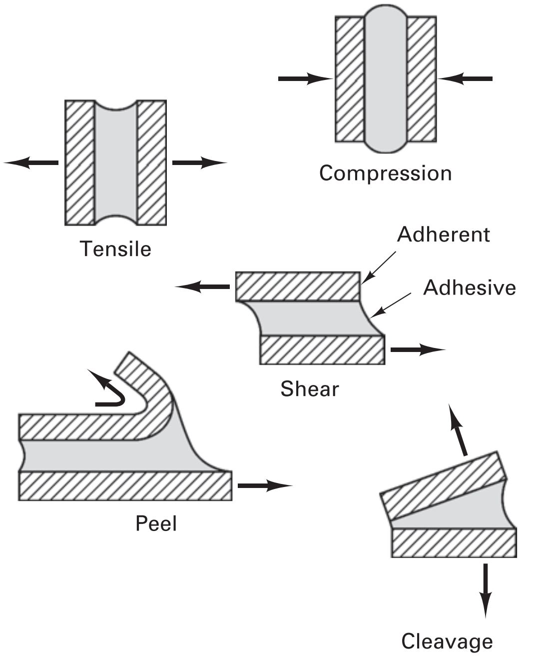

FIGURE 34-3 Types of stresses in adhesive-bonded joints.

increasing the bond area through the addition of straps or the conversion to some form of lap design. The scarf joint, shown previously in Figure 34-14, is also used when uniform thickness is required. Figure 34-5 shows some recommended designs for corner and angle joints. Adhesives can also be used in combination with welding, brazing, or mechanical fasteners. Spot welds or rivets can provide additional strength or simply prevent movement of the components when the adhesive is not fully cured or is softened by exposure to elevated temperature.

To obtain satisfactory and consistent quality in adhesive-bonded joints, it is essential that the surfaces be properly prepared. Procedures vary widely but frequently include cleaning of the surfaces to be joined. Contaminants, such as oil, grease, rust, scale, or even mold-release agents, must be removed to ensure adequate wetting of the surfaces by the adhesive. Solvent or vapor cleaning is usually adequate. Chemical alteration of the surface to form a new intermediate layer, chemical etching, steam cleaning, or abrasive techniques may also be employed to further enhance wetting and bonding. While thick or loose oxide films are detrimental to adhesive bonding, a thin porous oxide or surface primer can often provide surface roughness and enhance adhesion.

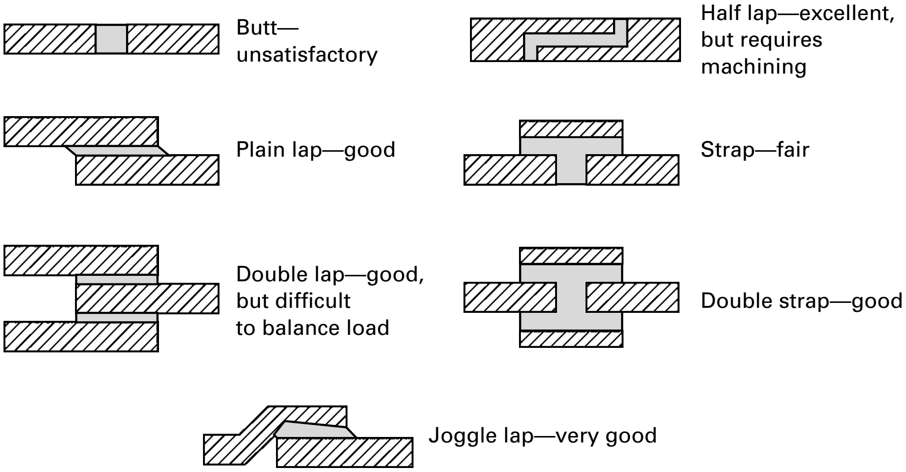

FIGURE 34-4 Possible designs of adhesive-bonded joints and a rating of their performance in service.

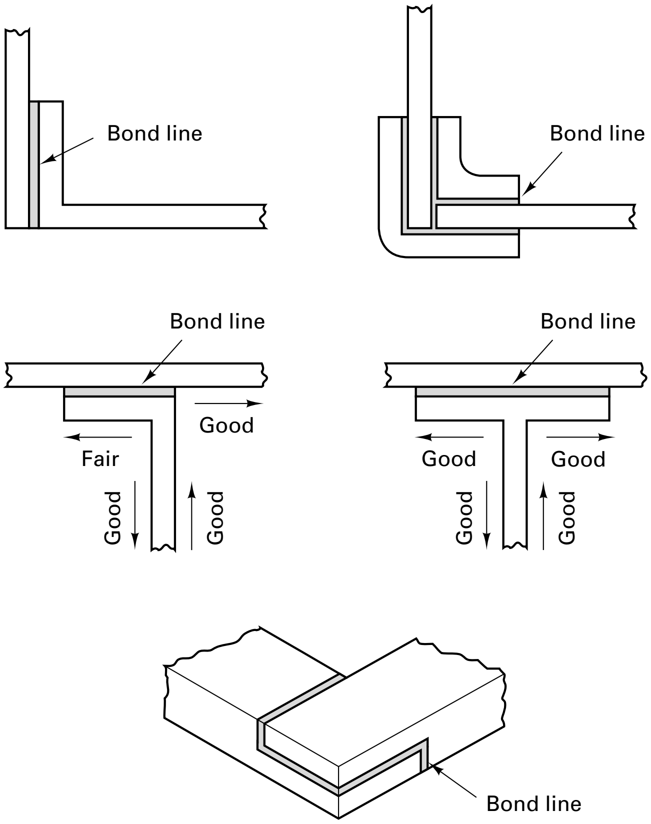

FIGURE 34-5 Adhesively bonded corner and angle joint designs.

The destructive testing of adhesive joints, or the examination of joint failures, can reveal much about the effectiveness of an adhesive system. If failure occurs by separation at the adhesive–substrate interface, as shown in Figure 34-6a, it is indicative of a bonding or adhesion problem. If the failure lies entirely within the adhesive, as in Figure 34-6b, then the bonding with the substrate is adequate, but the strength of the adhesive may need to be enhanced. Finally, if failure occurs within the substrate materials, as in Figure 34-6c, the joint is good, and failure is unrelated to the adhesive bonding operation.

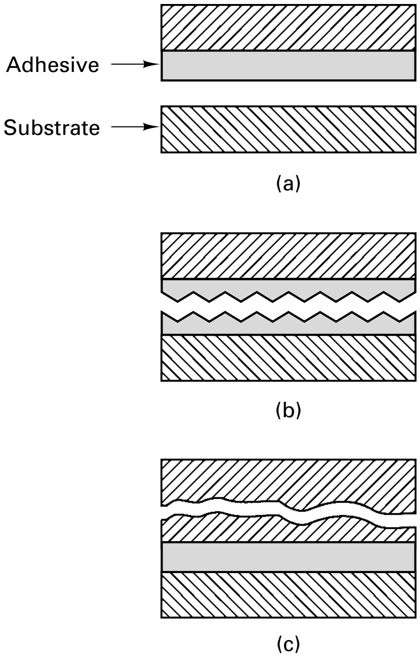

FIGURE 34-6 Failure modes of adhesive joints. (a) Adhesive failure, (b) cohesive failure within the adhesive, and (c) cohesive failure within the substrate.

ADVANTAGES AND LIMITATIONS

Adhesive bonding has many obvious advantages. Almost any material or combination of materials can be joined in a wide variety of sizes, shapes, and thicknesses. For most adhesives, the curing temperatures are low, seldom exceeding 180°C (350°F). A substantial number cure at room temperature or slightly above and can provide adequate strength for many applications. As a result, very thin or delicate materials, such as foils, can be joined to each other or to heavier sections. Heat-sensitive materials can be joined without damage, and heat-affected zones are not present in the product. When joining dissimilar materials that experience changes in temperature, the adhesive often provides a bond that can tolerate the stresses of differential expansion and contraction.

Because adhesives bond the entire joint area, good load distribution and fatigue resistance are obtained, and stress concentrations (such as those observed with screws, rivets, and spot welds) are avoided. Because of the high extension and recovery properties of flexible adhesives, the fatigue resistance can be up to 20 times that of riveted or spot-welded assemblies. The large contact areas that are usually employed provide a total joint strength that compares favorably with alternative methods of joining or attachment. Shear strengths of industrial adhesives can exceed 20 MPa, or 3000 psi, and additives can be incorporated to enhance strength, increase flexibility, or provide resistance to various environments.

Adhesives are generally inexpensive and frequently weigh less than the fasteners needed to produce a comparable-strength joint. In addition, an adhesive can also provide thermal and electrical insulation; act as a damper to noise, shock, and vibration; stop a propagating crack; and provide protection against galvanic corrosion when dissimilar metals are joined. By providing both a joint and a seal against moisture, gases, and fluids, adhesive-bonded assemblies often offer improved corrosion resistance throughout their useful lifetime. When used to bond polymers or polymer-matrix composites, the adhesive can be selected from the same family of materials to ensure good compatibility.

From a manufacturing viewpoint, the formation of a joint does not require the capillary-induced flow of material, as in brazing and soldering. The bonding adhesive is applied directly to the surfaces, and the joint is then formed by the application of heat and/or pressure. Most adhesives can be applied quickly, and useful strengths are achieved in a short period of time. Some curing mechanisms take as little as two to three seconds! Surface preparation may be reduced since bonding can occur with an oxide film in place, and rough surfaces are actually beneficial because of the increased contact area. Tolerances are less critical since the adhesives are more forgiving than alternative methods of bonding. The adhesives are often invisible; exposed surfaces are not defaced; smooth contours are not disturbed; and holes do not have to be made, as with rivets or bolts. These factors contribute to reduced manufacturing costs, which can be further reduced through the elimination of the mechanical fasteners and the absence of highly skilled labor. Bonding can often be achieved at locations that would prevent the access of many types of welding apparatus. Robotic dispensing systems can often be utilized.

The major disadvantages of adhesive bonding are the following:

1. There is no universal adhesive. Selection of the proper adhesive is often complicated by the wide variety of available options.
2. Most industrial adhesives are not stable above 180°C (350°F). Oxidation reactions are accelerated, thermoplastics can soften and melt, and thermosets decompose. While some adhesives can be used up to 260°C (500°F), elevated temperatures are usually a cause for concern.
3. Some adhesives shrink significantly during curing.
4. High-strength adhesives are often brittle (poor impact properties). Resilient ones often creep. Some become brittle when exposed to low temperatures.
5. Surface preparation and cleanliness, adhesive preparation, and curing can be critical if good and consistent results are to be obtained. Some adhesives are quite sensitive to the presence of grease, oil, or moisture on the surfaces to be joined. Surface roughness and wetting characteristics must be controlled.
6. Assembly times may be greater than for alternative methods, depending upon the curing mechanism. Elevated temperatures may be required, as well as specialized fixtures.

7. It is difficult to determine the quality of an adhesive-bonded joint by traditional nondestructive techniques, although some inspection methods have been developed that give good results for certain types of joints.
8. Some adhesives contain objectionable chemicals or solvents, or produce them upon curing.
9. Many structural adhesives deteriorate under certain operating conditions. Environments that may be particularly hostile include heat, ultraviolet light, ozone, acid rain (low pH), water and humidity, salt, and numerous solvents. Thus, long-term durability and reliability may be questioned, and life expectancy is hard to predict.
10. Adhesively bonded joints cannot be readily disassembled.

Nevertheless, the extensive and successful use of adhesive bonding provides ample evidence that these limitations can be overcome if adequate quality control procedures are adopted and followed.

34.2 MECHANICAL FASTENING

INTRODUCTION AND METHODS

Mechanical fastening is a classification that includes a wide variety of techniques and fasteners designed to suit the individual requirements of a multitude of joints and assemblies. Included within this family are integral fasteners, threaded discrete fasteners (which includes screws, bolts, studs, and inserts), nonthreaded discrete fasteners (such as rivets, pins, retaining rings, nails, staples, and wire stitches), special-purpose fasteners (such as the quick-release and tamper-resistant types), shrink and expansion fits, press fits, seams, and others. Selection of the specific fastener or fastening method depends primarily on the materials to be joined, the function of the joint, strength and reliability requirements, weight limitations, dimensions of the components, and environmental conditions. Other considerations include cost, installation equipment and accessibility, appearance, and the need or desire for disassembly. When disassembly and reassembly are desired (as for parts replacement, maintenance, or repair), threaded fasteners, snap-fits, or other fasteners that can be removed quickly and easily should be specified. Such fasteners should not have a tendency to loosen after installation, however. If disassembly is not necessary, permanent fasteners are often preferred, or threaded fasteners can be coupled with anaerobic adhesives that cure to full strength at room temperature and "lock" the fastener in place.

A mechanical joint acquires its strength through either mechanical interlocking or interference of the surfaces as a result of a clamping force. No fusion or adhesion of the surfaces is required. The fasteners and fastening processes should be selected to provide the required strength and properties in view of the nature and magnitude of subsequent loading. Consider the possibility of vibrations and/or cyclic stresses that might promote loosening over a period of time. Added weight may be a significant factor in certain applications, such as aerospace and automotive. The need to withstand corrosive environments, operate at high or low temperatures, or face other severe conditions may be additional constraints to the selection of fasteners or fastening processes.

The effectiveness of a mechanical fastener often depends upon (1) the material of the fastener, (2) the fastener design (including the load-bearing area of the head), (3) hole preparation, and (4) the installation procedure. The general desire is to achieve a uniform load transfer, a minimum of stress concentration, and uniformity of installation torque or interference fit. Various means are available for achieving these goals, as described in the following paragraphs.

Integral fasteners are formed areas of a component that interfere or interlock with other components of the assembly; they are most commonly found in sheet metal products. Examples include lanced or shear-formed tabs, extruded hole flanges, embossed protrusions, edge seams, and crimps. Figure 34-7 shows some of these techniques, each of which involve some form of metal shearing and/or forming. The common beverage can includes several of these joints—an edge seam to join the top of the can to the body (as in Figure 34-7e) and an embossed protrusion that is subsequently flattened to attach the opener-tab (as in Figure 34-7d).

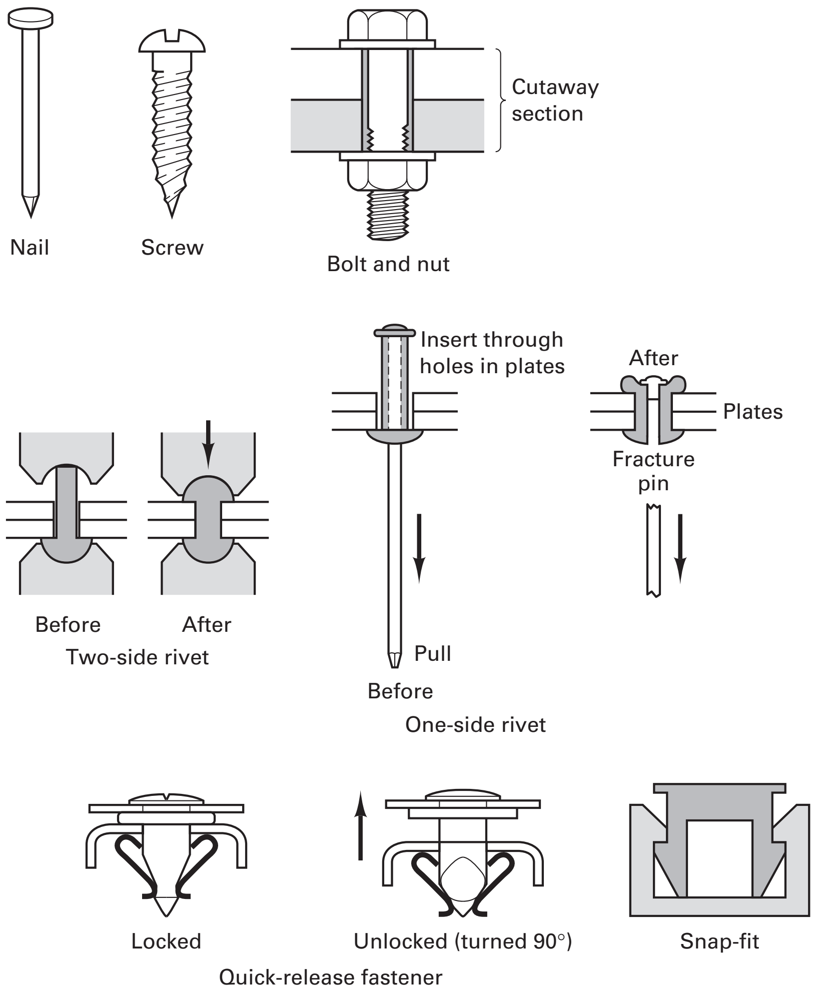

FIGURE 34-8 Various types of discrete fasteners, including a nail, screw, nut and bolt, two-side access supported rivet, one-side access blind rivet, quick-release fastener, and snap-fit.

Discrete fasteners, like those illustrated in Figure 34-8, are separate pieces whose function is to join the primary components. These include bolts and nuts (with accessory washers, etc.), screws, nails, rivets, quick-release fasteners, staples, and wire stitches. Over 150 billion discrete fasteners are consumed annually in the United States, with a variety so immense that the major challenge is usually selection of an appropriate, and hopefully optimum, fastener for the task at hand. Fastener selection is further complicated by inconsistent nomenclature and identification schemes. Some fasteners are identified by their specific product or application, while others are classified by the material from which they are made, their size, their shape, their strength, or primary operational features.[1] The commercial availability of such a wide range of standard and special types, sizes, materials, strengths, and finishes virtually ensures that an appropriate fastener can be found for most all joining needs. Discrete fasteners are easy to install, remove, and replace. In addition, most standard varieties are interchangeable. Steel is the most common material due to its high strength and low cost. Various finishes and coatings can be applied to withstand a multitude of service conditions.

Shrink and expansion fits form another major class of mechanical joining. Here, a dimensional change is introduced to one or both of the components by heating or cooling (heating one part only, heating one and cooling the other, or cooling one). Assembly is then performed, and a strong interference fit is established when the temperatures return to uniformity. Joint strength can be exceptionally high. A corrosion-resistant cladding or lining can also be applied to a less costly bulk material.

---

[1] Discussion of the primary terms used in identifying discrete fasteners can be found in ANSI Standard B18.12. Both the Society of Automotive Engineers (SAE) and the American Society of Testing and Materials (ASTM) have formalized various "grades" of bolts and identified them by markings that are stamped on the bolt head. These grades often relate to allowable stress and temperatures of operation.

Press fits are similar to shrink and expansion fits, but the results are obtained through mechanical force instead of differential temperatures.

REASONS FOR SELECTION

Mechanical fastening offers a number of attractive features, among them the following:

1. They are easy to disassemble and reassemble. The threaded fasteners are noteworthy for this feature, and semipermanent fasteners (such as rivets) can be drilled out for a major disassembly.
2. They have the ability to join similar or different materials in a wide variety of sizes, shapes, and joint designs. Some joint designs, such as hinges and slides, permit limited motion between the components.
3. Manufacturing cost is low. The fasteners are usually small formed components that cost little compared to the components being joined. They are readily available in a variety of mass-produced sizes.
4. Installation does not adversely affect the base materials, as is often the case with techniques involving the application of heat and/or pressure.
5. Little or no surface preparation or cleaning is required.

MANUFACTURING CONCERNS

Many mechanical fasteners require that the components contain aligned holes. Castings, forgings, extrusions, and powder metallurgy components can be designed to include integral holes. Holes can also be produced by such techniques as punching, drilling, and electrical, chemical, or laser-beam machining. Each of these techniques produces holes with characteristic surface finish, dimensional features, and properties. Secondary operations, such as shaving, deburring, reaming, and honing, can be used to improve precision and surface finish. Hole making and the proper positioning and alignment of the holes are major considerations in mechanical fastening.

Some fasteners, such as bolts coupled with nuts, require access to both sides of an assembly during joining. In contrast, screws offer one-side joining. If a bolt can be inserted into a threaded (tapped) hole, however, the nut can be eliminated, and only one-side access is required. If the bolt or screw is sufficiently hard, the fastener can often form its own threads, thereby eliminating the need for a threaded receptacle. This self-tapping feature is particularly attractive when assembling plastic products.

Stapling is a fast way of joining thin materials and does not require prior hole making. Rivets offer good strength but produce permanent or semipermanent joints. Snap-fits utilize the elasticity of one of the components, but the necessary elastic deformation must be possible without fracture.

DESIGN AND SELECTION

The design and selection of a fastening method requires numerous considerations, including the possible means of joint failure. When a product is assembled with fastened joints, the fasteners are extremely vulnerable sites. Mechanical joints generally fail because of oversight or lack of control in one of four areas: (1) the design of the fastener itself and the manufacturing techniques used to make it, (2) the material from which the fastener is made, (3) joint design, or (4) the means and details of installation. Fasteners may have insufficient strength or corrosion resistance or may be subject to stress corrosion cracking or hydrogen embrittlement. They may be unable to withstand the temperature extremes (both high and low) experienced by the final assembly. Metal fasteners provide electrical conductivity between the components, and an inappropriate choice of fastener or component material can cause severe galvanic corrosion. Nonmetallic fasteners (such as threaded nylon) can be used for low-strength applications where corrosion is a concern, but creep under load is a concern for these materials. Since mechanical fasteners only join at discrete points, gases or liquids can easily penetrate the joint area and further aggravate conditions.

Many failures are the result of poor joint preparation or improper fastener installation. A high percentage of the cracks in aircraft structures originate at fastener holes, and fatigue of fasteners is the largest single cause of fastener failure. Installation frequently imparts too much or too little preload (too tight or too loose). The joint surfaces may not be flat or parallel, and the area under the fastener head may be insufficient to bear the load. Vibrational loosening enhances fastener fatigue. The details of joint design should further consider stress distribution, since much of the load will be concentrated on the fasteners (in contrast to the previously discussed adhesive joints that distribute the load uniformly over the entire joint area).

Nearly all fastener failures can be avoided by proper design and fastener selection. Consideration should be given to the operating environment, required strength, and magnitude and frequency of vibration. Fastener design should incorporate a shank-to-head fillet whenever possible. Rolled threads can be specified for their superior strength and fracture resistance. Corrosion-resistant coatings can be employed for enhanced performance. Joint design should seek to avoid such features as offset or oversized holes. Proper installation and tightening are critical to good performance. Standard sizes, shapes, and grades should be used whenever possible, with as little variety as is absolutely necessary.

34.3 JOINING OF PLASTICS

Mechanical fasteners, adhesives, and welding processes can all be employed to form joints between engineering plastics. Fasteners are quick and are suitable for most materials, but they may be expensive to use, they generally do not provide leak-tight joints, and the localized stresses may cause them to pull free of the polymeric material. Threaded metal inserts may have to be incorporated into the plastic components to receive the fasteners, further increasing the product cost. Adhesives can provide excellent properties and fully sound joints, but they are often difficult to handle and relatively slow to cure. In addition, considerable attention is required in the areas of joint preparation and surface cleanliness. In a modification of adhesive bonding, solvents may be used to soften surfaces, which are then pressed together to form a bond. Welding can be used to produce bonded joints with mechanical properties that approach those of the parent material. Unfortunately, only the *thermoplastic polymers* can be welded, since these materials can be melted or softened by heat without degradation and good bonds can be formed with the subsequent application of pressure. The *thermosetting polymers* do not soften with heat, tending only to char or burn, and must be joined by alternative methods, such as mechanical fasteners, adhesives, snap-fits, or possible co-curing (placing the components together and curing while in contact).

Because the thermoplastics soften and melt at such low temperatures, the heat required to weld these materials is significantly less than that required in the welding of metals. The processes used to weld plastics can be divided into two groups: (1) those that utilize mechanical movement and friction to generate heat, such as ultrasonic welding, spin welding, and vibration welding, and (2) those that involve external heat sources, such as hot-plate welding, hot-gas welding, and resistive and inductive implant welding. In both groups, it is important to control the rate of heating. Plastics have low thermal conductivity, and it is easy to induce burning, charring, or other material degradation before softening has occurred to the desired depth.

Ultrasonic welding of plastics uses high-frequency mechanical vibrations to create the bond. Parts are held together and are subjected to ultrasonic vibrations (20 to 40 kH frequency and 10 to 100 micron amplitude) perpendicular to the area of contact. The high-frequency stresses generate heat at the joint interface sufficient to produce a high-quality weld in a period of $^1/_2$ to $1^1/_2$ seconds. The process can be readily automated, but the tools are expensive and large production runs are generally required. Ultrasonic welding is usually restricted to small components where relative movement is restricted and weld lengths do not to exceed a few centimeters.

In *vibration welding*, or linear friction welding, relative movement between the two parts is again used to generate the heat, but the direction of movement is now parallel to the interface and aligned with the longest dimension of the joint. The vibration amplitudes are 10 times larger than in ultrasonic welding, and the frequencies are considerably less (on the order of 100 to 240 Hz). When molten material is produced, the vibration is stopped, parts are aligned, and the weld region is allowed to cool and solidify. The entire process takes about one to five seconds. Long-length, complex joints can be produced at rather high production rates. Nearly all thermoplastics can be joined, independent of whether their prior processing was by injection molding, extrusion, blow molding, thermoforming, foaming, or stamping.

The *friction welding* of plastics (also called *spin welding*) is similar to vibration welding, except the relative motion is now continuous and rotational. The process is essentially the same as the friction welding of metals, but melting now occurs at the joint interface. High-quality welds are produced with good reproducibility, and little end preparation is required. The major limitation is that at least one of the components must exhibit circular symmetry, and the axis of rotation must be perpendicular to the mating surface. Weld strengths vary from 50 to 95% of the parent material in bonds of the same plastic. Joints between dissimilar materials generally have poorer strengths. Butt welds can be made between plates of thermoplastic using the *friction-stir welding* process described in Chapter 32.

FIGURE 34-9 Using a hot-gas torch to make a weld in plastic pipe.

Hot-plate welding uses an external heat source and is probably the simplest of the mass-production techniques used to join plastics. The parts to be joined are held in fixtures and pressed against the opposite sides of an electrically heated tool. Contact is maintained until the surfaces have melted and the adjacent material has softened to a specified distance from the interface. The parts separate, the tool is removed, and the two prepared surfaces are pressed together and allowed to cool. Contaminated surface material is usually displaced into a flash region. Weld times are comparatively slow, ranging from 10 seconds to several minutes. The joint strength can be equal to that of the parent material, but the joint design is usually limited to a square-butt configuration, like that encountered when joining sections of plastic pipe. If the bond interface has a nonflat profile, shaped heating tools can be employed. Heated-tool welding can also be used to produce lap seams between flexible plastic sheets. Rollers apply pressure after the material has passed over a heater.

The *hot-gas welding* of plastics is similar to the oxyacetylene welding of metals, and V-groove or fillet welds are the most common joint configuration. A gas (compressed air, nitrogen, hydrogen, oxygen, or carbon dioxide) is heated by an electric coil as it passes through a welding gun, like the one shown in Figure 34-9. The hot-gas stream emerges from the gun at 200° to 300°C (400° to 570°F) and impinges on the joint area. Thin rods of plastic material are heated along with the workpiece and are then forced into the softened joint area, providing both the filler material and the pressure needed to produce coalescence. Because this process is usually slow and the results are generally dependent on operator skill, it is seldom used in production applications. It is, however, a popular process for the repair of thermoplastic materials.

Extrusion welding is similar to the hot-gas process, except that the external filler material rod is replaced by a stream of fully molten polymer that emerges from the weld tool as it moves along the joint. This is similar to the wire feed in the metal-welding processes.

In the *implant welding* of plastics, metal inserts are placed between the parts to be joined and are then heated by means of induction (radio frequency) or resistance heating. The resistance method requires that a current-carrying path exist to conduct the current to the implants, a feature that is not required for induction heating. The thermoplastic material melts around the heated implants and flows to form a joint. Since a weld forms only in the vicinity of the implants, the process resembles spot welding and produces joints that are considerably weaker than those formed by processes that bond the entire contact area. When bonding is desired over larger areas, tapes, rods, or gaskets of thermoplastic material laced with iron oxide or metal particles can be used to concentrate the heat at the interface and provide filler material. In all cases of implant welding, the metal implant material remains as an integral part of the final assembly.

Still other processes to weld thermoplastics are based on *infrared radiation* or *microwave heating*. Laser welding has also been performed on plastics.

The most common method of joining plastics to one another and joining metal to plastic is through *mechanical fasteners*. It is important that the plastic be able to withstand the strain of fastener insertion and the localized stresses around the fastener. Conventional machine screws are rarely used, except with extremely strong plastics. Instead, there are a number of fasteners designed specifically for use with plastics. Threaded fasteners work best with thick sections. Self-tapping, thread-cutting screws are used on hard plastics, and thread-forming screws are used with softer materials. If the joint is to undergo disassembly and reassembly, threaded metal inserts may be incorporated into the part to receive the fasteners. Because of the low elastic modulus of plastic materials, snap-fit assemblies are often an attractive alternative to the use of fasteners.

As described previously in this chapter, adhesives provide an attractive means of joining plastics. Since adhesives are polymeric materials, the joint material can be selected for compatibility with the material being joined. Probably the most common application is the adhesive joining of PVC (polyvinyl chloride) pipes and fittings in household plumbing.

34.4 JOINING OF CERAMICS AND GLASS

The properties of ceramic materials are significantly different from the engineering metals, and these differences restrict or limit the processes that can be used for joining. High melting temperatures can be a significant deterrent to fusion welding. More significant, however, are the effects of low thermal conductivity and brittleness. Heating and cooling will likely result in nonuniform temperatures, and the thermally induced stresses are likely to result in cracking or fracture. The lack of useful ductility virtually eliminates any form of deformation bonding. Mechanical fasteners, and their associated threads and holes, create high concentrated stresses, and these stresses often lead to material fracture. As a result, most ceramic materials are joined by some form of adhesive bonding, brazing, diffusion or sinter bonding, or ceramic cements.

Adhesives and cements are probably the most common methods of joining ceramics to ceramics, ceramics to glasses, and ceramics to metals and other materials. The inserted material (polymer adhesive, glass or glass-ceramic frit, or ceramic cement or mortar) will bond to the surfaces and bridge what are often radically different compositions and structures.

Brazing and soldering use a low-melting-point metal or lower-melting ceramic as the intermediate material. Some materials, such as indium solders, directly wet ceramic surfaces. To promote adhesion and bonding with other joint materials, it may be necessary to first coat the ceramic with some form of metallized or deposited layer. These coatings bond to the ceramic, and the braze or solder material bonds to the coating.

Sinter bonding is a means of joining ceramic materials during their initial production. As the component pieces are held together and co-fired, diffusion bonds form across the interface while similar bonds form within the components. This process is best performed when the components are of identical material or materials with similar composition and structure. Various intermediate materials have been used to assist the joining of dissimilar ceramics.

The joining of glass is a much easier operation. Heating softens the two materials, which are then pressed together and cooled. A wide variety of heating methods are used, depending on the size, shape, and quantity of components to be joined.

34.5 JOINING OF COMPOSITES

The joining of composite materials can be an extremely complex subject, especially when one considers the variety of composites and the fact that the joint interface is likely to be a distinct disruption to the continuity of structure and properties.

Particulate composites may have the least structural difference at an interface. Laminar composites will certainly behave differently if the joint surface is a core (or multilayer) surface or a single-material exposed face. Fiber-reinforced composites, regardless of the type of fiber and fiber configuration, will certainly lack fiber continuity across the joint.

The usual joining methods tend to be those used with the matrix of the composite. Metal-matrix composites can be welded, brazed, or soldered, or joined with screws or bolts or any of the other techniques applied to metals. The techniques for polymer-matrix and ceramic-matrix follow those for plastics and ceramics, as discussed previously in this chapter.

Theoretically, all composites can be adhesively bonded, but there may be limits set by the applied stresses, operating temperatures, or size of the workpiece (since many adhesives require a thermal cure). When working with polymer-matrix composites, the adhesive is often selected to match or be compatible with the matrix polymer. In many cases, however, the adhesive is being asked to bond to already-cured polymer surfaces.

■ Review Questions

1. What would be some of the characteristics of an ideal adhesive?
2. What are some of the newer applications that have helped promote increased use of adhesive bonding?
3. What are some of the types of materials that have been used as industrial adhesives?
4. What are some of the ways in which adhesives can be cured?
5. What is a structural adhesive?
6. Characterize the temperature range over which epoxies might be used, typical values of shear strength, and commonly observed curing times.
7. What promotes the curing of cyanoacrylates? Of anaerobics?
8. What features or characteristics might favor the selection of a silicone adhesive?
9. What are some common applications of hot-melt adhesives?
10. What features or properties are provided or enhanced by adhesive additives?
11. What are some types of nonstructural or special adhesives?
12. How can polymeric adhesives be made electrically or thermally conductive?
13. What are some of the temperature considerations that apply when selecting an adhesive?
14. What are some of the environmental conditions that might reduce the performance or lifetime of a structural adhesive?
15. Why is it desirable for adhesive joints to be designed so the adhesive is loaded in shear, tension, or compression?
16. Why are butt joints unattractive for adhesive bonding?
17. What types of joints provide large bonding areas?
18. What are some common techniques by which surfaces are prepared for adhesive bonding?
19. Why are the structural adhesives an attractive means of joining dissimilar metals or materials? Different sizes or thicknesses?
20. What are some of the other attractive properties of structural adhesives?
21. In what ways might a structural adhesive offer manufacturing ease or reduced manufacturing cost?
22. In view of the relatively low strengths of the structural adhesives, how can adhesively bonded joints attain strengths comparable to other methods of joining?
23. Why are adhesive joints unattractive for applications that involve exposure to elevated temperature? Is low temperature a concern?
24. What factors would influence the selection of a specific type of mechanical fastener or fastening method?
25. What types of fasteners are attractive if the application requires the ability to disassemble and reassemble the product?
26. What factors determine the overall effectiveness of a mechanical fastener?
27. What is an integral fastener? Provide an example.
28. What are some of the primary types of discrete fasteners?
29. How are press fits similar to shrink or expansion fits? How do they differ?
30. What are some of the major assets of mechanical fasteners?
31. What are some of the ways that fastener holes can be made in manufactured products?

32. What are some of the common causes for failure of mechanically fastened joints?
33. From a manufacturing viewpoint, why is it desirable to use standard fasteners and minimize the variety of fasteners within a given product?
34. Why can the thermoplastic polymers be welded, but not the thermosetting varieties?
35. Describe several of the plastic joining processes that use mechanical movement or friction to generate the required heat.
36. What are some of the external heat sources that can be used in the welding of plastic materials?
37. Why are the crystalline ceramic materials particularly difficult to join?
38. What is sinter bonding, and how does it join ceramic materials?
39. When materials are joined, we create interfaces between the various components. Describe the structural features that might result at the interface when we join: (a) particulate composites, (b) laminar composites, and (c) fiber-reinforced composites.

Problems

1. Some automakers are using adhesives and sealants that cure under the same conditions used for the paint-bake operation. Determine the conditions used for paint-bake, and identify some adhesives and sealants that could be used. What are some of the pros and cons of such an integration?
2. A contractor has installed aluminum siding on a house with steel nails. Use the galvanic series to evaluate the corrosion properties of this assembly. (*Note*: The aluminum is exposed to air, so it should be considered to be in its passive condition.) What do you expect will be the outcome of this fastener selection? Can you recommend a better alternative?
3. Mechanical fasteners are an attractive means of joining composite materials because they avoid exposing the composite to heat and/or high pressure. Assume that the composite is a polymer-based fiber-reinforced material with either uniaxial or woven fibers. For this particular system, what are some possible fastener-related problems? Consider joint preparation, assembly, and possible service failure.
4. The heat-resisting tiles on the U.S. space shuttle are made from heat-resisting ceramics. Determine the method or methods used to attach them to the structure. What difficulties or problems have been encountered relating to this bonding?
5. The bicycle frames used by riders in recent Tour de France races have been single-piece fiber-reinforced composites. What difficulties or property compromises might be associated with a fabrication method that uses joints? What methods might be available to join the carbon fiber–epoxy composite materials commonly used in these bicycles?
6. The processes described for the joining of plastics focused almost exclusively on the thermoplastic polymers. What types of joining techniques could be applied to thermosetting polymers? To elastomeric polymers? To ceramic materials?

Chapter 34 CASE STUDY

Golf Club Heads with Insert

You are employed by a small manufacturer of sporting goods equipment, and your design team has recently proposed a new line of high-performance golf clubs. While the club head of the irons is to be a "standard" AISI 431 martensitic stainless steel investment casting, the striking face will incorporate a metal insert, as shown in the figure. This insert will be produced by powder metallurgy and will consist of a copper-based alloy laced with presized particles of tungsten carbide. After a mild acid etching of the copper matrix, the carbide particles will protrude sufficiently to better grip the surface of the ball, imparting an enhanced amount of backspin to better control the "bite" of the ball upon landing. Since its purpose is to modify the striking face, the insert is rather thin, about 1.5 to 3 mm ($^1/_{16}$ to $^1/_8$ in.). It is important that the insert be incorporated into the club face in a manner that does not dampen the impact or compromise the "feel" of the club.

1. You must devise a means of incorporating the proposed insert into the face of the club. What are some possible means of joining or bonding the dissimilar materials? What are the advantages and limitations of each of your alternatives? What would you recommend?
2. An additional joint occurs where the club head is attached to the shaft. If a graphite fiber–reinforced epoxy is being considered for the shaft, how might it be attached to the stainless steel head? If the composite shaft were selected, which joining method would you recommend? If the shafts were metal, what other methods might be possible?
3. For production simplicity, it might be preferable to use the same joining procedure at all locations. In view of your answers to Questions 1 and 2, does this appear to be a possibility for this product?
4. If the bonding process and resulting interface prove to be problematic, there may be other ways to produce a raised-carbide surface on a stainless steel golf club face. Consider processes such as thermal spray, friction-stir to embed particles, and others. What do you see as the advantages and limitations for each of these alternatives, considering both manufacturing and performance? Would you expect them to be cheaper or more expensive than the proposed insert?
5. If quality and performance were the primary objective, which of the options in Question 4 would you recommend? Why?
6. If cost minimization were to become important as you seek an edge over competitors, what would be your recommendation and why?

CHAPTER 35

SURFACE ENGINEERING

35.1 INTRODUCTION

Surface engineering is a multidisciplinary activity intended to tailor the properties of the surfaces of manufactured components so that their function and serviceability can be improved. Processes include solidification treatments such as hot-dip coatings, weld-overlay coatings, and thermal spray surfaces; deposition surface treatments such as electrodeposition, chemical vapor deposition, and physical vapor deposition; and heat treatment coatings such as diffusion coatings and surface hardening. Electroplating means the electrodeposition of an adherent metallic coating onto an object that serves as the cathode in an electrochemical reaction. The resulting surface provides wear resistance, corrosion resistance, high-temperature resistance, or electrical properties different from those in the bulk material.

Many manufacturing processes influence surface properties, which in turn may significantly affect the way the component functions in service. The demands for greater strength and longer life in components often depend on changes in the surface properties rather than the bulk properties. These changes may be mechanical, thermal, chemical, and/or physical and therefore are difficult to describe in general terms. For example, two different surface finishes on Inconel 718 can have a marked effect on the fatigue life, changing the fatigue limit from 60 ksi after gentle grinding to as low as 22 ksi using electrical discharge machining (Figure 35-1).

Many metalcutting processes specified by the manufacturing engineer to produce a specific geometry can often have the effect of producing alterations in the surface material of the component, which, in turn, produces changes in performance.

The term *surface integrity* was coined by Field and Kahles in 1964 in reference to the nature of the surface condition that is produced by the manufacturing process. If we view the process as having five main components (workpiece, tool, machine tool, environment, and process variables), we see that surface properties can be altered by all of these parameters (see Table 35-1) by producing the following:

- High temperatures involved in the machining process
- Plastic deformation of the work material (residual stress)
- Surface geometry (roughness, cracks, distortion)
- Chemical reactions, particularly between the tool and the workpiece

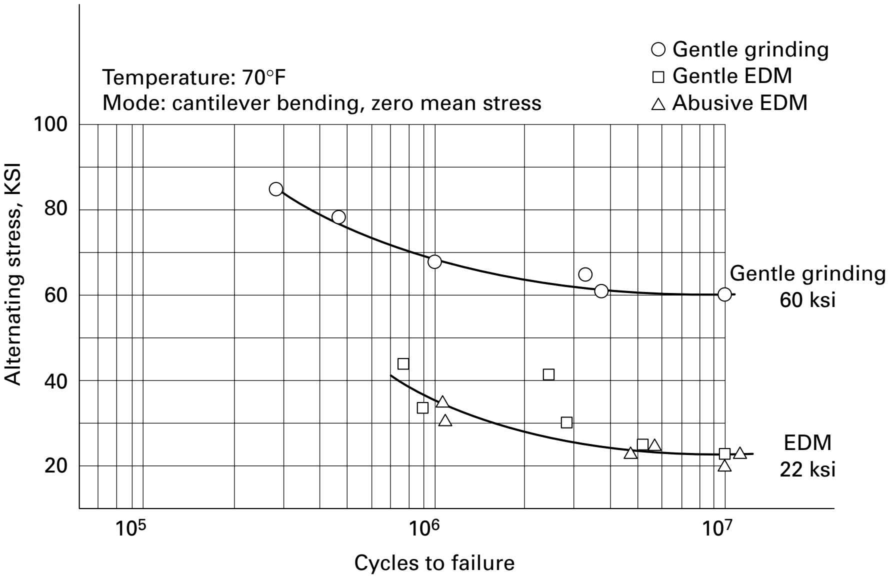

FIGURE 35-1 Fatigue strength of Inconel 718 components after surface finishing by grinding or EDM. *(Field and Kahles, 1971).*

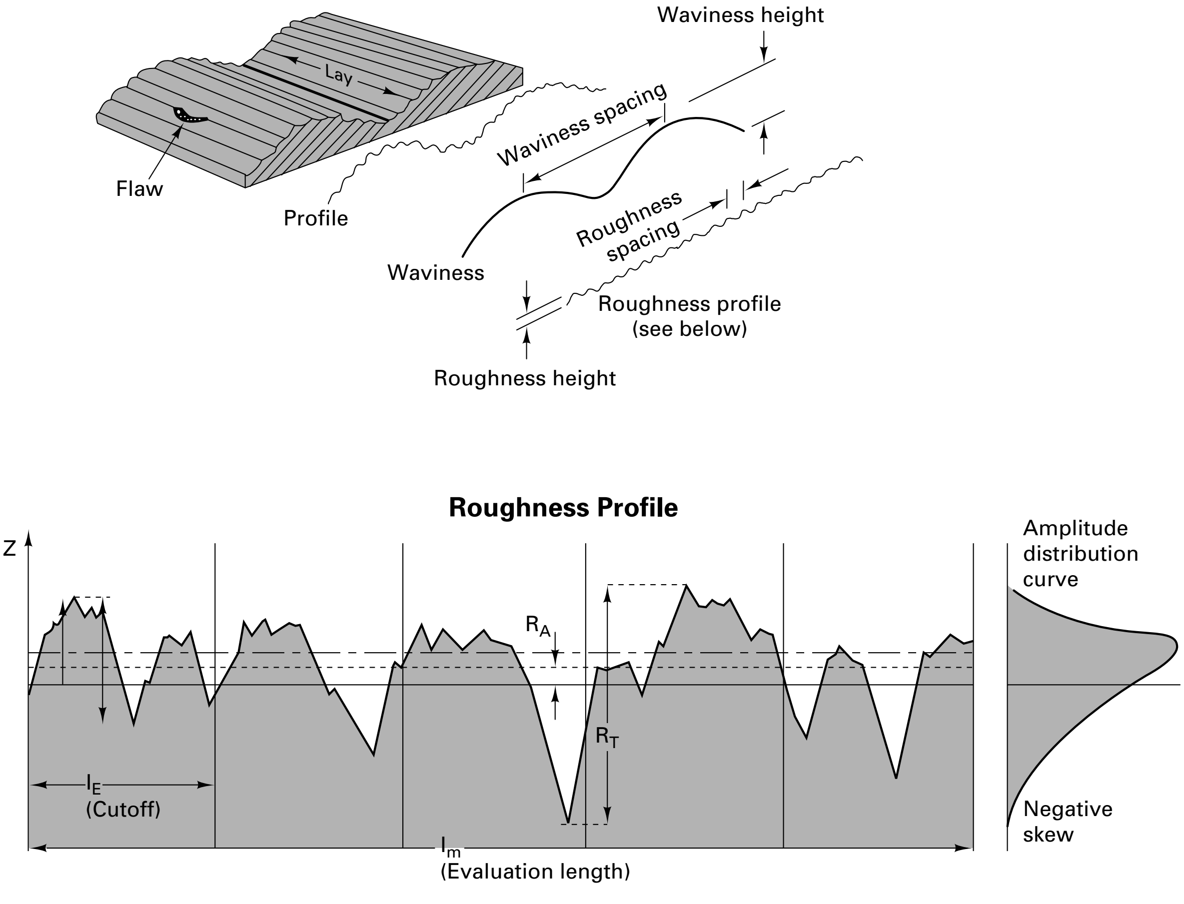
More specifically, *surface integrity* refers to the impaired or enhanced surface condition of a component or specimen that influences its performance in service. Surface integrity has two aspects: topography characteristics and surface-layer characteristics. Topography is made up of surface roughness, waviness, errors of form, and flaws (Figure 35-2).



R_T = Maximum roughness depth (peak to valley) along l_m

R_A = Arithmetic roughness average

FIGURE 35-2 Machining processes produce surface flaws, waviness, and roughness that can influence the performance of the component.

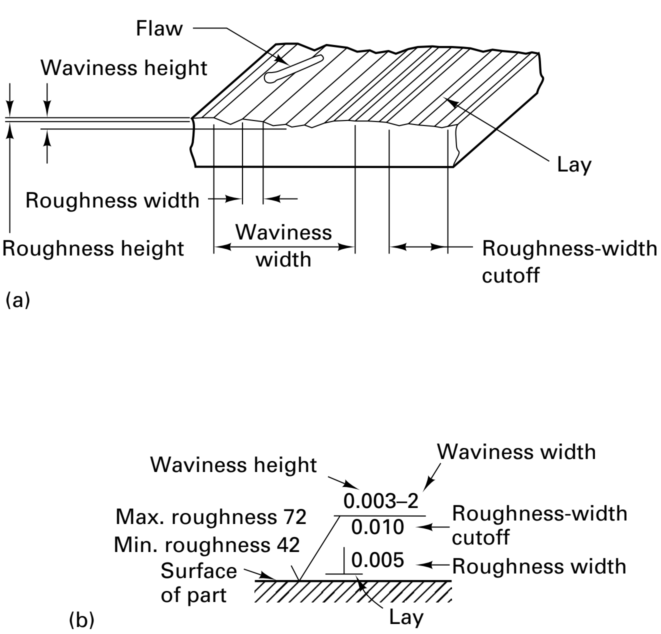
Source: Advanced Manufacturing Engineering, Vol. 1, July 1989.

A typical roughness profile includes the peaks and valleys that are considered separately from waviness. Flaws also add to texture but should be measured independent of it. Changes in the surface layer, as a result of processing, include plastic deformation, residual stresses, cracks, and other metallurgical changes (hardness, overaging, phase changes, recrystallization, intergranular attack, and hydrogen embrittlement). See Figure 30-2. The surface layer will always contain local surface deformation due to any machining passes.

The material removal processes generate a wide variety of surfaces textures, generally referred to as *surface finish*. The cutting processes leave a wide variety of surface patterns on the materials. *Lay* is the term used to designate the direction of the predominant surface pattern produced by the machining process. In addition, certain other terms and symbols have been developed and standardized for specifying the surface quality. The most important terms are *surface roughness*, *waviness*, and *lay* (Figure 35-3). *Roughness* refers to the finely spaced surface irregularities. It results from machining operations in the case of machined surfaces. *Waviness* is surface irregularity of greater spacing than in roughness. It may be the result of warping, vibration, or the work being deflected during machining.



Lay symbols

= Parallel to the boundary line of the nominal surface
⊥ Perpendicular to the boundary line of the nominal surface
X Angular in both directions to the boundary line of the nominal surface
M Multidirectional
C Approximately circular relative to the center
R Approximately radial relative to the center of the nominal surface

(c)

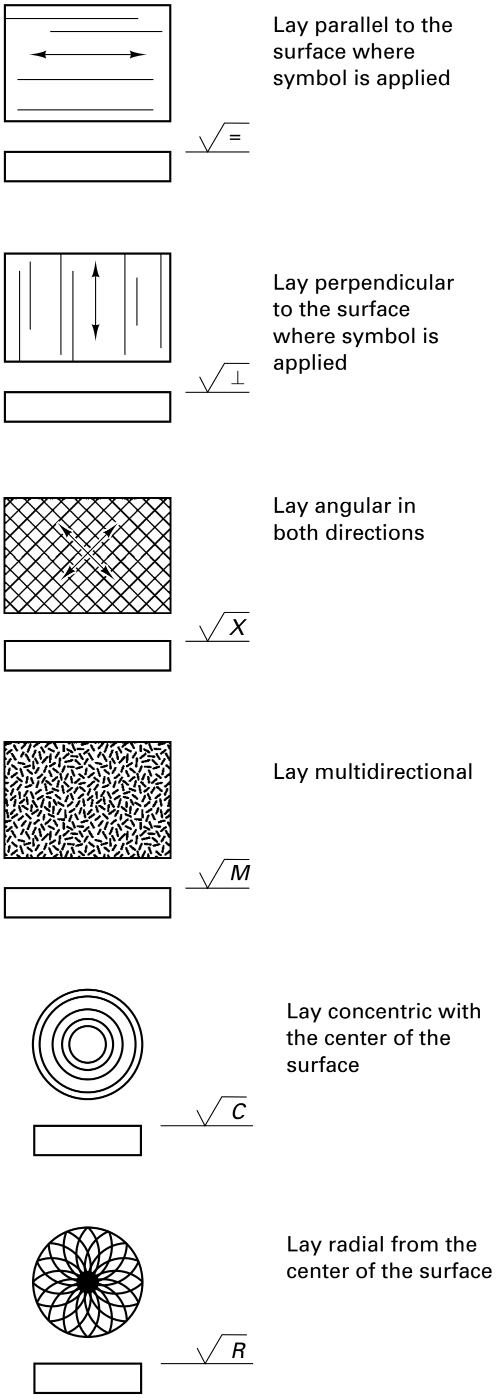


FIGURE 35-3 (a) Terminology used in specifying and measuring surface quality; (b) symbols used on drawing by part designers, with definitions of symbols; (c) lay symbols; (d) lay symbols applied on drawings.

A variety of instruments are available for measuring surface roughness and surface profiles. The majority of these devices use a diamond stylus that is moved at a constant rate across the surface, perpendicular to the lay pattern. The rise and fall of the stylus is detected electronically [often by a Linear Variable Differential Transformer Device (LVTD)], is amplified and recorded on a strip-chart, or is processed electronically to produce average or root-mean-square readings for a meter (Figure 35-4). The unit containing the stylus and the driving motor may be handheld or supported by skids that ride on the workpiece or some other supporting surface.

Roughness is measured by the height of the irregularities with respect to an average line. These measurements are usually expressed in micrometers or microinches.

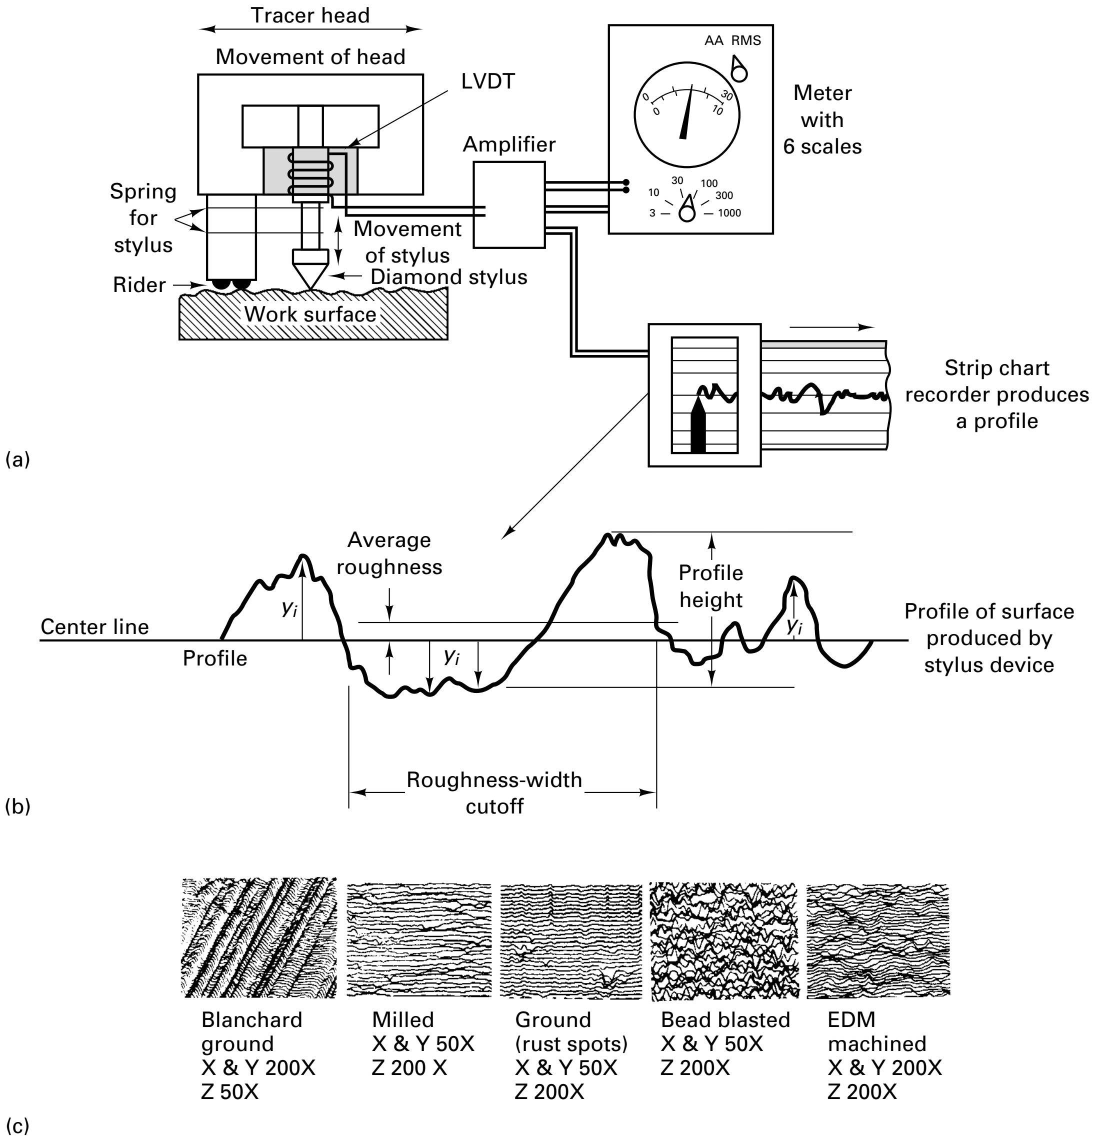

FIGURE 35-4 (a) Schematic of stylus profile device for measuring surface roughness and surface profile with two readout devices shown: a meter for AA or rms values and a strip chart recorder for surface profile. (b) Profile enlarged. (c) Examples of surface profiles.

In most cases, the arithmetical average (AA) is used. In terms of the measurements, the AA would be as follows:

$$\mathrm{AA} = \frac{\sum_{i=1}^{n} y_i}{n}$$

Cutoff refers to the sampling length used for the calculation of the roughness height. When it is not specified, a value of 0.030 in. (0.8 mm) is assumed. In the previous equation, y_i is a vertical distance from the centerline and n is the total number of vertical measurements taken within a specified cutoff distance. This average roughness value is also called R_a, occasionally used is the *root-mean-square* (rms) value, which is defined as

$$\mathrm{rms} = \sqrt{\frac{\sum_{i=1}^{n} y_i^2}{n}}$$

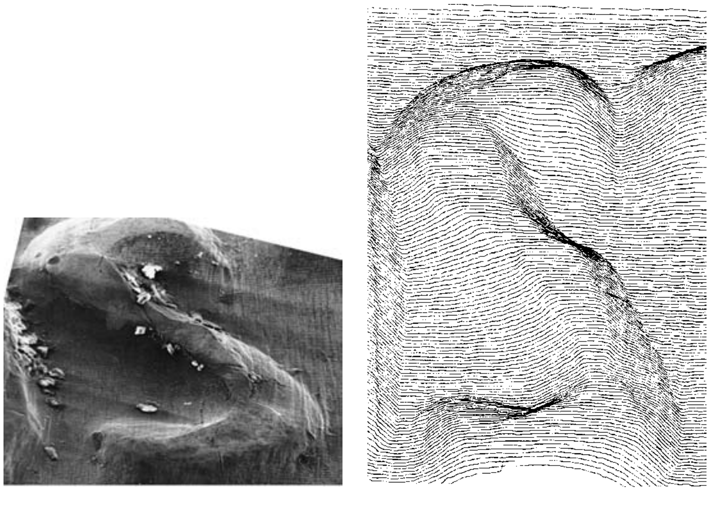
The resolution of stylus profile devices is determined by the radius or the diameter of the tip of the stylus. When the magnitude of the geometric features begins to

FIGURE 35-5 Typical machined steel surface as created by face milling and examined in the SEM. A micrograph (same magnification) of a 0.00005-in. stylus tip has been superimposed at the top.

approach the magnitude of the tip of the stylus, great caution should be used in interpreting the output from these devices. As a case in point, Figure 35-5 shows a scanning electron micrograph of a face-milled surface on which has been superimposed (photographically) a scanning electron micrograph of the tip of a diamond stylus (tip radius of 0.0005 in.). Both micrographs have the same final magnification. Surface flaws of the same general size as the roughness created by the machining process are difficult to resolve with the stylus-type device, where both these features are about the same size as the stylus tip.

This example points out the difference between resolution and detection. Stylus tracing devices can often detect the presence of a surface crack, step, or ridge on the part but cannot resolve the geometry of the defect when the defect is of the same order of magnitude as the stylus tip or smaller.

Another problem with these devices is that they produce a reading (a line on the chart) where the stylus tip is not touching the surface, as is demonstrated in Figure 35-6a, which shows the *S* from the word *TRUST* on a U.S. dime. The scanning electron microscope (SEM) micrograph was made after the topographical map of Figure 35-6b had been made. Both figures are at about the same magnification. The tracks produced by the stylus tip are easily seen in the micrograph. Notice the difference between the features shown in the micrograph and the trace, indicating that the stylus tip was not in contact with the surface many times during its passage over the surface (left no track in the surface), yet the trace itself is continuous.

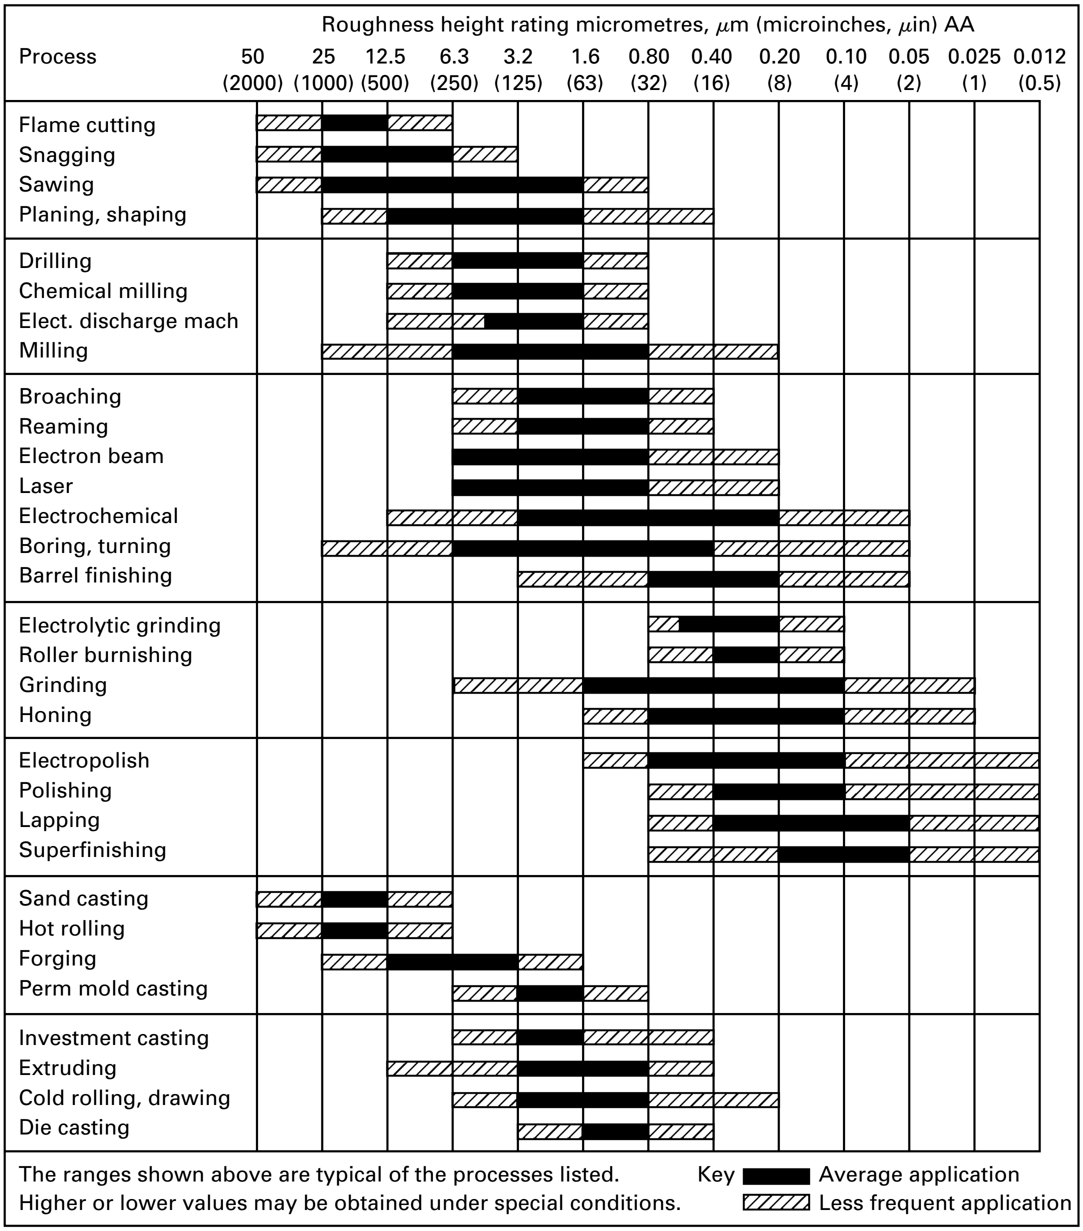


(a) (b)

FIGURE 35-6 (a) SEM micrograph of a U.S. dime, showing the *S* in the word *TRUST* after the region has been traced by a stylus-type machine. (b) Topographical map of the *S* region of the word *TRUST* from a U.S. dime [compare to part (a)].

The range of surface roughnesses that are typically produced by various manufacturing processes is indicated in Figure 35-7, which is a very general picture of typical ranges associated with these processes. However, one can usually count on its being more expensive to generate a fine finish (low roughness). To aid designers, metal samples with various levels of surface roughness are available.

All of the processes used to manufacture components are important if their effects are present in the finished part. It is convenient to divide processes that are used to manufacture parts into three categories: traditional, nontraditional, and finishing treatments. In *traditional processes* the tool contacts the workpiece. Examples are grinding, milling, and turning. These material removal processes will inflict damage to the surface if improper parameters are used. Examples of improper parameters are dull tools, excessive infeed, inadequate coolant, and improper grinding wheel hardness. The *nontraditional processes* have intrinsic characteristics that, even if well controlled, will change the surface. In these processes the workpiece does not touch the tool. Electrochemical machining (ECM), electrical discharge machining (EDM), laser machining, and chemical milling are examples of



Extracted from General Motors Drafting Standards, June 1973 revision

FIGURE 35-7 Comparison of surface roughness produced by common production processes. *(Courtesy of* American Machinist.*)*

nontraditional methods. Such methods can leave stress-free surfaces, remelted layers, and excessive surface roughness. *Finishing treatments* can be used to negate or remove the impact of both traditional and nontraditional processes as well as providing good surface finish. For example, residual tensile stresses can be removed by shot peening or roller burnishing. Chemical milling can remove the recast layer left by EDM.

The objectives of the surface-modification processes can be quite varied. Some are designed to clean surfaces and remove the kinds of defects that occur during processing or handling (such as scratches, pores, burrs, fins, and blemishes). Others further improve or modify the products' appearance, providing features such as smoothness, texture, or color. Numerous techniques are available to improve resistance to wear or corrosion, or to reduce friction or adhesion to other materials. Scarce or costly materials can be conserved by making the interior of a product from a cheaper, more common material and then coating or plating the product surface.

As with all other processes, surface treatment requires time, labor, equipment, and material handling, and all of these have an associated cost. Efficiencies can be realized through process optimization and the integration of surface treatment into the entire manufacturing system. Design modifications can often facilitate automated or bulk finishing, eliminating the need for labor-intensive or single-part operations. Process selection should further consider the size of the part, the shape of the part, the quantity to be processed, the temperatures required for processing, the temperatures encountered during subsequent use, and any dimensional changes that might occur due to the surface treatment. Through knowledge of the available processes and their relative advantages and limitations, finishing costs can often be reduced or eliminated while maintaining or improving the quality of the product.

In addition to the above, the field of surface finishing has recently undergone another significant change. Many chemicals that were once "standard" to the field, such as cyanide, cadmium, chromium, and chlorinated solvents, have now come under strict government regulation. Wastewater treatment and waste disposal have also become significant concerns. As a result, processes may have to be modified or replacement processes may have to be used.

Because of their similarity to other processes, many surface finishing techniques have been presented elsewhere in the book. The *case hardening* techniques, both selective heating (flame, induction, and laser hardening) and altered surface chemistry (diffusion methods such as carburizing, nitriding, and carbonitriding), are presented in Chapter 5 as variations of heat treating. *Shot peening* and *roller burnishing* are presented in Chapter 17 as cold-working processes. *Roll bonding* and explosive bonding are discussed in Chapter 15 as means of producing laminar composites. *Hard facing* and metal spraying are included in Chapter 33 as adaptations of welding techniques. Chemical vapor deposition and physical vapor deposition are discussed in Chapters 19 and 21. Sputtering and ion implantation are also discussed in Chapter 19 as processes needed in electronics manufacturing. In this chapter we focus on techniques for cleaning and surface preparation as well as the remaining methods of surface finishing or surface modification.

35.2 MECHANICAL CLEANING AND FINISHING

BLAST CLEANING

It is not uncommon for the various manufacturing processes to produce certain types of surface contamination. Sand from the molds and cores used in casting often adheres to product surfaces. Scale (metal oxide) can be produced whenever metal is processed at elevated temperatures. Oxides such as rust can form if material is stored between operations. These and other contaminants must be removed before decorative or protective surfaces can be produced. While vibratory shaking can be useful, some form of *blast cleaning* is usually required to remove the foreign material. Blast cleaning uses a media (abrasive) propelled into the surface using air, water, or even a wheel (wheel blasting uses a high-rpm blocked wheel to deliver the media). The bulk of the work is done by kinetic energy of the impacting media; $KE = {}^{1}/_{2}\,MV^{2}$ where m = mass of the median and v = the velocity. Abrasives, steel grit, metal shot, fine glass shot, plastic beads, and even CO_2 are mechanically impelled against the surface to be cleaned. When sand is used, it should be clean, sharp-edged silica sand. Steel grit tends to clean more rapidly and generates much less dust, but it is more expensive and less flexible.

When the parts are large, it may be easier to bring the cleaner to the part rather than the part to the cleaner. A common technique for such applications is *sand blasting* or *shot blasting,* where the abrasive particles are carried by a high-velocity blast of air emerging from a nozzle with about a $^3/_8$-in . opening. Air pressures between 60 and 100 psi, producing particle speeds of 400 mph, are common when cleaning ferrous metals, and 10 to 60 psi is common for nonferrous metals. The abrasive may be sand or shot, or materials such as walnut shells, dry-ice pellets, or even baking soda. Pressurized water can also be used as a carrier medium.

When production quantities are large or the parts are small, the operation can be conducted in an enclosed hood, with the parts traveling past stationary nozzles. For large parts or small quantities, the blast may be delivered manually. Protective clothing and breathing apparatus must be provided and precautions taken to control the spread of the resulting dust. The process may even require a dedicated room or booth that is equipped with integrated air pollution control devices.

From a manufacturing perspective, these processes are limited to surfaces that can be reached by the moving abrasive (line-of-sight) and cannot be used when sharp edges or corners must be maintained (since the abrasive tends to round the edges).

BARREL FINISHING OR TUMBLING

Barrel finishing or *tumbling* is an effective means of finishing large numbers of small parts. In the Middle Ages, wooden casks were filled with abrasive stones and metal parts and were rolled about until the desired finish was obtained. Today, modifications of this technique can be used to deburr, radius, descale, remove rust, polish, brighten, surface-harden, or prepare parts for further finishing or assembly. The amount of stock removal can vary from as little as 0.0001 to as much as 0.005 in.

In the typical operation, the parts are loaded into a special barrel or drum until a predetermined level is reached. Occasionally, no other additions are made, and the parts are simply tumbled against one another. In most cases, however, additional media of metal slugs or abrasives (such as sand, granite chips, slag, or ceramic pellets) are added. Rotation of the barrel causes the material to rise until gravity causes the uppermost layer to cascade downward in a "landslide" movement, as depicted in Figure 35-8. The sliding produces abrasive cutting that can effectively remove fins, flash, scale, and adhered sand. Since only a small portion of the load is exposed to the abrasive action, long times may be required to process the entire contents.

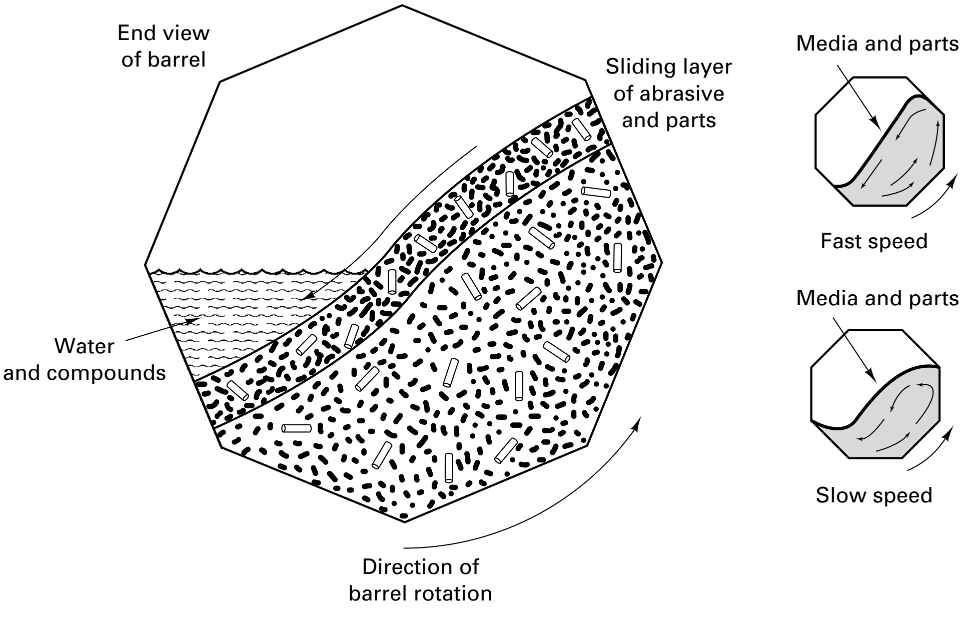


FIGURE 35-8 Schematic of the blow of material in tumbling or barrel finishing. The parts and media mass typically account for 50 to 60% of capacity.

Increasing the speed of rotation adds centrifugal forces that cause the material to rise higher in the barrel. The enhanced action can often accelerate the process, provided that the speed is not so great as to destroy the cascading action and that the additional action does not damage the workpiece. By a suitable selection of abrasives, filler, barrel size, ratio of workpieces to abrasive, fill level, and speed, a wide range of parts can be tumbled successfully. Delicate parts may have to be attached to racks within the barrel to reduce their movement while permitting the media to flow around them.

Natural and synthetic abrasives are available in a wide range of sizes and shapes, including those depicted in Figure 35-9, that enable the finishing of complex parts with irregular openings. The various media are often mixed in a given load, so that some will reach into all sections and corners to be cleaned.

Tumbling is usually done dry, but it can also be performed with an aqueous solution in the barrel. Chemical compounds can be added to the media to assist in cleaning, or descaling, or to provide features such as rust inhibition. Support equipment usually assists with loading and unloading the barrels as well as, with the separation of the workpieces from the abrasive media. The latter operation often uses mesh screens with selected size openings.

Barrel tumbling can be a very inexpensive way to finish large quantities of small parts and produce rounded edges and corners. Unfortunately, the abrasive action occurs on all surfaces and cannot be limited to selected areas. The cycle time is often long, and the process can be quite noisy.

In the *barrel burnishing* process, no cutting action is desired. Instead, the parts are tumbled against themselves or with media such as steel balls, shot, rounded-end pins, or ballcones. If the original material is free of visible scratches and pits, the combination of peening and rubbing will reduce minute irregularities and produce a smooth, uniform surface.

Barrel burnishing is normally done wet, using a solution of water and lubricating or cleaning agents, such as soap or cream of tartar. Because the rubbing action between the work and the media is very important, the barrel should not be loaded more than half full, and the volume ratio of media to work should be about 2:1 so the workpieces rub against the media, not each other. The speed of rotation should be set to maintain the cascading action and not fling the workpieces free of the tumbling mass.

Centrifugal barrel tumbling places the tumbling barrel at the end of a rotating arm. This adds centrifugal force to the weight of the parts in the barrel and can accelerate the process by as much as 25 to 50 times.

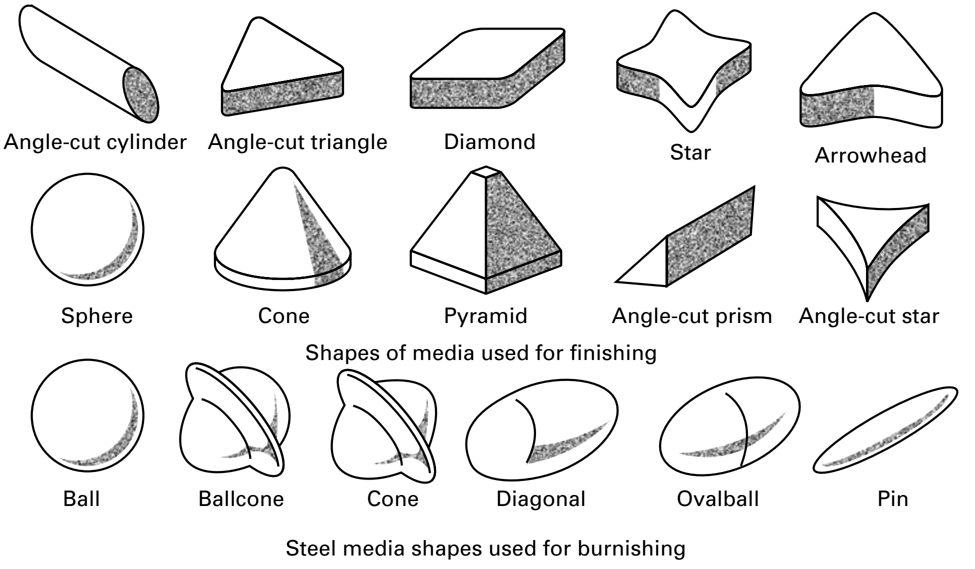

FIGURE 35-9 Synthetic abrasive media are available in a wide variety of sizes and shapes. Through proper selection, the media can be tailored to the product being cleaned.

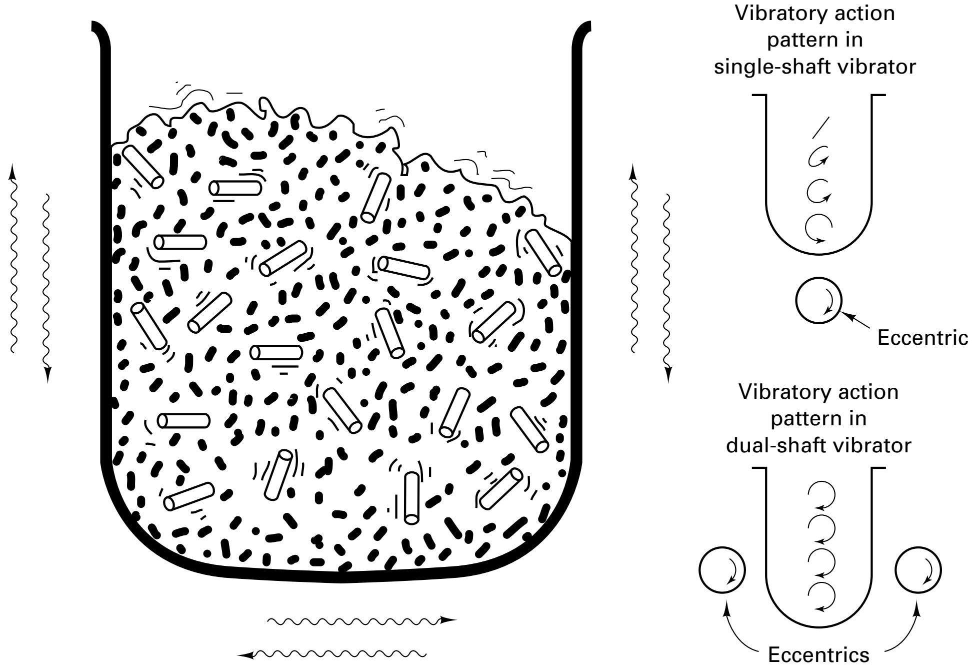

FIGURE 35-10 Schematic diagram of a vibratory-finishing tub loaded with parts and media. The single eccentric shaft drive provides maximum motion at the bottom, which decreases as one moves upward. The dual-shaft design produces more uniform motion of the tub and reduces processing time.

In *spindle finishing* the workpieces are attached to rotating shafts, and the assembly is immersed in media moving in a direction opposite to part rotation. This process is commonly applied to cylindrical parts and avoids the impingement of workpieces on one another. The abrasive action is accelerated, but time is required for fixturing and removal of the parts.

VIBRATORY FINISHING

Vibratory finishing is a versatile process widely used for deburring, radiusing, descaling, burnishing, cleaning, brightening, and fine finishing. In contrast to the barrel processing, *vibratory finishing* is performed in open containers. As illustrated in Figure 35-10, tubs or bowls are loaded with workpieces and media and are vibrated at frequencies between 900 and 3600 cycles per minute. The specific frequency and amplitude are determined by the size, shape, weight, and material of the pan, as well as the media and compound. Because the entire load is under constant agitation, cycle times are less than with barrel operations. The process is less noisy and is easily controlled and automated. In addition, the open tubs allow for direct observation during the process, which can also deburr or smooth internal recesses or holes.

MEDIA

The success of any of the mass-finishing processes depends greatly on *media* selection and the ratio of media to parts, as presented in Table 35-2. The media may prevent the parts from impinging upon one another as it simultaneously cleans and finishes. Fillers, such as scrap punchings, minerals, leather scraps, and sawdust, are often added to provide additional bulk and cushioning.

Natural abrasives include slag, cinders, sand, corundum, granite chips, limestone, and hardwood shapes, such as pegs, cylinders, and cubes. Synthetic media typically contain 50 to 70 wt% of abrasives, such as alumina (Al_2O_3), emery, flint, and silicon carbide. This material is embedded in a matrix of ceramic, polyester, or resin plastic, which is softer than the abrasive and erodes, allowing the exposed abrasive to perform the work. The synthetics are generally produced by some form of casting operation, so their sizes and shapes are consistent and reproducible (as opposed to the random sizes and shapes of the natural media). Steel media with no added abrasive are frequently specified for burnishing and light deburring.

TABLE 35-2 Typical Media-to-Part Ratios for Mass Finishing

Media/Part Ratio by Volume	Typical Application
0:1	Part-on-part processing or burr removal without media
1:1	Produces very rough surfaces and is suitable for parts in which part-on-part damage is not a problem
2:1	Somewhat less severe part-on-part damage, but more action from less media
3:1	May be acceptable for very small parts and very small media. Part-on-part contact is likely on larger and heavier parts
4:1	In general, a good average ratio for many parts; a good ratio for evaluating a new deburring process
5:1	Better for nonferrous parts subject to part-on-part damage
6:1	Suitable for nonferrous parts, especially preplate surfaces on zinc parts with resin-bonded media
8:1	For improved preplate surfaces with resin-bonded media
10:1	Produces very fine finishes

Source: American Machinist, August 1983.

Media selection should also be correlated with part geometry, since the abrasives should be able to contact all critical surfaces without becoming lodged in recesses or holes. This requirement has resulted in a wide variety of sizes and shapes, including those presented in Figure 35-9. The different abrasives, sizes, and shapes can be selected or combined to perform tasks ranging from light deburring with a very fine finish to heavy cutting with a rough surface.

COMPOUNDS

A variety of functions are performed by the *compounds* that are added in addition to the media and workpieces. These compounds can be liquid or dry, abrasive or nonabrasive, and acid, neutral, or alkaline. They are often designed to assist in deburring, burnishing, and abrasive cutting, as well as to provide cleaning, descaling, or corrosion inhibition.

In deburring and finishing, many small particles are abraded from both the media and the workpieces, and these must be suspended in the compound solution to prevent them from adhering to the parts. Deburring compounds also act to keep the parts and media clean and to inhibit corrosion. Burnishing compounds are often selected for their ability to develop desired colors and enhance brightness.

Cleaning compounds such as dilute acids and soaps are designed to remove excessive soils from both the parts and media and are often specified when the incoming materials contain heavy oil or grease. Corrosion inhibitors can be selected for both ferrous and nonferrous metals and are particularly important when steel media are being used.

Another function of the compounds may be to condition the water when aqueous solutions are being used. Consistent water quality, in terms of "hardness" and metal ion content, is important to ensure uniform and repeatable finishing results. Liquid compounds may also provide cooling to both the workpieces and the media.

SUMMARY OF MASS-FINISHING METHODS

The barrel and vibratory finishing processes are really quite simple and economical and can process large numbers of parts in a batch procedure. Soft, nonferrous parts can be finished in as little as 10 minutes, while the harder steels may require 2 hours or more. Sometimes the operations are sequenced, using progressively finer abrasives. Figure 35-11 shows a variety of parts before and after the mass-finishing operation, using the triangular abrasive shown with each component.

Despite the high volume and apparent success, these processes may still be as much art as science. The key factors of workpiece, equipment, media, and compound are all interrelated, and the effect of changes can be quite complex. Media, equipment, and compounds are often selected by trial and error, with various approaches being tested until the desired result is achieved. Even then, maintenance of consistent results may still be difficult.

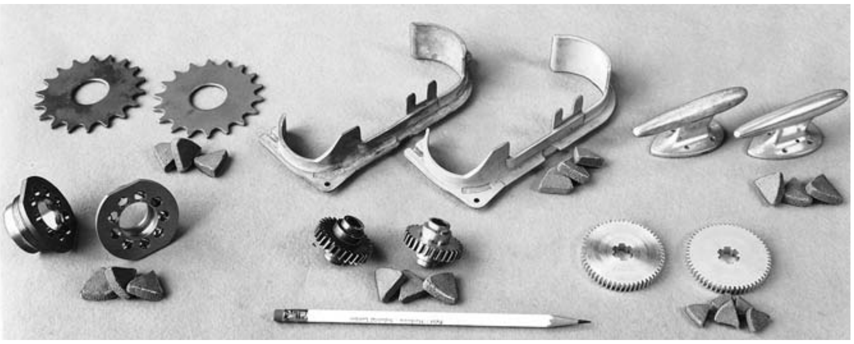

FIGURE 35-11 A variety of parts before and after barrel finishing with triangular-shaped media. *(Courtesy of Norton Company.)*

BELT SANDING

In the *belt sanding* operation, the workpieces are held against a moving abrasive belt until the desired degree of finish is obtained. Because of the movement of the belt, the resulting surface contains a series of parallel scratches with a texture set by the grit of the belt. When smooth surfaces are desired, a series of belts may be employed, with progressively finer grits.

The ideal geometry for belt sanding is a flat surface, for the belt can be passed over a flat table where the workpiece can be held firmly against it. Belt sanding is frequently a hand operation and is therefore quite labor intensive. Furthermore, it is difficult to apply when the geometry includes recesses or interior corners. As a result, belt sanding is usually employed when the number of parts is small and the geometry is relatively simple. See Chapter 28.

WIRE BRUSHING

High-speed rotary *wire brushing* is sometimes used to clean surfaces and can also impart some small degree of material removal or smoothing. The resulting surface consists of a series of uniform curved scratches. For many applications, this *may* be an acceptable final finish. If not, the scratches can easily be removed by barrel finishing or buffing.

Wire brushing is often performed by hand application of a small workpiece to the brush or the brush to a larger workpiece. Automatic machines can also be used where the parts are moved past a series of rotating brushes. In another modification the brushes are replaced with plastic or fiber wheels that are loaded with abrasive.

BUFFING

Buffing is a polishing operation in which the workpiece is brought into contact with a revolving cloth wheel that has been charged with a fine abrasive, such as polishing rouge. The “wheels”, which are made of disks of linen, cotton, broadcloth, or canvas, achieve the desired degree of firmness through the amount of stitching used to fasten the layers of cloth together. When the operation calls for very soft polishing or polishing into interior corners, the stitching may be totally omitted, the centrifugal force of the wheel rotation being sufficient to keep the layers in the proper position. Various types of polishing compounds are also available, with many consisting of ferric oxide particles in some form of hinder or carrier.

The buffing operation is very similar to the lapping process that was discussed in Chapter 27. In buffing, however, the abrasive removes only minute amounts of metal from the workpiece. Fine scratch marks can be eliminated and oxide tarnish can be removed. A smooth, reflective surface is produced. When soft metals are buffed, a small amount of metal flow may occur, which further helps to reduce high spots and produce a high polish.

In manual buffing, the workpiece is held against the rotating wheel and manipulated to provide contact with all critical surfaces. Once again, the labor costs can be quite extensive. If the workpieces are not too complex, semiautomatic machines can be used, where the workpieces are held in fixtures and move past a series of individual buffing wheels. By designing the part with buffing in mind, good results can be obtained quite economically.

ELECTROPOLISHING

Electropolishing is the reverse of electroplating (discussed later in this chapter) since material is removed from the surface rather than being deposited. A DC electrolytic circuit is constructed with the workpiece as the anode. As current is applied, material is stripped from the surface, with material removal occurring preferentially from any raised location. Unfortunately, it is not economical to remove more than about 0.001 in. of material from any surface. However, if the initial surface is sufficiently smooth (less than 8 in. rms), and the grain size is small, the result will be a smooth polish with irregularities of less than 2 μin.—a mirrorlike finish.

Electropolishing was originally used to prepare metallurgical specimens for examination under the microscope. It was later adopted as a means of polishing stainless steel sheets and other stainless products. It is particularly useful for polishing irregular shapes that would be difficult to buff.

35.3 CHEMICAL CLEANING

Chemical cleaning operations are effective means of removing oil, dirt, scale, or other foreign material that may adhere to the surface of a product, as a preparation for subsequent painting or plating. Because of environmental, health, and safety concerns, however, many processes that were once the industrial standard have now been eliminated or substantially modified. While the major concern with the mechanical methods has usually been airborne particles, the chemical methods often require the disposal of spent or contaminated solutions, and they occasionally use hazardous, toxic, or environmentally unfriendly materials. Chlorofluorocarbons (CFCs) and carbon tetrachloride, for example, have been identified as ozone-depleting chemicals and have been phased out of commercial use. Process changes to comply with added regulations can significantly shift process economics. Manufacturers must now ask themselves if a part really has to be cleaned, what soils have to be removed, how clean the surfaces have to be, and how much they are willing to pay to accomplish that goal. Selection of the cleaning method will depend on cost of the equipment, power, cleaning materials, maintenance and labor, plus the cost of recycling and disposal of materials. Specific processes will depend on the quantity of parts to be processed (part per hour), part configuration, part material, desired surface finish, temperature of the process, and flexibility. Manufacturers want machines they can integrate with manufacturing cells so changes in products can be quickly handled.

ALKALINE CLEANING

Alkaline cleaning is basically the "soap and water" approach to parts cleaning and is a commonly used method for removing a wide variety of soils (including oils, grease, wax, fine particles of metal, and dirt) from the surfaces of metals. The cleaners are usually complex solutions of alkaline salts, additives to enhance cleaning or surface modification, and surfactants or soaps that are selected to reduce surface tension and displace, emulsify, and disperse the insoluble soils. The actual cleaning occurs as a result of one or more of the following mechanisms: (1) saponification, the chemical reaction of fats and other organic compounds with the alkaline salts; (2) displacement, where soil particles are lifted from the surface; (3) dispersion or emulsification of insoluble liquids; and (4) dissolution of metal oxides.

Alkaline cleaners can be applied by immersion or spraying, and they are usually heated to accelerate the cleaning action. The cleaning is then followed by a water rinse to remove all residue of the cleaning solution, as well as flush away some small amounts of remaining soil. A drying operation may also be required since the aqueous cleaners do not evaporate quickly, and some form of corrosion inhibitor (or rust preventer) may be required, depending on subsequent use.

Environmental issues relating to alkaline cleaning include (1) reducing or eliminating phosphate effluent, (2) reducing toxicity and increasing biodegradability, and (3) recycling the cleaners to extend their life and reduce the volume of discard.

SOLVENT CLEANING

In *solvent cleaning*, oils, grease, fats, and other surface contaminants are removed by dissolving them in organic solvents derived from coal or petroleum, usually at room temperature. The common solvents include petroleum distillates (such as kerosene, naphtha, and mineral spirits), chlorinated hydrocarbons (such as methylene chloride and trichloroethylene), and liquids such as acetone, benzene, toluene, and the various alcohols. Small parts are generally cleaned by immersion, with or without assisting agitation, or by spraying. Products that are too large to immerse can be cleaned by spraying or wiping. The process is quite simple, and capital equipment costs are rather low. Drying is usually accomplished by simple evaporation.

Solvent cleaning is an attractive means of cleaning large parts, heat-sensitive products, materials that might react with alkaline solutions (such as aluminum, lead, and zinc), and products with organic contaminants (such as soldering flux or marking crayon). Virtually all common industrial metals can be cleaned, and the size and shape of the workpiece are rarely a limitation. Insoluble contaminants, such as metal oxides, sand, scale, and the inorganic fluxes used in welding, brazing, and soldering, cannot be removed by solvents. In addition, resoiling can occur as the solvent becomes contaminated. As a result, solvent cleaning is often used for preliminary cleaning.

Many of the common solvents have been restricted because of health, safety, and environmental concerns. Fire and excessive exposure are common hazards. Adequate ventilation is critical. Workers should use respiratory devices to prevent inhalation of vapors and wear protective clothing to minimize direct contact with skin. In addition, solvent wastes are often considered to be hazardous materials and may be subject to high disposal cost.

VAPOR DEGREASING

In *vapor degreasing*, the vapors of a chlorinated or fluorinated solvent are used to remove oil, grease, and wax from metal products. A nonflammable solvent, such as trichloroethylene, is heated to its boiling point, and the parts to be cleaned are suspended in its vapors. The vapor condenses on the work and washes the soluble contaminants back into the liquid solvent. Although the bath becomes dirty, the contaminants rarely volatilize at the boiling temperature of the solvent. Therefore, vapor degreasing tends to be more effective than cold solvent cleaning, since the surfaces always come into contact with clean solvent. Since the surfaces become heated by the condensing solvent, they dry almost instantly when they are withdrawn from the vapor.

Vapor degreasing is a rapid, flexible process that has almost no visible effect on the surface being cleaned. It can be applied to all common industrial metals, but the solvents may attack rubber, plastics, and organic dyes that might be present in product assemblies. A major limitation is the inability to remove insoluble soils, forcing the process to be coupled with another technique, such as mechanical or alkaline cleaning. Since hot solvent is present in the system, the process is often accelerated by coupling the vapor cleaning with an immersion or spray using the hot liquid.

Unfortunately, environmental issues have forced the almost complete demise of the process. While the vapor degreasing solvents are chemically stable, have low toxicity, are nonflammable, evaporate quickly, and can be recovered for reuse, the CFC materials have been identified as ozone-depleting compounds and have essentially been banned from use. Solvents that can be used in the same process, or in a replacement process that offers the necessary cleaning qualities, include chlorinated solvents (methylene chloride, perchloroethylene, and trichloroethylene), most manufacturers have converted to some form of water-based process using alkaline, neutral, or acid cleaners or to a process using chlorine-free, hydrocarbon-based solvents. Sealed chamber machines use non-VOC, nonchlorinated solvents that are continuously recycled.

ULTRASONIC CLEANING

When high-quality cleaning is required for small parts, *ultrasonic cleaning* may be preferred. Here the parts are suspended or placed in wire-mesh baskets that are then immersed in a liquid cleaning bath, often a water-based detergent. The bath contains an ultrasonic transducer that operates at a frequency that causes *cavitation* in the liquid. The bubbles that form and implode provide the majority of the cleaning action, and if gross dirt, grease, and oil are removed prior to the immersion, excellent results can usually be obtained in 60 to 200 seconds. Most systems operate at between 10 and 40 kHZ. Because of the ability to use water-based solutions, ultrasonic cleaning has replaced many of the environmentally unfriendly solvent processes.

ACID PICKLING

In the *acid-pickling* process, metal parts are first cleaned to remove oils and other contaminants and then dipped into dilute acid solutions to remove oxides and dirt that are left on the surface by the previous processing operations. The most common solution is a 10% sulfuric acid bath at an elevated temperature between 150° and 185° F. Muriatic acid is also used, either cold or hot. As the temperature increases, the solutions can become more dilute.

After the parts are removed from the pickling bath, they should be rinsed to flush the acid residue from the surface and then dipped in an alkaline bath to prevent rusting. When it will not interfere with further processing, an immersion in a cold *milk of lime* solution is often used. Caution should be used to avoid overpickling, since the acid attack can result in a roughened surface.

■ 35.4 COATINGS

Each of the surface finishing methods previously presented has been a material removal process, designed to clean, smooth, and otherwise reduce the size of the part. Many other techniques have been developed to add material to the surface of a part. If the material is deposited as a liquid or organic gas (*or* from a liquid or gas medium), the process is called *coating*. If the added material is a solid during deposition, the process is known as *cladding*.

PAINTING, WET OR LIQUID

Paints and enamels are by far the most widely used finish on manufactured products, and a great variety are available to meet the wide range of product requirements. Most of today's commercial paints are synthetic organic compounds that contain pigments and dry by polymerization or by a combination of polymerization and adsorption of oxygen. Water is the most common carrying vehicle for the pigments. Heat can be used to accelerate the drying, but many of the synthetic paints and enamels will dry in less than an hour without the use of additional heat. The older oil-based materials have a long drying time and require excessive environmental protection measures. For these reasons they are seldom used in manufacturing applications.

Paints are used for a variety of reasons, usually to provide protection and decoration but also to fill or conceal surface irregularities, change the surface friction, or modify the light or heat absorption or radiation characteristics. Table 35-3 provides a list of some of the more commonly used organic finishes, along with their significant characteristics. *Nitrocellulose lacquers* consist of thermoplastic polymers dissolved in organic solvent. Although fast drying (by the evaporation of the solvent) and capable of producing very beautiful finishes, they are not sufficiently durable for most commercial applications. The *alkyds* are a general-purpose paint but are not adequate for hard-service applications. *Acrylic enamels* are widely used for automotive finishes and may require catalytic or oven curing. *Asphaltic paints*, solutions of asphalt in a solvent, are used extensively in the electrical industry, where resistance to corrosion is required and appearance is not of prime importance.

When considering a painted finish, the temptation is to focus on the outermost coat, to the exclusion of the underlayers. In reality, painting is a complex system that includes the substrate material, cleaning and other pretreatments (such as anodizing, phosphating, and various conversion coatings), priming, and possible intermediate layers. The method of application is another integral feature to be considered.

TABLE 35-3 Commonly Used Organic Finishes and Their Qualities

Material	Durability (Scale of 1–10)	Relative Cost (Scale of 1–10)	Characteristics
Nitrocellulose lacquers	1	2	Fast drying; low durability
Epoxy esters	1	2	Good chemical resistance
Akyd-amine	2	1	Versatile; low adhesion
Acrylic lacquers	4	1.7	Good color retention; low adhesion
Acrylic enamels	4	1.3	Good color retention; though; high baking temperature
Vinyl solutions	4	2	Flexible; good chemical resistance; low solids
Silicones	4–7	5	Good gloss retention; low flexibility
Flouropolymers	10	10	Excellent durability; difficult to apply

PAINT APPLICATION METHODS

In manufacturing, almost all painting is done by one of four methods: *dipping, hand spraying, automatic spraying*, or *electrostatic spray finishing*. In most cases, at least two coats are required. The first (or *prime*) coat serves to (1) ensure adhesion, (2) provide a leveling effect by filling in minor porosity and other surface blemishes, and (3) improve corrosion resistance and thus prevent later coatings from being dislodged in service. These properties are less easily attainable in the more highly pigmented paints that are used in the final coats to promote color and appearance. When using multiple coats, however, it is important that the carrying vehicles for the final coats do not unduly soften the underlayers.

Dipping is a simple and economical means of paint application when all surfaces of the part are to be coated. The products can be manually immersed into a paint bath or passed through the bath while on or attached to a conveyor. Dipping is attractive for applying prime coats and for painting small parts where spray painting would result in a significant waste due to overspray. Conversely, the process is unattractive where only some of the surfaces require painting or where a very thin, uniform coating would be adequate, as on automobile bodies. Other difficulties are associated with the tendency of paint to run, producing both a wavy surface and a final drop of paint attached to the lowest drip point. Good-quality dipping requires that the paint be stirred at all times and be of uniform viscosity.

Spray painting is probably the most widely used paint application process because of its versatility and the economy in the use of paint. In the conventional technique, the paint is atomized and transported by the flow of compressed air. In a variation known as *airless spraying,* mechanical pressure forces the paint through an orifice at pressures between 500 and 4500 psi. This provides sufficient velocity to produce atomization and also propel the particles to the workpiece. Because no air pressure is used for atomization, there is less spray loss (paint efficiency may be as high as 99%) and less generation of gaseous fumes.

Hand spraying is probably the most versatile means of application but can be quite costly in terms of labor and production time. When air or mechanical means provide the atomization, workers must exercise considerable skill to obtain the proper coverage without allowing the paint to "run" or "drape." Only a very thin film can be deposited at one time, usually less than 0.001 in. As a result, several coats may be required with intervening time for drying.

One means of applying thicker layers in a single application is known as *hot spraying*. Special solvents are used that reduce the viscosity of the material when heated. Upon atomization, the faster-evaporating solvents are removed, and the drop in temperature produces a more viscous, run-resistant material that can be deposited in thicker layers.

When producing large quantities of similar or identical parts, some form of automatic system is usually employed. The simplest automatic equipment consists of some form of parts conveyor that transports the parts past a series of stationary spray heads.

While the concept is simple, the results may be unsatisfactory. A large amount of paint is wasted, and it is difficult to get uniform coverage.

Industrial robots can be used to move the spray heads in a manner that mimics the movements of a human painter, maintaining uniform separation distance and minimizing waste. This is an excellent application for the robot, since a monotonous and repetitious process can be performed with consistent results. In addition, use of a robot removes the human from an unpleasant, and possibly unhealthy, environment. Nowdays, cars are painted almost exclusively with robots.

Both manual and automatic spray painting can benefit from the use of *electrostatic deposition*. A DC electrostatic potential is applied between the atomizer and the workpiece. The atomized paint particles assume the same charge as the atomizer and are therefore repelled. The oppositely charged workpiece then attracts the particles, with the actual path of the particle being a combination of the kinetic trajectory and the electrostatic attraction. The higher the DC voltage, the greater the electrostatic attraction. Overspraying can be reduced by as much as 60 to 80%, as can the generation of airborne particles and other emissions. Unfortunately, part edges and holes receive a heavier coating than flat surfaces due to the concentration of electrostatic lines of force on any sharp edge. Recessed areas will receive a reduced amount of paint, and a manual touch-up may be required using conventional spray techniques. Despite these limitations, electrostatic spraying is an extremely attractive means of painting complex-shaped products where the geometry would tend to create large amounts of overspray.

In an electrostatic variation of airless spraying, the paint is fed onto the surface of a rapidly rotating cone or disk that is also one electrode of the electrostatic circuit. Centrifugal force causes the thin film of paint to flow toward the edge, where charged particles are spun off without the need for air assist. The particles are then attracted to the workpiece, which serves as the other electrode of the electrostatic circuit. Because of the effectiveness of the centrifugal force, paints can be used with high-solids content, reducing the amount of volatile emissions and enabling a thicker layer to be deposited in a single application.

Electrocoating or *electrodeposition* applies paint in a manner similar to the electroplating of metals. As shown schematically in Figure 35-12, the paint particles are suspended in an aqueous solution and are given an electrostatic charge by applying a DC voltage between the tank (cathode) and the workpiece (anode). As the electrically conductive workpiece enters and passes through the tank, the paint particles are attracted to it and deposit on the surface, creating a uniform, thin coating that is more than 90% resin and pigment. When the coating reaches a desired thickness, determined by the bath conditions, no more paint is deposited. The workpiece is then removed from the tank, rinsed in a water spray, and baked at a time and temperature that depends on the particular type of paint. Baking of 10 to 20 minutes at 375°F is somewhat typical.

Electrocoating combines the economy of ordinary dip painting with the ability to produce thinner, more uniform coatings. The process is particularly attractive for applying the prime coat to complex structures, such as automobile bodies, where good corrosion resistance is a requirement. Hard-to-reach areas and recesses can be effectively coated.

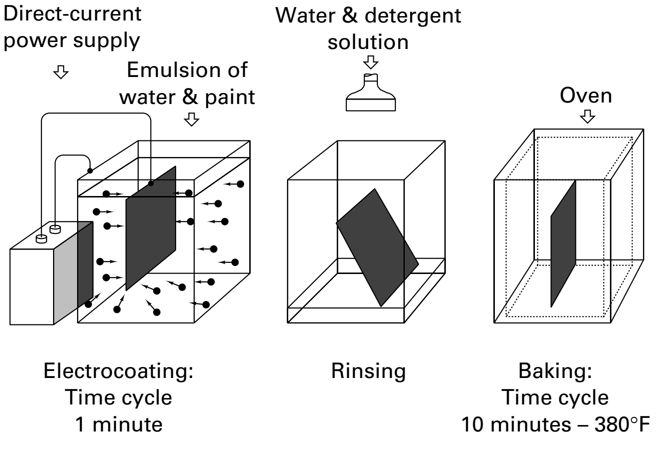

FIGURE 35-12 Basic steps in the electrocoating process.

Since the solvent is water, no fire hazard exists (as with the use of many solvents), and air and water pollution is reduced significantly. In addition, the process can be readily adapted to conveyor line production.

DRYING

Most paints and enamels used in manufacturing require from 2 to 24 hours to dry at normal room temperature. This time can be reduced to between 10 minutes and 1 hour if the temperature can be raised to between 275° and 450°F. As a result, elevated-temperature drying is often preferred. Parts can be batch processed in ovens or continuously passed through heated tunnels or under panels of infrared heat lamps.

Elevated-temperature drying is rarely a problem with metal parts, but other materials can be damaged by exposure to the moderate temperatures. For example, when wood is heated, the gases, moisture, and residual sap are expanded and driven to the surface beneath the hardening paint. Small bubbles tend to form that roughen the surface, or break, producing small holes in the paint.

POWDER COATING

Powder coating is yet another variation of electrostatic spraying, but here the particles are solid rather than liquid. Several coats, such as primer and finish, can be applied and then followed by a single baking, in contrast to the baking after each coat that is required in the conventional spray processes. In addition, the overspray powder can often be collected and reused. While volatilized solvents are no longer a concern, operators must now address the possibility of powder explosion, as well as the health hazards of airborne particles.

Modern powder technology can produce a high-quality finish with superior surface properties and usually at a lower cost than liquid painting. Powder painting is more efficient in the use of materials (the overspray can be captured and reused) and lower energy requirements. The economic advantages must be weighed against the limitations of powder coating. Dry systems have a longer color change time than wet systems. The process is not good for large objects (massive tanks) or heat-sensitive objects. It is not easy to produce film thickness less than 1 mil (0.03 mm).

Table 35-4 provides details on powders that are used in powder coatings. Thermoplastics can also be used, but thermosetting powders are most common. The elements

TABLE 35-4 Thermosetting Powder Coatings (Dry Painting) Have a Wide Variety of Properties and Applications

Properties	Epoxy	Epoxy/Polyester Hybrid	TGIC Polyester	Polyester Urethane	Acrylic Urethane
Application thickness	0.5–20 mils[a]	0.5–10 mils	0.5–10 mils	0.5–10 mils	0.5–10 mils
Cure cycle (metal temperatures)[b]	450°F—3 min 250°F—30 min	450°F—3 min; 325°F—25 min	400°F—7 min; 310°F—20 min	400°F — 7 min; 350°F—17 min	400°F—7 min; 360°F—25 min
Outdoor weatherability	Poor	Poor	Very good	Very good	Excellent
Pencil hardness	HB-5H	HB-2H	HB-2H	HB-3H	H-3H
Direct impact resistance, in lb[c]	80–160	80–160	80–160	80–160	20–60
Chemical resistance	Excellent	Very good Least expensive	Good	Good	Very good Most expensive
Cost (relative)	2	1	3	4	5
Applications	Furniture, cars, ovens, appliances	Water heaters, radiators, office furniture	Architectural aluminum, outdoor furniture, farm equipment	Car wheels/rims, playground equipment	Washing machines, refrigerators, ovens

[a] Thickness up to 150 mils can be applied via multiple coats in a fluidized bed.

[b] Time and temperature can be reduced, by utilizing accelerated curing mechanisms, while maintaining the same general properties.

[c] Tested at a coating thickness of 2.0 mils.

of a powder coating system are shown in Figure 35-13. The following aspects of the process must be considered:

- Types of guns—corona charged or tribo charged
- Number of guns—depends on many factors, such as parts per hour, size of parts, line speed, and powder types
- Color change time/frequency
- Safety
- Curing oven—coated parts put in ovens to melt, flow, and cure the powder

HOT-DIP COATINGS

Large quantities of metal products are given corrosion-resistant coatings by direct immersion into a bath of molten metal. The most common coating materials are zinc, tin, aluminum, and tene (an alloy of lead and tin).

Hot-dip galvanizing is the most widely used method of imparting corrosion resistance to steel. (The zinc acts as a sacrificial anode, protecting the underlying iron.) After the products, or sheets, have been cleaned to remove oil, grease, scale, and rust, they are fluxed by dipping into a solution of zinc ammonium chloride and dried. Next, the article is completely immersed in a bath of molten zinc. The zinc and iron react metallurgically to produce a coating that consists of a series of zinc–iron compounds and a surface layer of nearly pure zinc.

The coating thickness is usually specified in terms of weight per unit area. Values between 0.5 and 3.0 oz/ft^2 are typical, with the specific value depending on the time of immersion and speed of withdrawal. Thinner layers can be produced by incorporating some form of air jet or mechanical wiping as the product is withdrawn. Since the corrosion resistance is provided through the sacrificial action of the zinc, the thin layers do not provide long-lasting protection. Extremely heavy coatings, on the other hand, may tend to crack and peel. The appearance of the coating can be varied through both the process conditions and alloy additions of tin, antimony, lead, and aluminum. When the coatings are properly applied, bending or forming can often follow galvanizing without damage to the integrity of the coating. Zinc-galvanized sheet can be heat treated with a zinc–iron alloy coating. The 10% iron content adds strength and makes for good corrosion and pitting/chipping resistance. In auto applications, galvannealing beats out pure zinc on several counts: spot weldability, pretreatability, and ease of painting. Electrogalvanized zinc–nickel coatings that contain 10 to 15% Ni can be used in thinner layers (5–6 microns) and are easier to form and spot weld.

The primary limitations to hot-dip galvanizing are the size of the product (which is limited to the size of the tank holding the molten zinc) and the "damage" that might occur when a metal is exposed to the temperatures of the molten material (approximately).

Tin coatings can also be applied by immersing in a bath of molten tin with a covering of flux material. Because of the high cost of tin and the relatively thick coatings applied by hot dipping, most tin coatings are now applied by electroplating. *Terne coating* utilizes an alloy of 15 to 20% tin and the remainder lead. This material is cheaper than tin and can provide satisfactory corrosion resistance for many applications.

CHEMICAL CONVERSION COATINGS

In *chemical conversion coating,* the surface of the metal is chemically treated to produce a nonmetallic, nonconductive surface that can impart a range of desirable properties. The most popular types of conversion coatings are chromate and phosphate. Aluminum, magnesium, zinc, and copper (as well as cadmium and silver) can all be treated by a *chromate* conversion process that usually involves immersion in a chemical bath. The surface of the metal is convened into a layer of complex chromium compounds that can impart colors ranging from bright clear through blue, yellow, brown, olive drab, and black. Most of the films are soft and gelatinous when they are formed but harden upon drying. They can be used to (1) impart exceptionally good corrosion resistance; (2) act as an intermediate bonding layer for paint, lacquer, or other organic finishes; or (3) provide specific colors by adding dyes to the coating when it is in its soft condition.

Phosphate coatings are formed by immersing metals (usually steel or zinc) in baths where metal phosphates (iron, zinc, and manganese phosphates are all common) have been dissolved in solutions of phosphoric acid. The resultant coatings can be used to precondition surfaces to receive and retain paint or enhance the subsequent bonding with rubber or plastic. In addition, phosphate coatings are usually rough and can provide an excellent surface for holding oils and lubricants. This feature can be used in manufacturing, where the coating holds the lubricants that assist in forming, or in the finished product, as with black-color bolts and fasteners, whose corrosion resistance is provided by a phosphate layer impregnated with wax or oil.

BLACKENING OR COLORING METALS

Many steel parts are treated to produce a black, iron oxide coating—a lustrous surface that is resistant to rusting when handled. Since this type of oxide forms at elevated temperatures, the parts are usually heated in some form of special environment, such as spent carburizing compound or special blackening salts.

Chemical solutions can also be used to blacken, blue, and even "brown" steels. Brown, black, and blue colors can also be imparted to tin, zinc, cadmium, and aluminum through chemical bath immersions or wipes. The surfaces of copper and brass can be made to be black, blue, green, or brown, with a full range of tints in between.

ELECTROPLATING

Large quantities of metal *and plastic* parts are electroplated to produce a metal coating that imparts corrosion or wear resistance, improves appearance (through color or luster), or increases the overall dimensions. Virtually all commercial metals can be plated, including aluminum, copper, brass, steel, and zinc-based die castings. Plastics can be electroplated, provided that they are first coated with an electrically conductive material.

The most common platings are zinc, chromium, nickel, copper, tin, gold, platinum, and silver. The electrogalvanized zinc platings are thinner than the hot-dip coatings and can be produced without subjecting the base metal to the elevated temperatures of

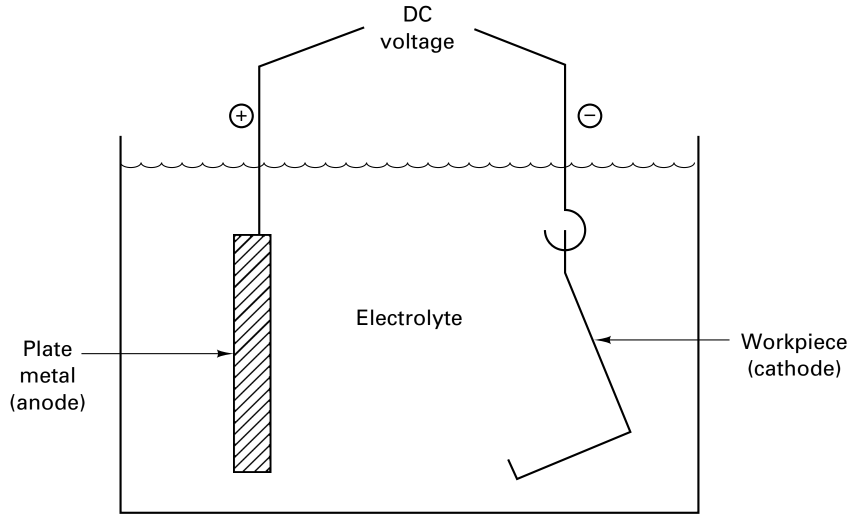

FIGURE 35-14 Basic circuit for an electroplating operation, showing the anode, cathode (workpiece), and electrolyte (conductive solution).

molten zinc. Nickel plating provides good corrosion resistance but is rather expensive and does not retain its lustrous appearance. Consequently, when lustrous appearance is desired, a chromium plate is usually specified. Chromium is seldom used alone, however. An initial layer of copper produces a leveling effect and makes it possible to reduce the thickness of the nickel layer that typically follows to less than 0.0006 in. The final layer of chromium then provides the attractive appearance. Gold, silver, and platinum platings are used in both the jewelry and electronics industries, where the thin layers impart the desired properties while conserving the precious metals.

Hard chromium plate, with Rockwell hardnesses between 66 and 70, can be used to build up worn parts to larger dimensions and to coat tools and other products that need reduced surface friction and good resistance to both wear and corrosion. Hard chrome coatings are always applied directly to the base material and are usually much thicker than the decorative treatments, typically ranging from .003 to .010 in. thick. Even thicker layers are used in applications such as diesel cylinder liners. Since hard chrome plate does not have a leveling effect, defects or roughness in the base surface will be amplified. If smooth surfaces are desired, subsequent grinding and polishing may be necessary.

Figure 35-14 depicts the typical electroplating process. A DC voltage is applied between the parts to be plated (which is made the cathode) and an anode material that is either the metal to be plated or an inert electrode. Both of these components are immersed in a conductive electrolyte, which may also contain dissolved salts of the metal to be plated as well as additions to increase or control conductivity. In response to the applied voltage, metal ions migrate to the cathode, lose their charge, and deposit on the surface. While the process is simple in its basic concept, the production of a high-quality plating requires selection and control of a number of variables, including the electrolyte and the concentrations of the various dissolved components, the temperature of the bath, and the electrical voltage and current. The interrelation of these features adds to the complexity and makes process control an extremely challenging problem.

The surfaces to be plated must also be prepared properly if satisfactory results are to he obtained. Pinholes, scratches, and other surface defects must be removed if a smooth, lustrous finish is desired. Combinations of degreasing, cleaning, and pickling are used to ensure a chemically clean surface, one to which the plating material can adhere.

As shown in Figure 35-15, the plated metal tends to be preferentially attracted to corners and protrusions. This makes it particularly difficult to apply a uniform plating to irregular shapes, especially ones containing recesses, corners, and edges. Design features can be incorporated to promote plating uniformity, and improved results can often be obtained through the use of multiple spaced anodes or anodes whose shape resembles that of the workpiece.

Electroplating is frequently performed as a continuous process, where the individual parts to be plated are hung from conveyors. As they pass through the process, they

Convex surfaces: Plate uniformly especially if edges are rounded

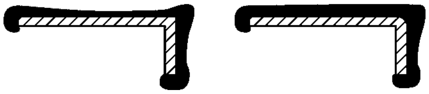
Concave recesses: Platability depends on dimensions

Flat surfaces: Not desirable. Use slight crown to hide undulations.

Slots: Narrow slots and holes should have rounded corners.

Blind holes: Must be exempted from minimum thickness requirements. Require vent hole at blind end.

V-shaped grooves: Difficult to plate. Should be avoided.



Sharply angled edges: Plating is thinner in center areas. Round all areas.

Fins: Increase plating time and costs. Reduce durability of finish.

FIGURE 35-15 Design recommendations for electroplating operations.

are lowered into successive plating, washing, and fixing tanks. Ordinarily, only one type of workpiece is plated at a time, because the details of solutions, immersion times, and current densities are usually changed with changes in workpiece size and shape.

In the *electroforming* process, the coating becomes the final product. Metal is electroplated onto a mandrel (or mold) to a desired thickness and is then stripped free to produce small quantities of molds or other intricate-shaped sheet-metal type products.

ANODIZING

Anodizing is an electrochemical process, that is somewhat the reverse of electroplating, which produces a conversion-type coating on aluminum that can improve corrosion and wear resistance and impart a variety of decorative effects. If the workpiece is made the anode of an electrolytic cell, instead of a plating layer being deposited on the surface, a reaction progresses inward, increasing the thickness of the hard hexagonal aluminum oxide crystals on the surface. The hardness depends on thickness, density, and porosity of the coating, which are controlled by the cycle time and applied currents along with the chemistry, concentration, and temperature of the electrolyte. The surface texture very nearly duplicates the prefinishing texture, so a buffing prefinish produces a smooth, lustrous coating while sand blasting produces a grainy or satiny coating.

The flow diagram in Figure 35-16 shows the anodizing process. Coating thicknesses range from 0.1 mils to 0.25 mils. Note that the product dimensions will increase, however, because the aluminum oxide coating occupies about twice the volume of the metal from which it formed.

The nature of the developed coating is controlled by the electrolyte. If the oxide coating is not soluble in the anodizing solution, it will grow until the resistance of the oxide prevents current from flowing. The resultant coating, which is thin, nonporous, and nonconducting, is used in a variety of electrical applications.

If the oxide coating is slightly soluble in the anodizing solution, dissolution competes with oxide growth and a porous coating will be produced, where the pores provide for continued current flow to the metal surface. As the coating thickens, the growth rate decreases until it achieves steady state, where the growth rate is equal to the rate of dissolution. This condition is determined by the specific conditions of the process, including voltage, current density, electrolyte concentration, and electrolyte temperature. Sulfuric, chromic, oxalic, and phosphoric acids all produce electrolytes that dissolve oxide, with a sulfuric acid solution being the most common.

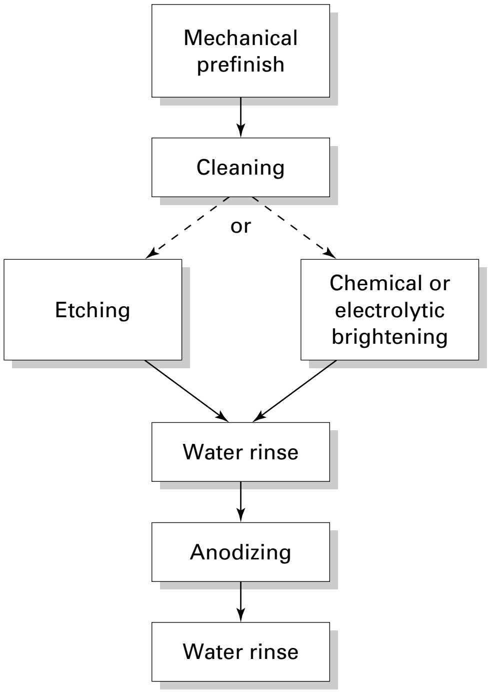


FIGURE 35-16 The anodizing process has many steps.

In a process variation known as *color anodizing,* a sulfuric acid bath is used to produce a layer of microscopically porous oxide that is transparent on pure aluminum and somewhat opaque on alloys. When this material is immersed in a dye solution, capillary action pulls the dye into the pores. The dye is then trapped in place by a sealing operation, usually performed simply by immersing the anodized metal in a bath of hot water. The aluminum oxide coating is converted to a monohydrate, with accompanying increase in volume. The pores close and become resistant to further staining or the leaching out of the dye.

While most people are familiar with the variety of colors in aluminum athletic goods, such as softball hats, the actual applications range from giftware, through automotive trim, to architectural use. Aluminum can be made to look like gold, copper, or brass, or it can take on a variety of colors with a combined metallic luster that cannot be duplicated by other methods.

If PTFE (Teflon) is introduced into the pores, coatings can be produced that couple high hardness and low friction. The porous oxide layer can also be used to enhance the adhesion of an additional layer of material, such as paint, or carry lubricant during a subsequent forming operation. Since the coating is integral to the part, subsequent operations can often be performed without destroying its integrity or reducing its protective qualities.

Anodizing can also be performed on other metals, such as magnesium, and the process is similar to the passivation of stainless steel.

ELECTROLESS PLATING

When using electroplating, it is almost impossible to obtain a uniform plating thickness on even moderately complex shapes, the platings cannot be applied to nonconductors, and a large amount of energy is required. For these reasons, a substantial effort has been directed toward the development of plating techniques that do not require an external source of electricity. These methods are known as *electroless*, or *autocatalytic, plating*. Considerable success has been achieved with nickel, but copper and cobalt, as well as some of the precious metals, can also be deposited.

In the electroless process, complex plating solutions (containing metal salts, reducing agents, complexing agents, pH adjusters, and stabilizers) are brought into contact with a substrate surface that acts as a catalyst or has been pretreated with catalytic material. The metallic ion in the plating solution is reduced to metal and deposits on the surface. Since the deposition is purely a chemical process, the coatings are uniform in thickness, independent of part geometry. Unfortunately, the rate of deposition is considerably slower than with electroplating.

Probably the most popular of the electroless coatings is electroless nickel, and various methods exist for its deposition using both acid and alkaline solutions. The coatings offer good corrosion resistance, as well as hardnesses between Rockwell C 49 and 55. In addition, the hardness can be increased further to as high as Rockwell C 80 by subsequent heat treatment.

ELECTROLESS COMPOSITE PLATING

A very useful adaptation of the electroless process has been developed wherein minute particles are co-deposited along with the electroless metal to produce composite-material coatings. Finely divided solid particles, with diameters between 1 and 10 in., are added to the plating bath and deposit up to 50 vol% with the matrix. While it may appear that a large variety of materials could be co-deposited, commercial applications have largely been limited to diamond, silicon carbide, aluminum oxide, and Teflon (PTFE).

Figure 35-17 shows a deposit of silicon carbide particles in a nickel-alloy matrix, where the particles constitute about 25% by volume. The coating offers the same corrosion resistance as nickel, but the high hardness of the silicon carbide particles (about 4500 on the Vickers scale, where tungsten carbide is 1300 and hardened steel is about 900) contributes outstanding resistance to wear and abrasion. Since the deposition is electroless, the thickness of the coating is not affected by the shape of the part. Applications include the coating of plastic-molding dies, for use where the polymer resin contains significant amounts of abrasive filler.

MECHANICAL PLATING

Mechanical plating, also known as peen plating or impact plating, is an adaptation of barrel finishing in which coatings are produced by cold-welding soft, malleable metal powder onto the substrate. Numerous small products are first cleaned and may be

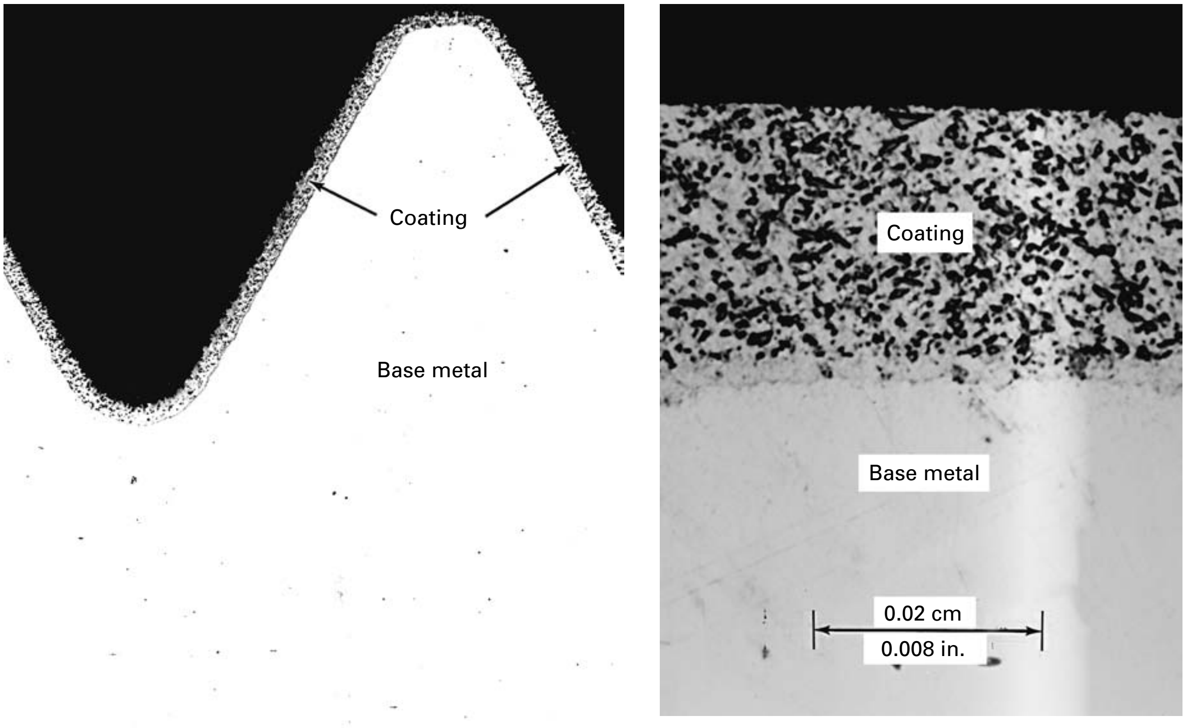

FIGURE 35-17 (Left) Photomicrograph of nickel carbide plating produced by electroless deposition. Notice the uniform thickness coating on the irregularly shaped product. (Right) High-magnification cross section through the coating. *(Courtesy of Electro-Coatings Inc.)*

given a thin galvanic coating of either copper or tin. They are then placed in a tumbling barrel, along with a water slurry of the metal powder to be plated, glass or ceramic tumbling media, and chemical promoters or accelerators. The media particles peen the metal powder onto the surface, producing uniform-thickness deposits (possibly a bit thinner on edges and thicker in recesses—the opposite of electroplating!). Any metal that can be made into fine powder can be deposited, but the best results are obtained for soft materials, such as cadmium, tin, and zinc. Since the material is deposited mechanically, the coatings can be layered or involve mixtures with bulk chemistries that would be chemically impossible due to solubility limits. The fact that the coatings are deposited at room temperature, and in an environment that does not induce hydrogen embrittlement, makes mechanical plating an attractive means of coating hardened steels.

PORCELAIN ENAMELING

Metals can also be coated with a variety of glassy, inorganic materials that impart resistance to corrosion and abrasion, decorative color, electrical insulation, or the ability to function in high-temperature environments. Multiple coats may be used, with the first or ground coat being selected to provide adhesion to the substrate and the cover coat to provide the surface characteristics. The material is usually applied in the form of a multicomponent suspension or slurry (by dipping or spraying), which is then dried and fired. An alternative dry process uses electrostatic spraying of powder and subsequent firing. During the firing operation, which may require temperatures in the range of 800° to 8000°F, the coating materials melt, flow, and resolidify. Porcelain enamel is often found on the inner, perforated tubs of many washing machines and may be used to impart the decorative exterior on cookpots and frying pans.

■ 35.5 VAPORIZED METAL COATINGS

Vapor deposition processes can be classified into two main categories: *physical vapor deposition* (PVD) and *chemical vapor deposition* (CVD). While sometimes used as though it were a specific process, the term *PVD* applies to a group of processes in which the material to be deposited is carried physically to the surface of the workpiece. Vacuum metallizing and sputtering are key PVD processes, as are complex variations, such as ion plating. All are carried out in some form of vacuum, and most are line-of-sight processes in which the target surfaces must be positioned relative to the source. In contrast, the CVD processes deposit material through chemical reactions and generally require significantly higher temperatures. Tool steels treated by CVD may have to be heat treated again, while most PVD processes can be conducted below normal tempering temperatures. See Chapter 21 for additional discussions on PVD and CVD processes.

■ 35.6 CLAD MATERIALS

Clad materials are actually a form of composite in which the components are joined as solids, using techniques such as roll bonding, explosive welding, and extrusion. The most common form is a laminate, where the surface layer provides properties such as corrosion resistance, wear resistance, electrical conductivity, thermal conductivity, or improved appearance, while the substrate layer provides strength or reduces overall cost. Alclad aluminum is a typical example. Here surface layers of weaker but more corrosion-resistant single-phase aluminum alloys are applied to a base of high-strength but less corrosion-resistant, age-hardenable material. Aluminum-clad steel meets the same objective but with a heavier substrate, and stainless steel can be used to clad steels, reducing the need for nickel- and chromium-alloy additions throughout.

Wires and rods can also be made as *claddings.* Here the surface layer often imparts conductivity, while the core provides strength or rigidity. Copper-clad steel rods that can be driven into the ground to provide electrical grounding for lightning rod systems are one example.

■ 35.7 TEXTURED SURFACES

While technically not the result of a surface finishing process or operation, *textured surfaces* can be used to impart a number of desirable properties or characteristics. The types of textures that are often rolled onto the sheets used for refrigerator panels serve to conceal dirt, smudges, and fingerprints. Embossed or coined protrusions can enhance the grip of metal stair treads and walkways. Corrugations provide enhanced strength and rigidity. Still other textures can be used to modify the optical or acoustical characteristics of a material.

■ 35.8 COIL-COATED SHEETS

Traditionally, sheet metal components, such as panels for appliance cabinets, have been fabricated from bare-metal sheets. Pans are blanked and shaped by the traditional metalforming operations, and the shaped panels are then finished on an individual basis. This requires individual handling and the painting or plating of geometries that contain holes, bends, and contours. In addition, there is the time required to harden, dry, or cure the applied surface finish.

An alternative approach is to apply the finish to the sheet material after rolling but before coiling. *Coatings* can be applied continuously to one or both sides of the material while it is in the form of a flat sheet. Thus the coiled material is effectively prefinished, and efforts need to be taken to protect the surface during the blanking and forming operations used to produce the final shape. Various paints have been applied successfully, as well as a full spectrum of metal coatings and platings. The sheared edges will not be coated, but if this feature can be tolerated, the additional measures to protect the surface may be an attractive alternative to the finishing of individual components. A second sequence that has some advantages takes the coils of steel that have been cut to length and stamps the holes and notches into them to create blanks. The blanks are pretreated, dried, powder coated, cured, and restacked. Then they are postformed to shape them into the back, side, and front panels of appliance cabinets.

The manufacturers call this *blank coating*. The coating thickness is about 1.5 mils ± 0.2 mil versus 2 mils ± 0.5 mil (less powder, better quality), and rusting at the corners of the holes is eliminated.

■ 35.9 EDGE FINISHING AND BURRS

Burrs are the small, sometimes flexible projections of material that adhere to the edges of workpieces that are formed by cutting, punching, or grinding, like the exit-side burrs formed in the milled slot of Figure 35-18. Dimensionally, they are typically only 0.003 in. thick and 0.001 to 0.005 in. in height, but if not removed, they can lead to assembly failures, short circuits, injuries to workers, or even fatigue failures.

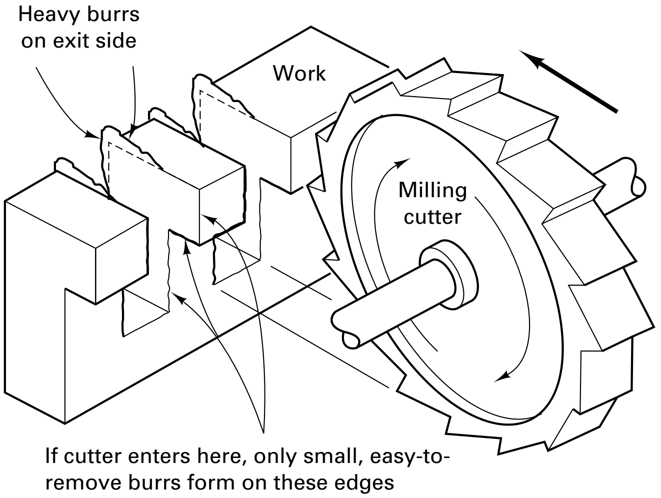

FIGURE 35-18 Schematic showing the formation of heavy burrs on the exit side of a milled slot. *(From L. X. Gillespie,* American Machinist, *November 1985.)*

The most basic way to detect a burr is to run your finger or fingernail over the edges of the part. Probes and visual inspection techniques (microscopes) are used to find burrs as well.

A number of different processes have been used for *burr removal,* including some discussed previously in this chapter and others presented as special types of machining. These include grinding, chamfering, barrel tumbling, vibratory finishing, centrifugal and spindle finishing, abrasive jet machining, water jet cutting, wire brushing, belt sanding, chemical machining, electropolishing, buffing, electrochemical machining, filing, ultrasonic machining, and abrasive flow machining (see Chapter 26).

Other burr removal methods may be quite specialized, such as thermal-energy deburring. Here the parts are loaded into a chamber, which is then filled with a combustible gas mixture. When the gas is ignited, the short-duration wavefront heats the small burrs to as much as 6000°F, while the remainder of the workpiece rarely exceeds 300°F. The burrs are vaporized in less than 20 ms, including those in inaccessible or difficult-to-

TABLE 35-5 Recommended Allowances for Deburring Processes[a]

Process	Edge Radius, mm (in.)	Stock Loss, mm (in.)	Surface Finish, μmAA (μin.AA[b])
Barrel tumbling	0.08–0.5 (0.003–0.020)	0.0025 (0–0.001)	1.5–0.5 (60–20)
Vibratory deburring	0.08–0.5 (0.003–0.020)	0–0.025 (0–0.001)	1.8–0.9 (70–35)
Centrifugal barrel tumbling	0.08–0.5 (0.003–0.020)	0–0.025 (0–0.001)	1.8–0.5 (70–20)
Spindle finishing	0.08–0.5 (0.003–0.020)	0–0.025 (0–0.001)	1.8–0.5 (70–20)
Abrasive-jet deburring	0.08–0.25 (0.003–0.010)	0–0.05 (0–0.002)[c]	0.8–1.3 (30–50)
Water-jet deburring	0–0.13 (0–0.005)(p)	0(p)	
Liquid hone deburring	0–0.13 (0–0.005)	0–0.013 (0–0.0005)	
Abrasive-flow deburring	0.025–0.5 (0.001–0.020)	0.025–0.13 (0.001–0.005)[d]	1.8–0.5 (70–20)
Chemical deburring	0–0.5 (0–0.002)	0–0.025 (0–0.001)	1.3–0.5 (50–20)
Ultrasonic deburring	0–0.05 (0–0.002)	0–0.025 (0–0.001)	0.5–0.4 (20–15)
Electrochemical deburring	0.05–0.25 (0.002–0.010)	0.025–0.08 (0.001–0.003)[e]	
Electropolish deburring	0–0.25 (0–0.010)	0.025–0.08 (0.001–0.003)[e]	0.8–0.4 (30–15)
Thermal-energy deburring	0.05–0.5 (0.002–0.020)	0	1.5–1.3(p) (60–50)
Power brushing	0.08–0.5 (0.003–0.020)	0–0.013 (0–0.0005)	
Power sanding	0.08–0.8 (0.003–0.030)[f]	0.013–0.08 (0.0005–0.003)	1.0–08 (40–30)
Mechanical deburring	0.08–1.5 (0.003–0.060)		
Manual deburring	0.05–0.4 (0.002–0.015)[g]		

[a] Based on a burr 0.08 mm (0.003 in.) thick and 0.13 mm (0.005 in.) high in steel. Thinner burrs can generally be removed much more rapidly. Values shown are typical. Stock-loss values are for overall thickness or diameter. Location A implies that loss occurs over external surfaces, B that loss occurs over all surfaces, and C that loss occurs only near edge. (p) indicates best estimate.

[b] Values shown indicate typical before and after measurements in a deburring cycle.

[c] Abrasive is assumed to contact all surfaces.

[d] Stock loss occurs only at surfaces over which medium flows.

[e] Some additional stray etching occurs on some surfaces.

[f] Flat sanding produces a small burr and no radius.

[g] Chamfer is generally produced with a small burr.

Source: L. X. Gillespie, *American Machinist,* November 1985.

reach locations. Since the process does not use abrasive media, there is no change to any of the product dimensions. The product surfaces are rarely affected by the generated heat, and the cycle (including loading and unloading) can be repeated as many as 100 times an hour. Unfortunately, there is a thin recast layer and heat-affected zone that forms where the burrs were removed. This region is usually less than 0.001 in. thick but may be objectionable in hardened steels and highly stressed parts.

Of all of the burr removal methods, tumbling and vibratory finishing are usually the most economical, typically costing in the neighborhood of a few cents per part. Since most of the common methods also remove metal from exposed surfaces and produce a radius on all edges, it is important that the parts be designed for deburring. Table 35-5 provides a listing of the various deburring processes, as well as the edge radius, stock loss, and surface finish that would result from removal of a "typical burr" of 0.003 in. thickness.

DESIGN TO FACILITATE OR ELIMINATE BURR REMOVAL

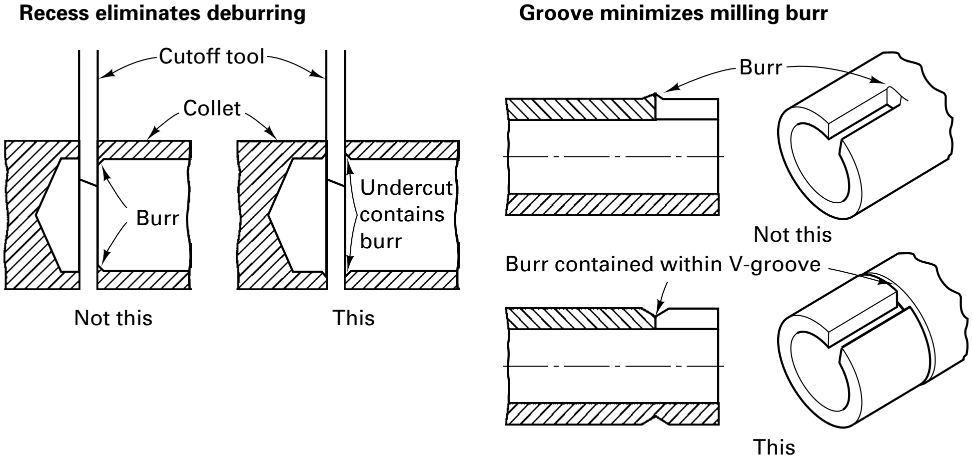
By knowing how and where burrs are likely to *form*, the engineer may be able to design parts to make the burrs easy to remove or even eliminate them. As shown in Figure 35-19, extra recesses or grooves can eliminate the need for deburring, since the burr produced by a cutoff tool or slot milling cutter will now lie below the surface. In this approach, one must determine whether it is cheaper to perform another machining operation (*undercutting* or grooving) or to remove the resulting burr.

Chamfers on sharp corners can also eliminate the need to deburr. The chamfering tool removes the large burrs formed by facing, turning, or boring and produces a relief for mating parts. The small burr formed during chamfering may be allowable or can easily be removed. Often, it may be preferable to give the manufacturer the freedom to use either a chamfer (produced by machining) or an edge radius (formed during the deburring operation) on all exposed corners or edges.

35.10 SURFACE INTEGRITY

Surface integrity has become the subject of intense interest because the traditional, nontraditional, and posttreatment methods used to manufacture hardware can change the material's properties. Although the consequence of these changes becomes a design problem, the preservation of properties is a manufacturing consideration. Designs that require a high degree of surface integrity are the ones that display the following qualities:

- Are highly stressed
- Employ low safety factors
- Operate in severe environments
- Must have prime reliability
- Have a high surface areas–to–volume ratio
- Are made with alloys that are sensitive to processing



Recess eliminates deburring

Groove minimizes milling burr

FIGURE 35-19 Designing extra recesses and grooves into a part may eliminate the need to deburr. *(From L.X. Gillespie,* American Machinist, *November 1985.)*

Surface integrity should be a joint concern of manufacturing and engineering. Manufacturing must balance cost and producibility with design requirements. It bears repeating to say that engineering must design components with knowledge of manufacturing processes. A reduction in fatigue life resulting from processing can be reversed with a posttreatment. This is another example of design for manufacturing.

It is important to understand that the various manufacturing and surface-finishing processes each impart distinct properties to the materials that will influence the performance of the product. The achievement of satisfactory product performance obviously depends on a good design, high-quality manufacturing (including surface treatment), and proper assembly. The failure of parts in service, however, is usually the result of a combination of factors. A brief survey of features associated with surfaces and surface processing follows.

Each of the various machining processes produces characteristic surface textures (roughness, waviness, and lay) on the workpieces. In addition, the various processes tend to produce changes in the chemical, physical, mechanical, and metallurgical properties on or near the surfaces that are created. For the most part, these changes are limited to a depth of 0.005 to 0.050 in. below the surface. The effects can be beneficial or detrimental, depending on the process, material, and function of the product.

Machining processes (both chip forming and chipless) induce plastic deformation into the surface layer, as shown in Figure 35-20. The cut surfaces are generally left with tensile residual stresses, microcracks, and a hardness that is different from the bulk material. Processes such as EDM and laser machining leave a layer of hard, recast metal on the surface that usually contains microcracks. Ground surfaces can have either residual tension or residual compression, depending on the mix between chip formation and plowing or rubbing during the grinding operation. If sufficient heat is generated, phase transformations can occur in the surface and subsurface regions.

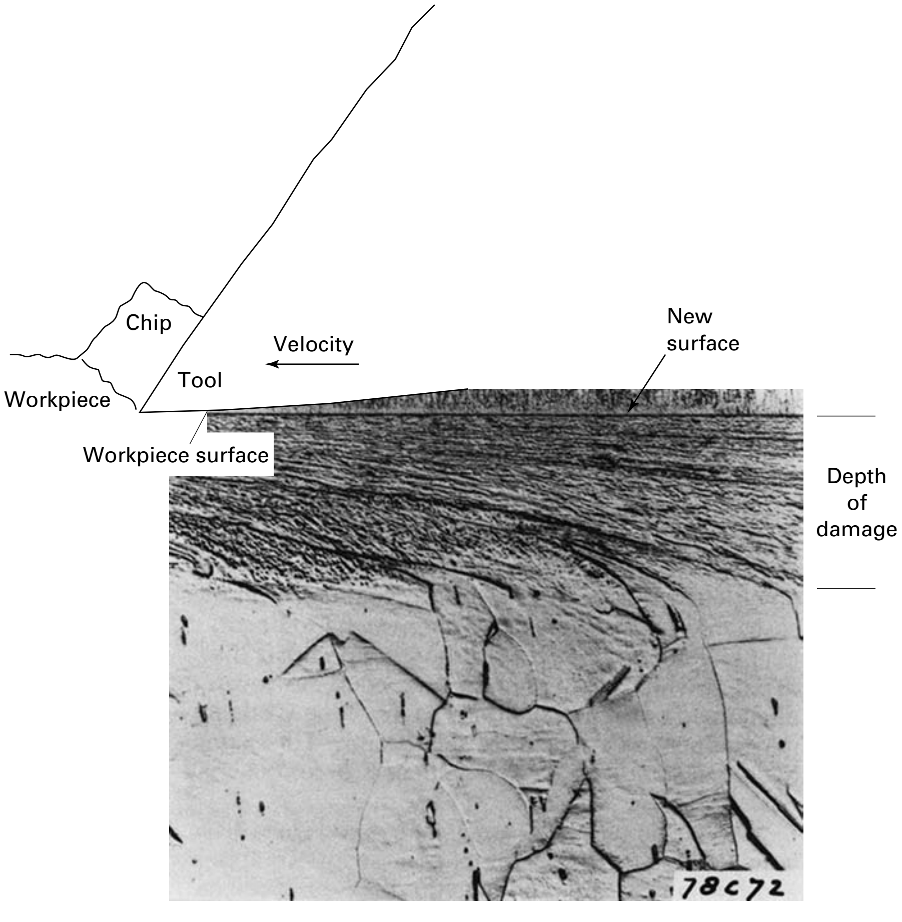


FIGURE 35-20 Plastic deformation in the surface layer after cutting. *(B. W. Kruszynski and C. W. Cuttervelt,* Advanced Manufacturing Engineering, *Vol. 1, 1989.)*

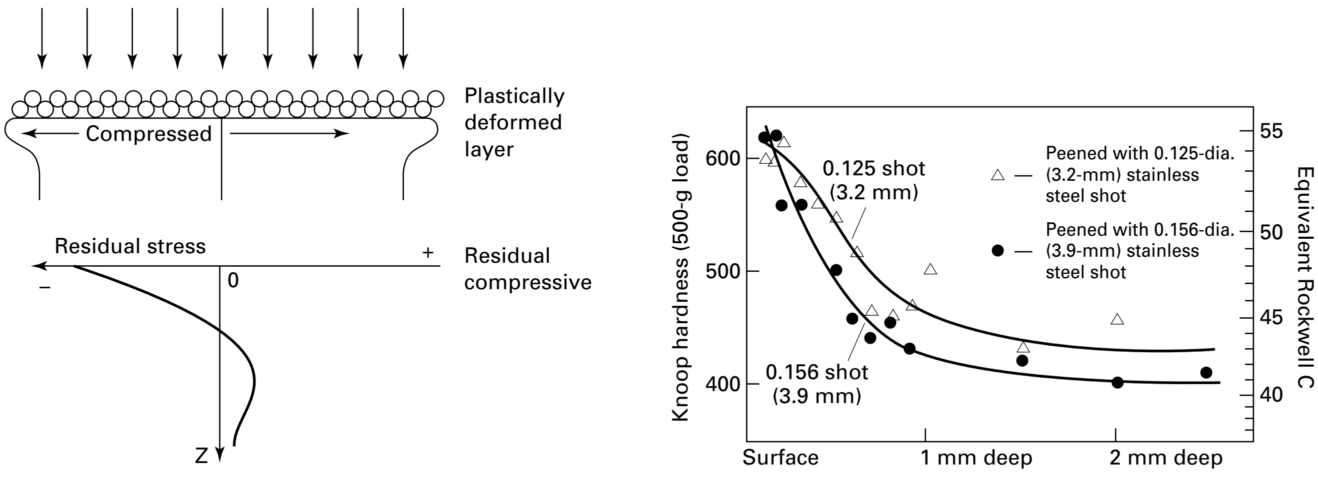

(a) (b)

FIGURE 35-21 (a) Mechanism for formation of residual compressive stresses in surface by cold plastic deformation (shot peening). (b) Hardness increased in surface due to shot peening.

Processes such as *roller burnishing* (described in Chapter 18) produce a smooth surface with compressive residual stresses. Shot peening (and tumbling) can increase the hardness in the surface and introduce a residual compressive stress, as shown in Figure 35-21a and 35-21b. Welding processes produce tensile residual stresses as the deposited material shrinks upon cooling. Similar shrinkage occurs in castings, but the resulting stresses may be complex due to the variation of shrinkage or the lack of restraint. Tensile stresses on the surface can often be offset by a subsequent exposure to shot peening or tumbling.

In summary, the surface and subsurface regions of a material can be significantly altered due to (1) plastic strain or plastic deformation, (2) high temperatures, (3) differential expansions or contractions due to temperature changes or variations, and (4) chemical reactions.

To illustrate the complex nature of surface effects, consider Figure 35-22, which shows the depth of "surface damage" due to machining as a function of the rake angle of the tool. To increase the cutting speed (and thereby increase the rate of production), an engineer might change from a high-speed tool steel cutter with a large rake angle (such as 30°) to a carbide tool with a zero rake. While the resulting surface finish may be similar, the depth of "surface damage" is doubled. Failures may occur in service, whereas previous parts had performed quite admirably.

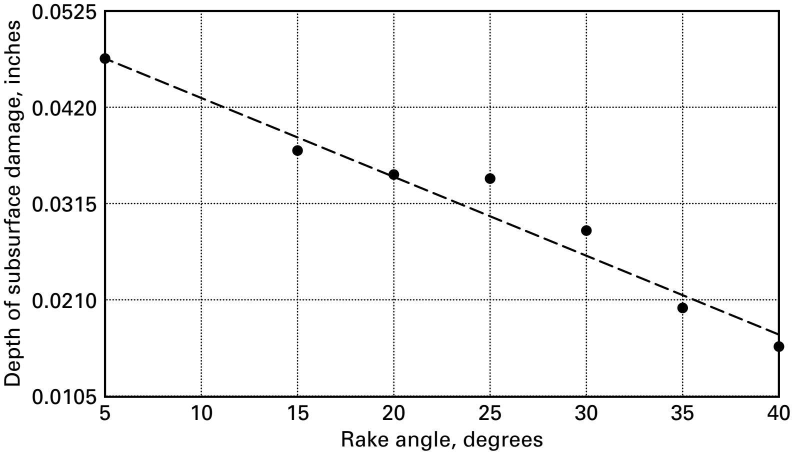

FIGURE 35-22 The depth of damage to the surface of a machined part increases with decreasing rake angle of the cutting tool.

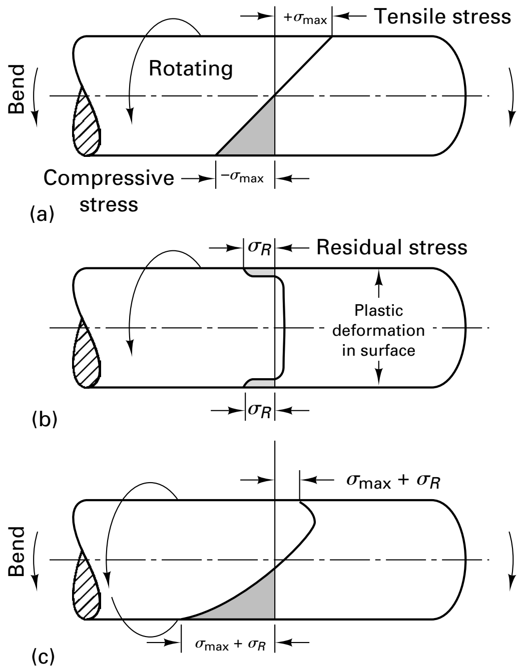

Rotating beam with bending results in cycles of tension and compression

Beam given roller burnish or shot peen to cold work surface and develop a residual compressive stress

Beam in service with reduced peak tensile stresses due to additive nature of applied and residual stresses

FIGURE 35-23 *(Top)* A cantilever-loaded (bent) rotating beam, showing the normal distribution of surface stresses (i.e., tension at the top and compression at the bottom). *(Center)* The residual stresses induced by roller burnishing or shot peening. *(Bottom)* Net stress pattern obtained when loading a surface-treated beam. The reduced magnitude of the tensile stresses contributes to increased fatigue life.

INFLUENCE OF SURFACE FINISH ON FATIGUE

Fatigue failure occurs as the result of repeated loading at some point typically below the yield strength of the material. Fatigue failures have been shown to almost always nucleate on or near the surface of a component. Fine surface cracks begin at discontinuities (such as microcracks, grooves, ridges, cavities, machining marks, imbedded particles, etc.) at the surface, and the cracks propagate with repeated cyclic loads.

Tensile residual stresses in the altered surface layer have an additive effect on the applied stresses in the component. This means that tensile residual stresses in the material add to external stresses to the component, reducing its fatigue strength. Alternatively, as shown in Figure 35-23, compressive residual stresses subtract from tensile external stresses, and since tensile stresses are those ultimately responsible for fatigue failure, the fatigue strength of the material is increased.

Figure 35-23 shows how residual stresses couple with applied stresses to affect product performance. Suppose that a round beam has a load applied to it so that it is bent while rotating. At the top of the rotation, the surface is in tension, and at the bottom, it is in compression. The result is a condition of cyclic fatigue and the likelihood of a service life limited by fatigue failure. If the part is roller burnished or shot peened, the compressive residual stress pattern of the middle figure is added to the applied stresses, producing the net pattern shown at the bottom. The net effect is a lowering of the peak tensile stress experienced by the surface and a related extension in fatigue life. The specific results will depend on the details of the process. For *shot peening*, the key variables include shot size, shot velocity, exposure time, distance between the nozzle and the surface, and the angle of impact.

Figure 35-24 presents the results of a study in which specimens were prepared by milling and turning and then either polished, shot peened, or roller burnished. If an applied stress between 41,000 and 42,000 psi is experienced in a fatigue application, the difference in fatigue life between a milled specimen and one that has been milled and roller burnished is 610,000 cycles (90,000 cycles as opposed to 700,000 cycles). In essence, roller burnishing serves to induce a sevenfold extension to the fatigue life of the product. Similar results have been observed in the resistance to stress–corrosion cracking.

As the data above show, both the designer and the manufacturer need to be aware of the effects that manufacturing processes can have on the performance of a product. Maintaining the proper sequence of operations may be as important to the surface properties as the selection of the processes and control of the operating parameters.

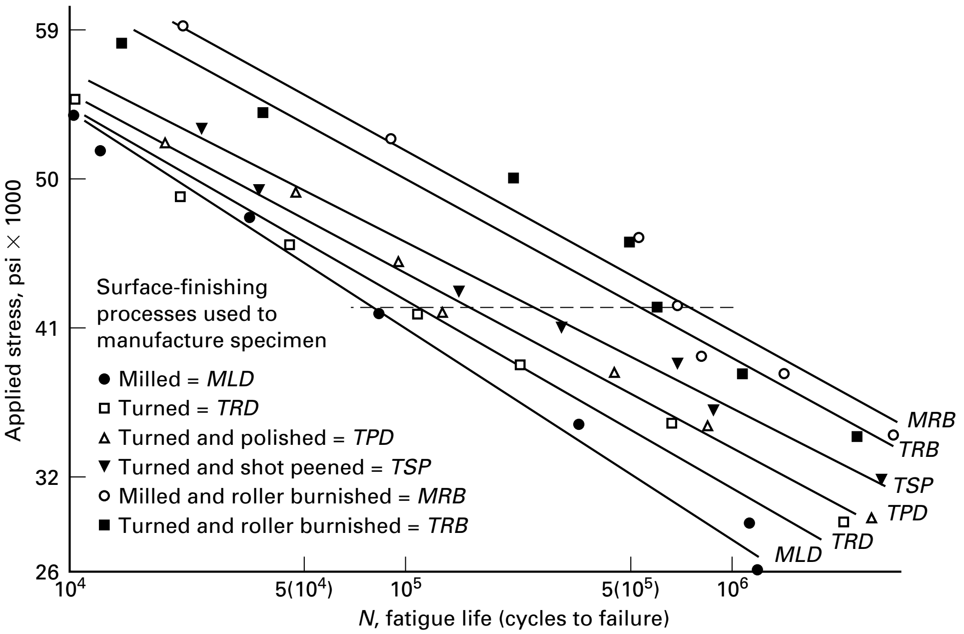

FIGURE 35-24 Fatigue life of rotating beam 2024-T4 aluminum specimens with a variety of surface-finishing operations. Note the enhanced performance that can be achieved by shot peening and roller burnishing.

Review Questions

1. What are some possible objectives of surface engineering processes?
2. What are some of the factors that should be considered when selecting a surface-modification process?
3. How are the surface and its integrity altered by the process of metalcutting?
4. Two surfaces can have the same microinch roughness but be different in appearance. Explain!
5. What limits the resolution of a stylus-type surface-measuring device in finding profiles?
6. What is the general relationship between surface roughness and tolerance? Between tolerance and cost to produce the surface and/or tolerance?
7. What are some of the sources of foreign material on the surface of manufactured products?
8. What are some the common abrasive media used in blasting or abrasive cleaning operations?
9. What types of quantities and part sizes are most attractive for barrel finishing operations?
10. Describe why there might be an optimum fill level in barrel finishing. How might you find the optimum rotational speed?
11. Describe the primary differences between barrel finishing and vibratory finishing.
12. What are some of the possible functions of the compounds that are used in abrasive finishing operations?
13. How is electropolishing different from electroplating?
14. What are some of the mechanisms of alkaline cleaning, and what types of soils can be removed?
15. What types of surface contaminants cannot be removed by solvent cleaning?
16. In view of its many attractive features, why has vapor degreasing become an unattractive process?
17. What is the primary type of surface contaminant removed by acid pickling?

18. What is the difference between coating and cladding operations?
19. What are some of the reasons that paints may be specified for manufactured items?
20. What are some of the functions of a prime coat in a painting operation? What features are desired in the final coat?
21. What produces atomization and propulsion in airless spraying?
22. What features make industrial robots attractive for spray painting?
23. What are some of the attractive features of electrostatic spraying?
24. Why would it be difficult to apply electrostatic spray painting to products made from wood or plastic?
25. What are some of the metal coatings that can be applied by the hot-dip process?
26. What are the two most common types of chemical conversion coatings?
27. How can nonconductive materials such as plastic be coated by electroplating?
28. What are the attractive properties of hard chrome plate?
29. What are some of the common process variables in an electroplating cell?
30. Why is it difficult to mix parts of differing size and shape in an automated electroplating system?
31. How is electroforming different from electroplating?
32. When anodizing aluminum, what features determine the thickness of the resulting oxide when the oxide is not soluble in the electrolyte? When it is partially soluble?
33. What produces the various colors in the color anodizing process?
34. What are some of the attractive features of electroless plating?
35. What types of particulate composites can be deposited by electroless plating?
36. What is mechanical plating?
37. What are some of the attractive properties of a porcelain enamel coating?
38. How are burrs made by the milling process? See Figure 35-18.
39. What deburring processes are available that were not described in this chapter?
40. Do all machining processes leave a residual stress?
41. Why would the depth of damage (i.e., plastic deformation) increase with negative rake angle cutting tools?
42. What types of surface features or surface modifications result from machining-type processes?
43. Why might processes that produce residual compressive stresses on product surfaces be attractive for mechanically loaded products?

■ Problems

1. Fishermen are among the most superstitious people in the world, and their superstitions affect the type of equipment that they use. As a result, hook manufacturers generally offer their products in a wide range of colors and finishes. Your company manufactures a range of hooks from AISI 1080 carbon steel wire, forming them to precision shape (eye, bends, barbs, and point) and then heat treating them by a quench-and-temper treatment.

   Consider the size and shape of the product and the various properties that are required. The hooks must be strong enough to resist bending, but not so brittle that they might break. They must be corrosion-resistant to both fresh and salt water, and the desired appearance must be provided without fouling the point or the barbs. If the surface is applied before heat treatment, it must endure that process and maintain its appearance. If it is applied afterward, it cannot weaken or embrittle the hook.

   a. Of the various surface-modification processes, which ones might be attractive for such an application? (*Note:* Make sure that the process is appropriate! For example, barrel plating would probably produce a hopelessly snarled mass of wires!)
   b. For each of the possible processes, describe the advantages, limitations, possible colors or finishes, and relative cost.

2. Select one or more of the following products (as directed) and recommend a surface treatment or coating. Consider the appropriateness of the technique to the size, shape, quantity, and material. Cite the specific features that make the recommended treatment the most attractive. What, if any, are the primary limitations or production concerns?

   a. The exterior housing for the motor and drive unit of a chain saw that has been made as a magnesium-alloy die casting.
   b. Large quantities of steel bolts that are intended for use in outdoor construction. They have been fabricated from 4140 steel, have a shank diameter of $^1/_2$ in., and have been quenched and tempered to a final hardness of Rockwell C 45.
   c. The handle of a household utility knife (retractable-blade cutter) has been made as a two-part zinc die casting.
   d. The scoop portion of an inexpensive ice cream scoop that has been made as a zinc die casting.
   e. A decorative handle for a kitchen cabinet that is made as a zinc die casting.
   f. The exterior of an office filing cabinet that has been made from low-carbon steel sheet.
   g. A high-quality combination wrench (open-end and box-end) that has been forged from 4147 steel bar stock.
   h. The case of a moderately priced wristwatch that has been fabricated from yellow brass (to have a gold appearance).
   i. Tubular frame of a lightweight bicycle that has been made from age-hardened aluminum.
   j. The basket section of a grocery-store shopping cart that has been fabricated from welded steel mesh.
   k. The exterior of an automobile muffler to be fabricated from steel sheet. Describe how the coating treatment might best be integrated into the fabrication sequence.
   l. An inexpensive interior door knob that has been fabricated from deep-drawn cartridge brass sheet.
   m. High-quality steel sockets for a socket-wrench set. These have been forged from AISI 4145 bar stock and subsequently heat treated by a quench-and-temper process.
   n. Refrigerator door panels that have been fabricated from textured AISI 1010 steel sheet.
   o. The interior and exterior surfaces of a 1000-gallon water storage tank that is fabricated by welding 5000 series

aluminum plates. The water will be held at room temperature and is intended for human consumption.

p. A standard office paper clip.
q. A flashlight case that has been fabricated from deep-drawn yellow brass sheet.
r. High-speed drill bits that have been fabricated from Ml tool steel.
s. Injection-molded ABS plastic wheel covers for cars that are intended to look like chrome-plated metal.
t. Inexpensive household scissors that have been cast from gray cast iron.
u. The blade of a high-quality screwdriver that has been forged from AISI 1053 steel and quenched and tempered to Rockwell C 55.
v. The exterior of high-quality, thick-walled cast aluminum cookware.
w. A bathroom sink basin made from deep-drawn 1008 steel sheet.
x. The body section of a child's toy wagon that has been deep-drawn from 1008 steel sheet.

Chapter 35 CASE STUDY

Dana Lynn's Fatigue Lesson

Dana Lynn has just come from her INSY 3000 lab in the manufacturing processes course.

The purpose of this lab was to introduce her to metal fatigue and its basic principles. Metal fatigue arises from the cyclic loading below the yield strength. It can be greatly influenced by the surface finish applied to the metal. Dr. Payton, her instructor, said fatigue most likely accounts for 90% of all mechanical failures, so it is important for an engineer to understand how materials respond to fatigue conditions.

The procedure of this lab was for each student to finish the aluminum specimen with the emery paper, then load the specimen into the fatigue machine (see Figure CS.35A). Students were required to record the number of cycles that was needed to fracture the specimen. It was important that the student wipe the specimen clean and inspect the specimen for burrs, ridges, or flats before inserting it into the drive spindle. The presence of stress raisers can decrease the cumulative number of cycles needed to start a fatigue crack and cause it to fail, hence reducing the fatigue life and static strength of the metal. Small surface cracks, surface flows, or machining marks are examples of stress raisers. Therefore, it is important that one strive to eliminate stress raiser or surface flaws in the specimen that will be exposed to cyclic loadings. The experimental factors for this experiment were the surface finish (grit size of energy paper), applied stress level, and the direction of the surface finish (parallel or perpendicular to the specimen axis). Dr. Payton explained that repeated applications of stress can cause metals to fracture, even if all of the stresses are less than the yield tensile strength and less than the ultimate strength of the material. Surface conditions can heavily influence fatigue life because most fatigue cracks start at the surface of a metal. The fatigue data in Table CS 35A is to be analyzed using statistical experimental design techniques and summarized in the ANOVA table. Factor A was the applied load (50 and 55 lbs), factor B was the treatment (fine and coarse emery paper), and factor C was the surface finish direction (horizontal and vertical). The experiment was replicated so a total of 16 tests were run by the class ($2 \times 2 \times 2 \times 2$). The specimen was tapered so that the stress acting along the test section (shaded) is constant. To make the specimen, you have to calculate θ and the diameter d (see Figure CS.35B).

Here are some of the questions that Dana Lynn had to answer.

1. Analyze the fatigue data collected by the class using statistical experiment (factorial experiment) design techniques. Include all calculations and summarize your results in an analysis of variance (ANOVA) table.
2. What are the effects of stress level, surface finish (grit size in our experiment) and surface finish direction. Are there any interactions between them on fatigue life? Discuss.
3. What effect would abrupt surface changes, such as tool marks or surface flaws, have on fatigue life?
4. The cylindrical specimen is designed such that the applied stress acting along the test section is constant. Why?
5. What is the endurance limit for a metal? Why is the endurance limit an important criteria in many design applications? Does aluminum have an EL?

CHAPTER 36

QUALITY ENGINEERING

36.1 INTRODUCTION

All manufacturing processes display some level of variation. No two items coming from the process will be exactly the same. The primary objective of quality engineering is the systematic reduction of variability, as shown schematically in Figure 36-1. Variability is measured by sigma, σ, the standard deviation, which decreases with the reduction in variability. Early on, acceptance sampling techniques were used to screen incoming goods. This was followed by statistical process control (SPC) efforts, which gave way to companywide quality control (CWQC) and Total Quality Control (TQC) programs. Variation can be further reduced by the application of statistical techniques, like multiple variable analysis, designed experiments, and Taguchi methods, techniques that are a routine part of six sigma efforts many companies are implementing. The drive toward zero defects has been led by Toyota, which achieved exceptional levels of quality by redesigning the manufacturing system so that each step in the making of the car and all

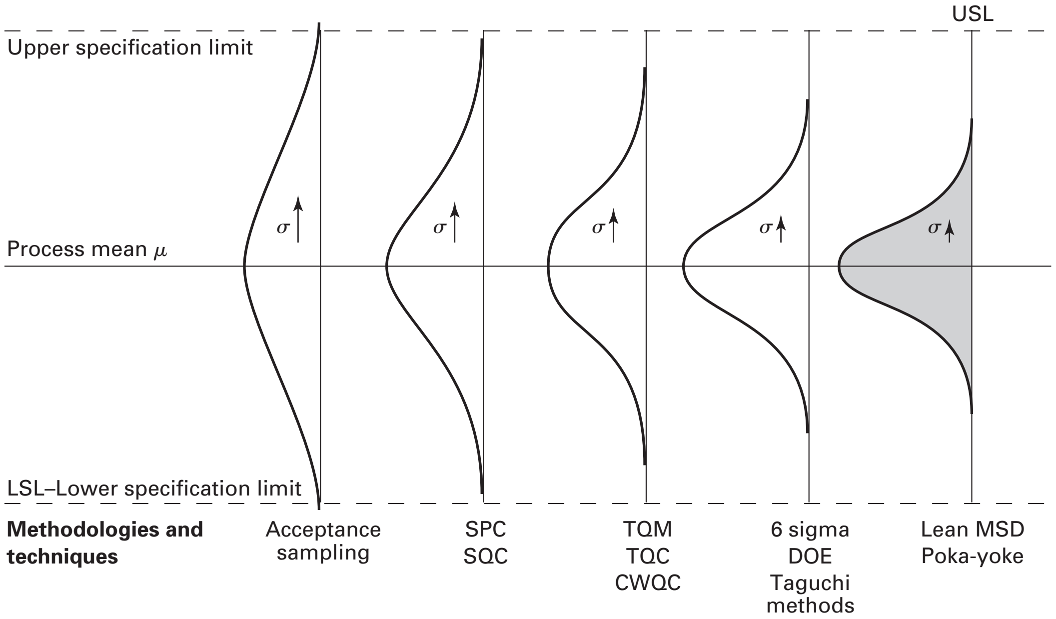

FIGURE 36-1 Over many years, many techniques have been used to reduce the variability in products and processes.

its components is checked before the part moves to the next step or stage in its manufacturing sequence. This system redesign is called lean manufacturing.

In a manufacturing process, the variation may be due to "chance causes" that produce random variations—these causes are said to be inherent and represent a stable source of variation. In addition, there are "assignable causes" of variation that can be detected and eliminated to help improve the process. For example, suppose that we view shooting at a metal target as a "process" for putting holes in a piece of metal. I hand you the gun and tell you to take nine shots at the bull's-eye. Figure 36-2 shows some possible results. You are the operator of the process. To measure the *process capability* (PC)—that is, your ability to consistently hit the bull's-eye you are aiming at—the target is inspected after you have finished shooting. So the capability of manufacturing processes is determined by measuring the output of the process. In *quality control* (QC), the product is examined to determine whether or not the processing accomplished was what was specified by the designer in the design, usually the nominal size and the tolerance. Of course, there are many other aspects of quality that quality engineers must address, such as performance, reliability, durability, aesthetics, and more. In this chapter, we will concentrate on the quality of conformance, meaning how well the product conforms to the specifications. And within that area, we will concentrate on PC studies that are directed at the machine tools used in the processing rather than the quality of the output or products from the processes. Going back to our example, a PC study would quantify the inherent accuracy and precision in the shooting process. Accuracy is reflected in your aim (the average of all your shots), whereas precision reflects the repeatability of the process. The objective is to root out problems that can cause defective products during production. Traditionally, the objective has been to find defects in the process. The more progressive point of view is to design the process to prevent the problems that can cause defective products from occurring during production.

36.2 DETERMINING PROCESS CAPABILITY

The *nature of the process* refers to both the *variability* (or inherent uniformity) and the *accuracy* or the *aim* of the process. Thus in the target-shooting example, a perfect process would be capable of placing nine shots right in the middle of the bull's-eye, one right on

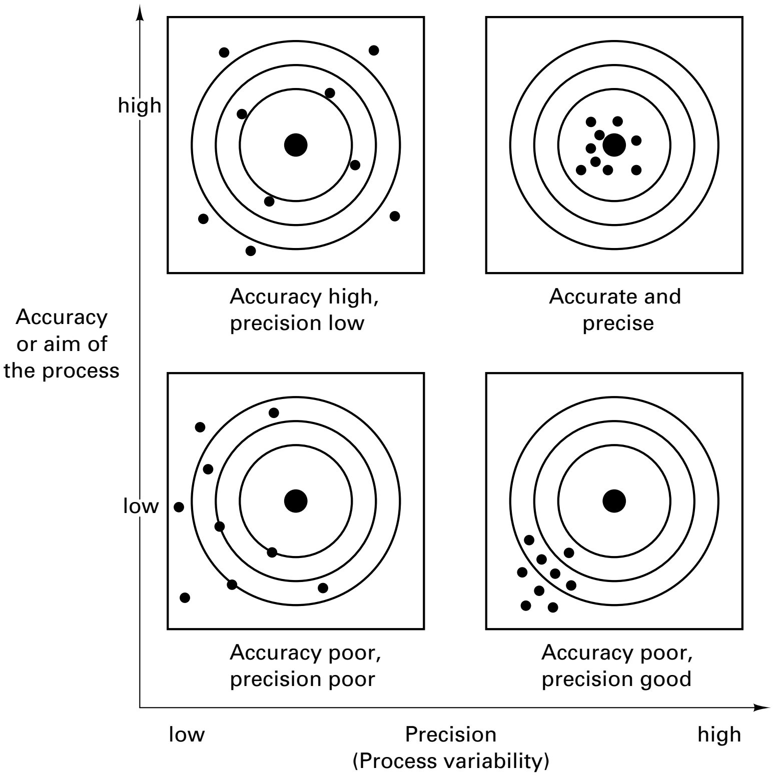

FIGURE 36-2 The concepts of accuracy (aim) and precision (repeatability) are shown in the four target outcomes. Accuracy refers to the ability of the process to hit the true value (nominal) on the average, while precision is a measure of the inherent variability of the process.

top of the other. The process would display no variability with perfect *accuracy*. Such performance would be very unusual in a real industrial process. The variability may have assignable causes and may be correctable if the cause can be found and eliminated. That variability to which no cause can be assigned and which cannot be eliminated is said to be inherent in the process and is therefore its nature.

Some examples of assignable causes of variation in processes include multiple machines for the same components, operator blunders, defective materials, or progressive wear in the tools during machining. Sources of inherent variability in the process include variation in material properties, operator variability, vibrations and chatter, and the wear of the sliding components in the machine, perhaps resulting in poorer operation of the machine. These kinds of variations, which occur naturally in processes, usually display a random nature and often cannot be eliminated. In quality control terms, these are referred to as *chance causes*. Sometimes the causes of assignable variation cannot be eliminated because of cost. Almost every process has multiple causes of variability occurring simultaneously, so it is extremely difficult to separate the effects of the different sources of variability during the analysis.

MAKING PC STUDIES BY THE TRADITIONAL METHODS

The object of the PC study is to determine the inherent nature of the process as compared to the desired specifications. The output of the process must be examined under normal conditions, or what is typically called *hands-off conditions*. The inputs (e.g., materials, setups, cycle times, temperature, pressure, and operator) are fixed or standardized. The process is allowed to run without tinkering or adjusting, while the output (i.e., the product or units or components) is documented with respect to (1) time, (2) source, and (3) order of production. A sufficient number of data have to be taken to ensure confidence in the statistical analysis of the data. The capability of the gage (its precision) used to measure the products must exceed the expected tolerance on the part by one order of magnitude. (See the discussion of the rule of 10 in Chapter 10.)

Prior to any data collection, these steps must be taken:

1. Design the PC experiment (standard method). Use normal or hands-off process conditions; specify machine settings for speed, feed, volume, pressure, material, temperature, operator, and so on.
2. Define the inspection method and the inspection means (the procedure and the instrumentation). In selecting the gage, consider these aspects:
   - **a.** Features that the gage will be checking
   - **b.** Speed or rate of operation
   - **c.** Level of accuracy and precision
   - **d.** Skill of the operator
   - **e.** Portability of gages or part, or both
   - **f.** Environment (clean and stable, cutting fluids)
   - **g.** Workpiece (clean, lubricants present)
   - **h.** Cost (initial, maintenance, daily)
3. Decide how many items (measurements) will be needed to perform the statistical analysis.
4. For a standard PC study, use homogeneous input material, and try to contrast it with normal (more variable) input material.
5. Data sheets must be designed to record date, time, source, order of production, and all the process parameters being used (or measured) while the data are being gathered.
6. Assuming that the standard PC study approach is being used, the process is run, and the parts are made and measured.

Now follow the steps outlined in Figure 36-3. Assume that the designer specified the part to be 1.000 ± 0.005 in. After manufacturing engineering has developed a process plan, some units are manufactured according to the process plan without any adjustment of the process. Each unit is measured, and the data are recorded on the data sheet.

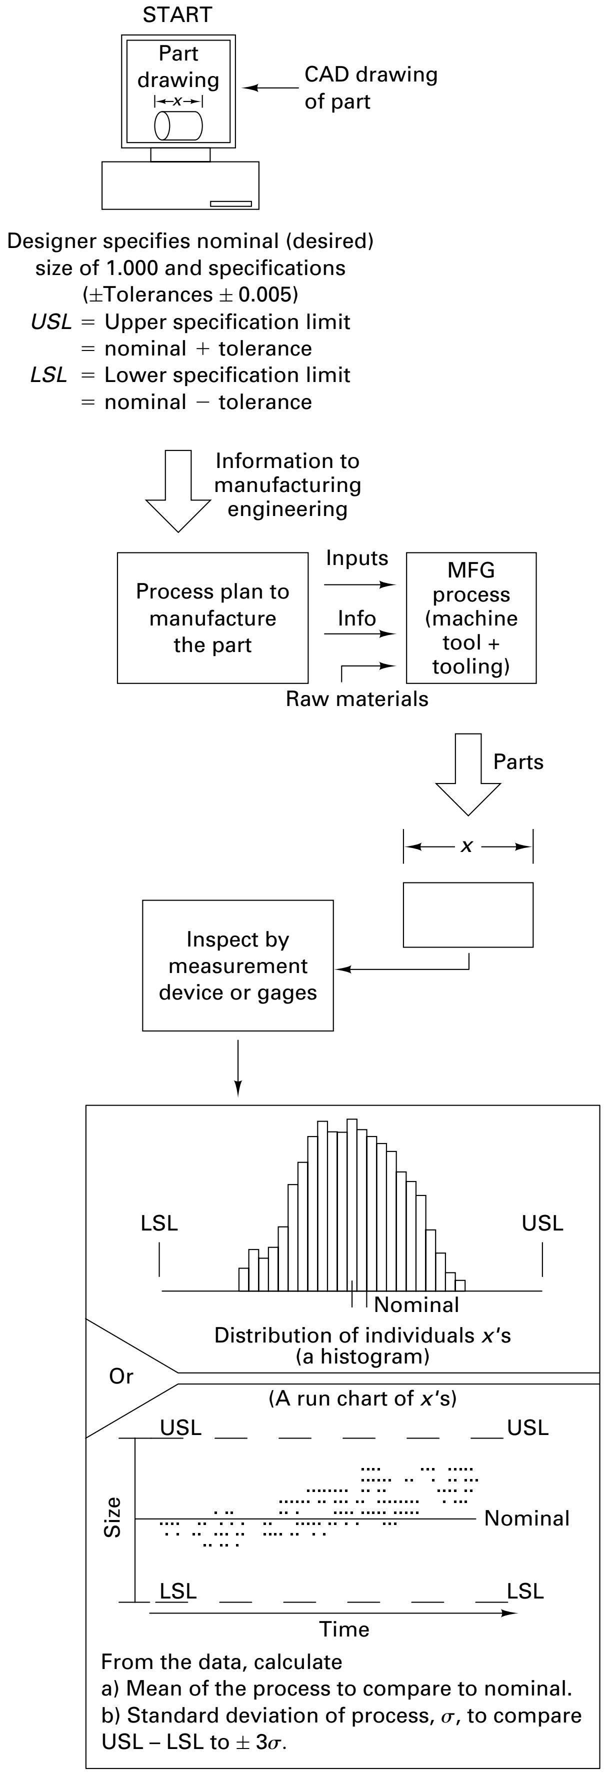

FIGURE 36-3 The process capability study compares the part as made by the manufacturing process to the specifications called for by the designer. Measurements from the parts are collected for run charts and for histograms for analysis—see Figure 36-4.

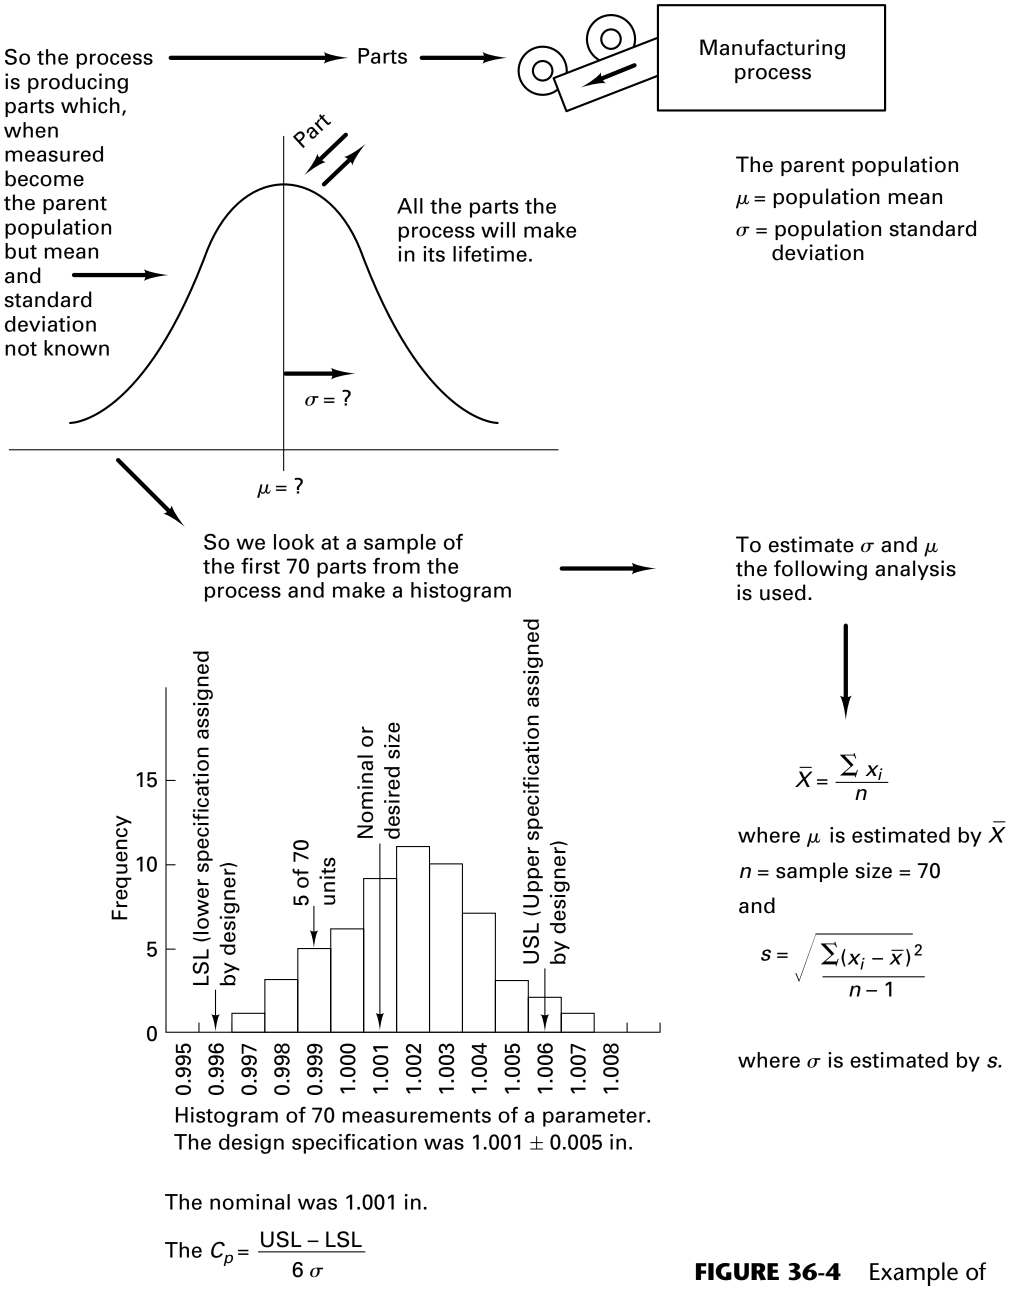

FIGURE 36-4 Example of calculations to obtain estimates of the mean (μ) and standard deviation (σ) of a process.

A frequency distribution, in the form of a *histogram*, or a *run chart* is developed. This histogram shows the raw data and the desired value, along with the upper and lower *specification limits*, where LSL represents lower specification limit and USL the upper specification limit. The statistical data are used to estimate the mean and the standard deviation of this distribution. The run chart shows the same data, but here the data are plotted against time.

The mechanics of this statistical analysis are outlined in Figure 36-4. The true mean of the distribution, designated μ, is to be compared with the nominal value specified by the designer. The estimate of the true *standard deviation*, designated σ (sigma), is used to determine how the process compares with the desired tolerance. *The purpose of the analysis is to obtain estimates of* μ *and* σ *values, the true process parameters, because they are not known.*

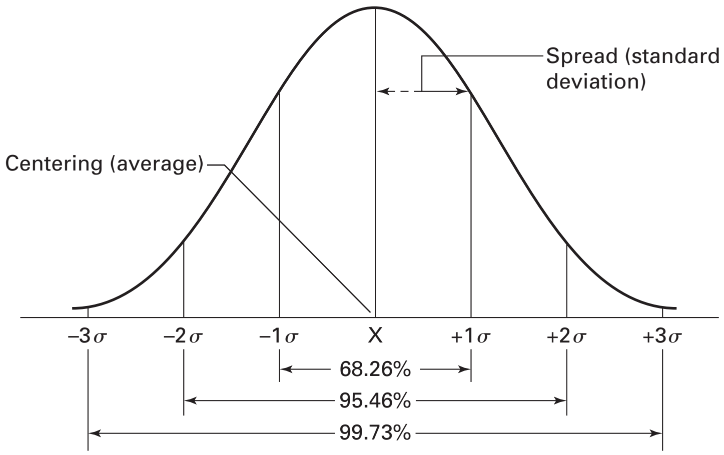

FIGURE 36-5 The normal or bell-shaped curve with the areas within ± 1σ, ± 2σ, and ± 3σ for a normal distribution; 68.26% of the observations will fall within ±1σ from the mean, and 99.73% will fall within ± 3σ from the mean.

The process capability is defined by ± 3σ or 6σ. Thus $\mu \pm 3\sigma$ defines the natural capability limits of the process, assuming the process is approximately normally distributed. Note that a distinction is made between a sample and a population. A sample is of a specified, limited size and is drawn from the population. The population is the large source of items, which can include all the items the process will ever produce under the specified conditions. Our calculations assume that this distribution was normal or bell-shaped. Figure 36-5 shows a typical normal curve and the areas under the curve as defined by the standard deviation. Other distributions, shown in Figure 36-6, are possible, but the histogram clearly suggested that this process can best be described by a normal probability distribution. Now it remains for the process engineer and the operator to combine their knowledge of the process with the results from the analysis in order to draw conclusions about the ability of this process to meet specifications.

HISTOGRAMS

A histogram is a representation of a frequency distribution that uses rectangles whose widths represent class intervals and whose heights are proportional to the corresponding frequencies. The frequency histogram is a type of diagram in which data are grouped into cells (or intervals), and the frequency of observations falling into each interval can be noted. All the observations within a cell are considered to have the same value, which is the midpoint of the cell. So, a histogram is a picture that describes the variation in a process. It is good to have this visual impression of the distribution of values, along with the mean and standard deviation. Histograms are used in many ways in QC, for example:

- To determine the process capability (central tendency and dispersion)
- To compare the process with the specifications
- To suggest the shape of the population (e.g., normality)
- To indicate discrepancies in data, such as gaps

There are several types of histograms. A histogram shows either absolute frequency (actual occurrence) or relative frequency (percentage). Cumulative histograms show cumulative frequency and reliability cumulative frequency. Each type has its own advantages and is used in different situations. Figure 36-7 shows frequency versus location for 150 measurements. The aim (accuracy) of the process is a bit low, but all the data are well within the tolerances. The disadvantage of the histogram is that it does not show trends and does not take time into account. We can take the data from the histogram and spread them out over time to create a run chart or run diagram.

RUN CHART OR DIAGRAM

A run diagram is a plot of a quality characteristic as a function of time. It provides some idea of general trends and degree of variability. Run charts reveal information that

Common probability distributions

Distribution	Form	Probability function	Comments
Normal		$y = \frac{1}{\sigma\sqrt{2\pi}}\, e{-}\frac{(X-\mu)/^2}{2\sigma^2}$ μ = Mean σ = Standard deviation	Applicable when there is a concentration of observations about the average and it is equally likely that observations will occur above and below the average. Variation in observations is usually the result of many small causes
Exponential		$y = \frac{1}{\mu} e^{-\frac{x}{\mu}}$	Applicable when it is likely that more observations will occur below the average than above
Weibull		$y = \alpha\beta(X-\gamma)^{\beta-1}e^{-\alpha(x-\gamma)^{\beta}}$ α = Scale parameter β = Shape parameter γ = Location parameter	Applicable in describing a wide variety of patterns of variation, including departures from the normal and exponential
Poisson*		$y = \frac{(np)^r e^{-np}}{r!}$ n = Number of trials r = Number of occurrences p = Probability of occurrence	Same as binomial but particularly applicable when there are many opportunities for occurence of an event but a low probability (less than 0.10) on each trial
Binomial*		$y = \frac{n!}{r!(n-r)!}\, p^r q^{n-r}$ n = Number of trials r = Number of occurrences p = Probability of occurrence $q = 1 - p$	Applicable in defining the probability of r occurrences in n trials of an event that has a probability of occurrence of p on each trial

* = discrete distributions but shown as curves for ease of comparison

FIGURE 36-6 Common probability distributions that can be used to describe the outputs from manufacturing processes. *(Source:* Quality Control Handbook, *3rd ed.)*

histograms cannot, such as certain trends over time or at certain times of day. Individual measurements (not samples) are taken at regular time intervals, and the points are plotted on a connected line graph as a function of time. The graph can be used to find obvious trends in the process, as shown in Figure 36-8, a run diagram with measurements made every hour over four shifts.

Run diagrams are very important at startup to identify the basic nature of a process. Without this information, one may use an inappropriate tool in analyzing the data. For example, a control chart or histogram might hide tool wear if frequent tool changes and adjustments are made between groups of observations. As a result, run diagrams (with 100% inspection where feasible) should always precede the use of control charts for averages and ranges.

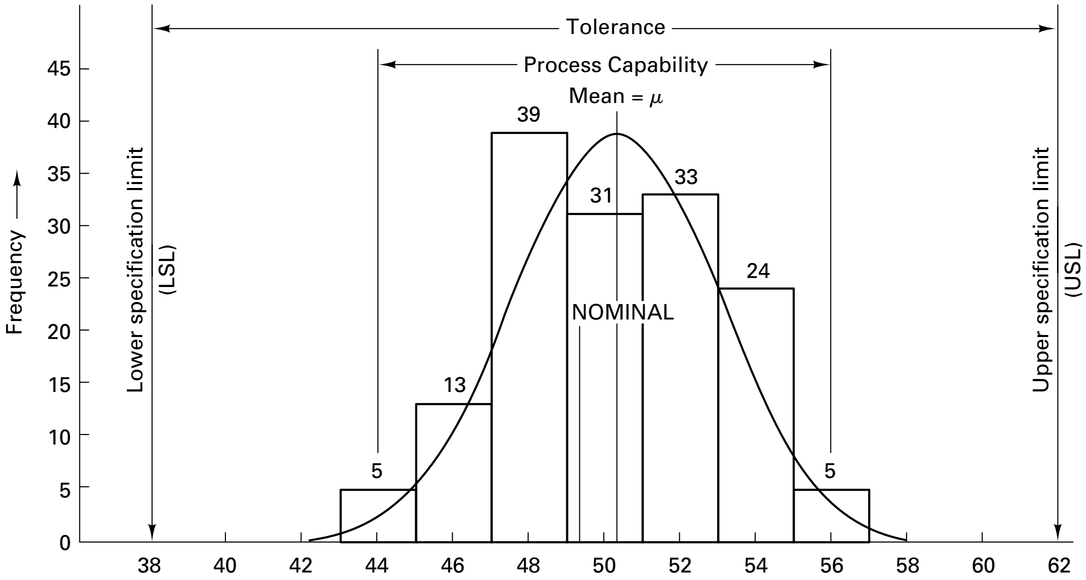

FIGURE 36-7 Histogram shows the output mean μ from the process versus nominal and the tolerance specified by the designer versus the spread as measured by the standard deviation σ. Here nominal = 49.2, USL = 60, LSL = 38, $\mu = 50.2$, $\sigma = 2$.

The lengths of manufactured components are measured. A run diagram is constructed to determine how the process is behaving. During 34 hours, measurements are made every hour (60 minutes) and plotted in the order that rack bars are produced.

First shift	35	40	27	30	30	34	26	31
Second shift	24	23	28	15	23	17	16	21
Third shift	15	13	28	8	20	9	5	11
First shift	16	5	9	13	16	10	9	10

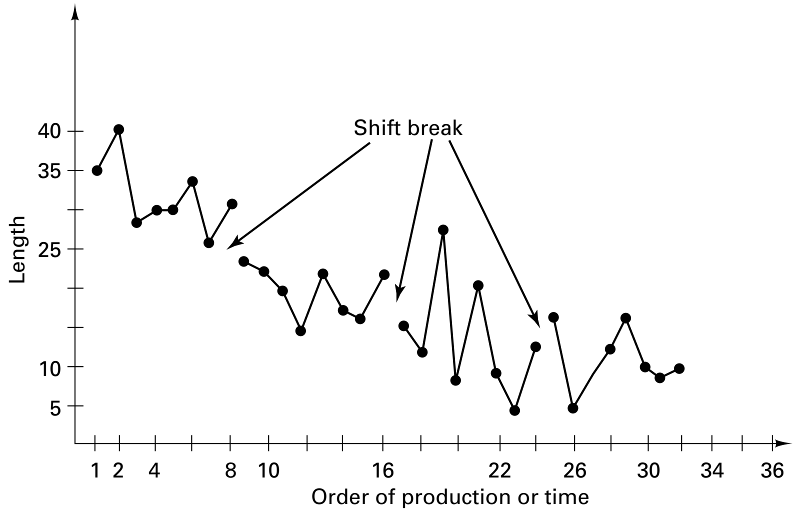

FIGURE 36-8 An example of a run chart or graph, which can reveal trends in the process behavior not shown by the histogram.

PROCESS CAPABILITY INDEXES

The most popular PC index tells you if the process has the ability to meet specifications. This process capability index, C_p, is often computed as follows:

$$C_p = \frac{\text{tolerance spread}}{6\sigma} = \frac{\text{USL} - \text{LSL}}{6\sigma} \tag{36-1}$$

A value of $C_p \geq 1.33$ is considered good

The example in Figure 36-7 has

$$C_p = \frac{\text{USL} - \text{LSL}}{6\sigma} = \frac{24}{12} = 2 \tag{36-2}$$

The process capability ratio, C_p, does not, however, take into account the location of the process mean, μ, with respect to the nominal or the specifications. C_p mearly looks at the variability or spread of process (compared to specifications) in terms of sigmas. So another process capability ratio has been developed for off-center processes. This ratio is called C_{pk}, where

$$\begin{aligned} C_{pk} &= \min C_{pu}, C_{pl} \qquad (36\text{-}3)\\ &= \min\left(C_{pu} = \frac{\text{USL} - \mu}{3\sigma}, C_{pl} = \frac{\mu - \text{LSL}}{3\sigma}\right) \end{aligned}$$

C_{pk} is simply a one-sided ratio for the specification nearest to the process average, μ. To compare the two, look at Figure 36-9. All the histograms have the same standard deviation ($\sigma = 2$) and the same USL − LSL specifications (62−37). For Figure 36-9a, the two indexes are the same. For Figure 36-9b, the mean has shifted to $\mu = 54$ so $C_{pk} = (62-54)/3(2) = 1.5$.

Can you calculate C_{pk} for (c), (d), and (e)? Answers are on the figure.

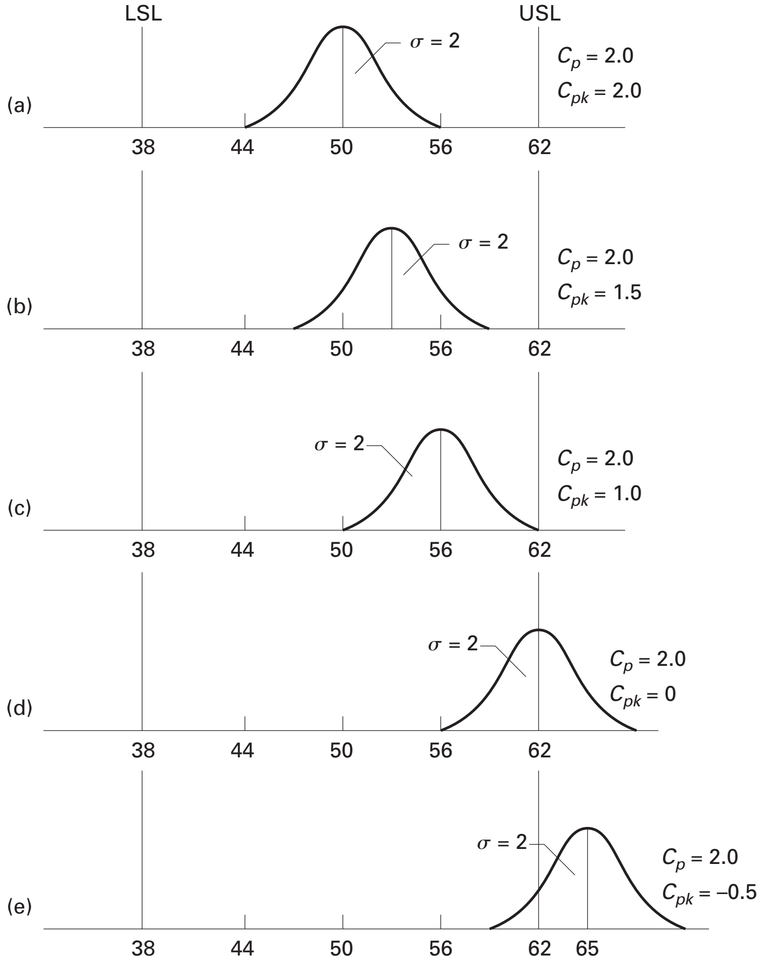

FIGURE 36-9 The output from the process is shifting toward the USL, which changes the C_{pk} ratio but not the C_p ratio.

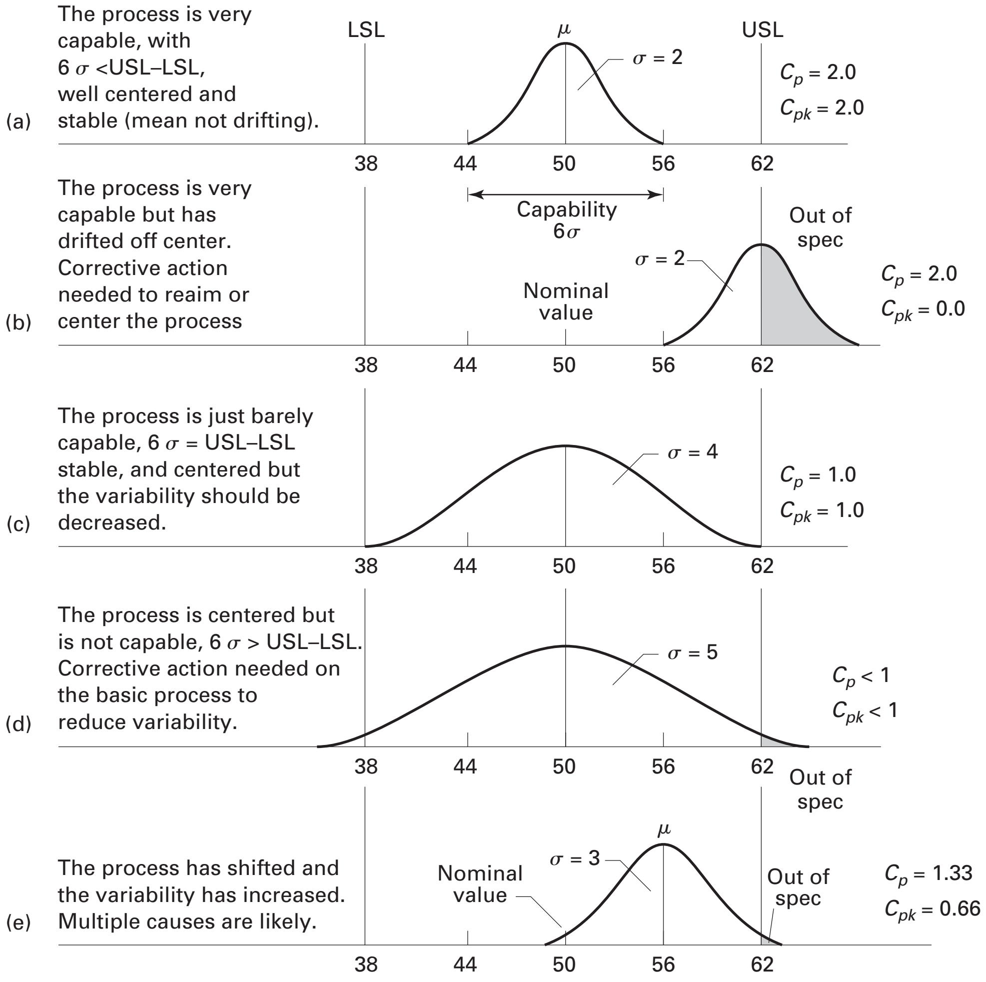

FIGURE 36-10 Five different scenarios for a process output versus the designer's specifications for the minimal (50) and upper and lower specifications of 65 and 38 respectively.

The capability indexes can tell you about the variance, where the width of the histogram is compared with the specifications (Figure 36-10). The natural spread of the process, 6σ, is computed and is then compared with the upper and lower tolerance limits. These situations can exist:

1. $6\sigma < \text{USL} - \text{LSL}$ *or* $C_p > 1$, or process variability less than tolerance spread. See Figure 36-10a.
2. $6\sigma < \text{USL} - \text{LSL}$ but process has shifted. See Figure 36-10b.
3. $6\sigma < \text{USL} - \text{LSL}$ *or* $C_p = 1$, or process variability is just equal to tolerance spread. See Figure 36-10c.
4. $6\sigma < \text{USL} - \text{LSL}$ *or* $C_p < 1$, or process variability is greater than tolerance spread. See Figure 36-10d.
5. The process mean and variability have both changed. See Figure 36-10d.

DISCUSSION OF PROCESS CAPABILITY SCENARIOS

In situation Figure 36-10a, the machine is capable of meeting the tolerances applied by the designer. Generally speaking, if process capability is on the order of two-thirds to three-fourths of the design tolerance, there is a high probability that the process will produce all good parts over a long period of time. If the PC is on the order of one-half or less of the design tolerance, it may be that the selected process is too good; that is, the company may be producing ball bearings when what is called for is marbles. In this case, it may be possible to trade off some precision in this process for looser specifications elsewhere, resulting in an overall economic gain. Quality in well-behaved processes can be maintained by checking the first, middle, and last part of a lot or production run. If these parts are good, then the lot is certain to be good. This is called $n = 3$.

Naturally, if the lot size is 3 or less, this is 100% inspection. Sampling and control charts are also used under these conditions to maintain the process aim and variability.

When the process is not capable of meeting the design specifications, there are a variety of alternatives, including the following:

1. Shifting this job to another machine with greater process capability.
2. Getting a review of the specifications to see if they may be relaxed.
3. Sorting the product to separate the good from the bad. This entails 100% inspection of the product, which may not be a feasible economic alternative unless it can be done automatically. Automatic sorting of the product on a 100% basis can ensure near-perfect quality of all the accepted parts. The automated station shown in Figure 36-11 checks parts for the proper diameter with the aid of a linear variable differential transformer (LVDT). As a part approaches the inspection station on a motor-driven conveyor system, a computer-based controller activates a clamping device. Embedded in the clamp is an LVDT position sensor with which the control computer can measure the diameter of the part. Once the measurement has been made, the computer releases the clamp, allowing the part to be carried away. If the diameter of the part is within a given tolerance, a solenoid-actuated gate operated by the computer lets the part pass. Otherwise, the part is ejected into a bin. With the fast-responding LVDT, 100% of manufactured parts can be automatically sorted quickly and economically.

   Sorting to find defects by automatic inspection is bad because you already paid to produce the defects. Also, automated sorting does not determine what caused the defects, so this example is an "automated defect finder." How would one change this inspection system to make it "inspect to prevent" the defect from occurring?
4. Determining whether the *precision* (repeatability) of the process can be improved by:
   - **a.** Switching cutting tools, workholding devices, or materials
   - **b.** Overhauling the existing process and/or developing a preventive maintenance program
   - **c.** Finding and eliminating the causes of variability, using cause-and-effect diagrams
   - **d.** Combinations of (a), (b), and (c)
   - **e.** Using designed experiments and Taguchi methods to reduce the variability of the process

In Figure 36-10c, the process capability is almost exactly equal to the assigned tolerance spread, so if the process is not perfectly centered, defective products will always result. Thus, this situation should be treated like the situation in Figure 36-10d unless the process can be perfectly centered and maintained. Tool wear, which causes the distribution to shift, must be negligible.

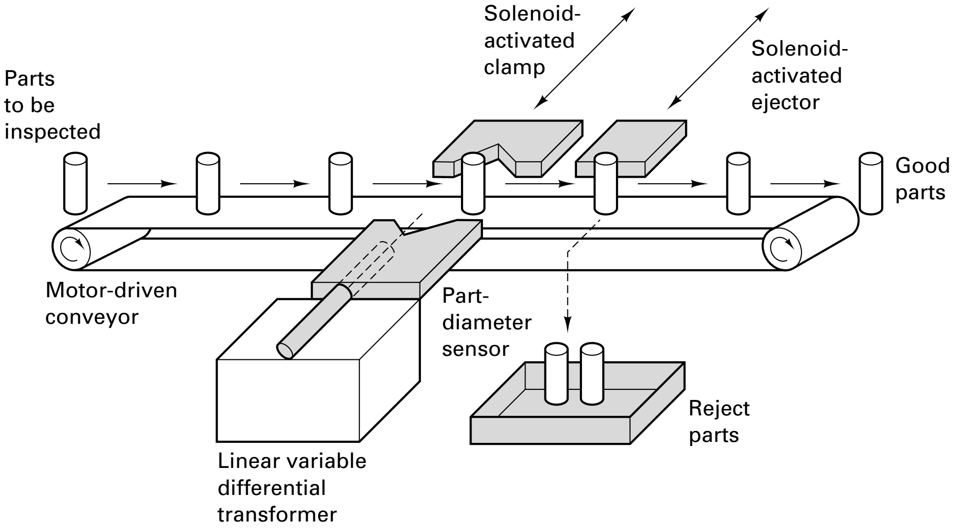

FIGURE 36-11 A linear variable differential transformer (LVDT) is a key element in an inspection station checking part diameters. Momentarily clamped into the sensor fixture, a part pushed the LVDT armature into the device winding. The LVDT output is proportional to the displacement of the armature. The transformer makes highly accurate measurements over a small displacement range.

PC studies can evaluate the ability of the process to maintain centering so that the average of the distribution comes as close as possible to the desired nominal value. Most processes can be re-aimed. Poor accuracy is often due to assignable causes, which can be eliminated.

In addition to direct information about the accuracy and the precision of the process, PC studies can also tell the manufacturing engineer how pilot processes compare with production processes, and vice versa. If the source and time of the manufacture of each product are carefully recorded, information about the instantaneous reproducibility can be found and compared with the repeatability of the process with respect to time (time-to-time variability). More important, since almost all processes are duplicated, PC studies generate information about machine-to-machine variability. Going back to our target-shooting example, suppose that nine different guns were used, all of the same make and type. The results would have been different, just as having nine marksmen use the same gun would have resulted in yet another outcome. Thus, PC studies generate information about the homogeneity and the differences in multiple machines and operators.

It is quite often the case in such studies that one variable dominates the process. Target shooting viewed as a process is “operator dominated” in that the outcome is highly dependent on the skill (the capability) of the “worker.” Processes that are not well engineered or highly automated, or in which the worker is viewed as “highly skilled,” are usually operator dominated. Processes that change or shift uniformly with time but that have good repeatability in the short run are often machine dominated. For example, the mean of a process (μ) will usually shift after a tool change, but the variability may decrease or remain unchanged. Machines tend to become more precise (to have less variability within a sample) after they have been “broken in” (i.e., the rough contact surfaces have smoothed out because of wear) but will later become less precise (will have less repeatability) due to poor fits between moving elements (called *backlash*) of the machine under varying loads. Other variables that can dominate processes are setup, input parameters, and even information.

In many machining processes in use today, the task of tool setting has been replaced by an automatic tool-positioning capability, which means that one source of variability in the process has been eliminated, making the process more repeatable. In the same light, it will be very important in the future for manufacturing engineers to know the process capability of robots they want to use in the workplace.

The discussion to this point has assumed that the *parent population* is normally distributed, that is, has the classic bell-shaped distribution in which the percentages (shown in Figure 36-5) are dictated by the number of standard deviations from the central value or mean. The shape of the histogram may reveal the nature of the process to be skewed to the left or the right (unsymmetrical), often indicating some natural limit in the process. Drilled holes exhibit such a trend, as the drill tends to make the hole oversize. Another possibility is a bimodal distribution (two distinct peaks), often caused by two processes being mixed together. Suppose you had a manufacturing cell as used in lean production and you were using a *check sheet* to gather data on one of the operations. See Figure 36-12. The time to perform an assembly task is being recorded. Why do you think the data are bimodal? In the cell design, shown in Chapter 1, Figure 1-9, operation 7 (caulking) was shared by two operators. The data would suggest that they do not do the assembly process the same way, since there appears to be a 5- or 6-second difference in their average time to complete this task. Clearly further study is needed to determine what the real problem was. For the next check sheet, use a different symbol for each worker.

The check sheet is an excellent way to view data while it is being collected. It can be constructed using predetermined parameters based on experience with the cell or system. The appropriate interval is checked as the data are being collected. This often allows the central tendency and the spread of the data to be seen. The check sheet can provide basically the same information as the histogram, but it is easier to build (once the check sheet is formatted).The possibilities are endless and require a careful recording of all the sources of the data to track down the factors that result in loss of precision and accuracy in the process. Rapid feedback on quality is perhaps the most important factor, so these data-gathering tasks are done right on the factory floor, by the operators.

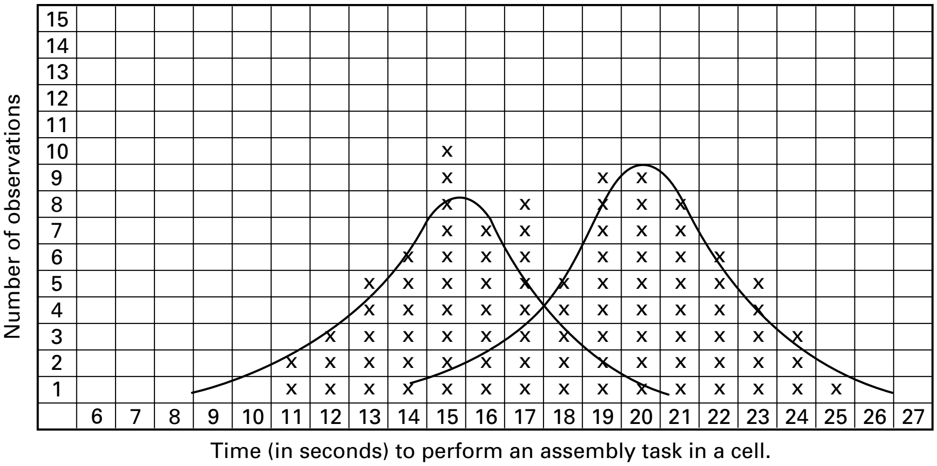

FIGURE 36-12 Example of a check sheet for gathering data on a process.

36.3 INSPECTION TO CONTROL QUALITY

In virtually all manufacturing, it is extremely important that the dimensions and quality of individual parts be known and maintained. This is of particular importance where large quantities of parts, often made in widely separated plants, must be capable of interchangeable assembly. Otherwise, difficulty may be experienced in subsequent assembly or in service, and costly delays and failures may result. In recent years, defective products resulting in death or injury to the user have resulted in expensive litigation and damage awards against manufacturers. Inspection is the function that controls the quality (e.g., the dimensions, the performance, and the color) manually, by using operators or inspectors, or automatically, with machines, as discussed previously.

The economics-based question "How much should be inspected?" has three possible answers:

1. *Inspect every item being made*. 100% inspect every item being made; 100% checking with prompt execution of feedback and immediate corrective action can ensure perfect quality.
2. *Sample.* Inspect some of the product by sampling and make decisions about the quality of the process based on the sample.
3. *None.* Assume that everything made is acceptable or that the product is inspected by the consumer, who will exchange it if it is defective. (This is not a recommended procedure).

The reasons for not inspecting all of the product (i.e., for sampling) include the following:

1. Everything has not yet been manufactured—the process is continuing to make the item—so we have to look at some before we are done with all.
2. The test is destructive.
3. There is too much product for all of it to be inspected.
4. The testing takes too much time or is too complex or too expensive.
5. It is not economically feasible to inspect everything even though the test is simple, cheap, and quick.

Some characteristics are nondissectible; that is, they cannot be measured during the manufacturing process because they do not exist until after a whole series of operations have taken place. The final edge geometry of a razor blade is a good example, as is the yield strength of a rolled bar of steel.

Sampling (looking at some percentage of the whole) requires the use of statistical techniques that permit decisions about the acceptability of the whole based on the quality found in the sample. This is known as *statistical process control*.

STATISTICAL PROCESS CONTROL (SPC)

Looking at some (sampling) and deciding about the behavior of the whole (the parent population) is common in industrial inspection operations. The most widely used basic SPC technique is the control charts.

In particular, *control charts for variables* are used to monitor the output of a process by sampling (looking at some), by measuring selected quality characteristics, by plotting the sample data on the chart, and then by making decisions about the performance of the process.

Figure 36-13 shows the basic structure of two charts commonly used for variable types of measurements. The $\overline{X}$ chart tracks the aim (accuracy) of the process. The R chart (or σ chart) tracks the precision or variability of the process. Usually, only the $\overline{X}$ chart and the R chart are used unless the sample size is large, and then σ charts are used in place of R charts. For each sample, the following calculations are made:

$$(\text{mean})\overline{X} = \frac{\sum x_i}{n} \qquad (36\text{-}4)$$

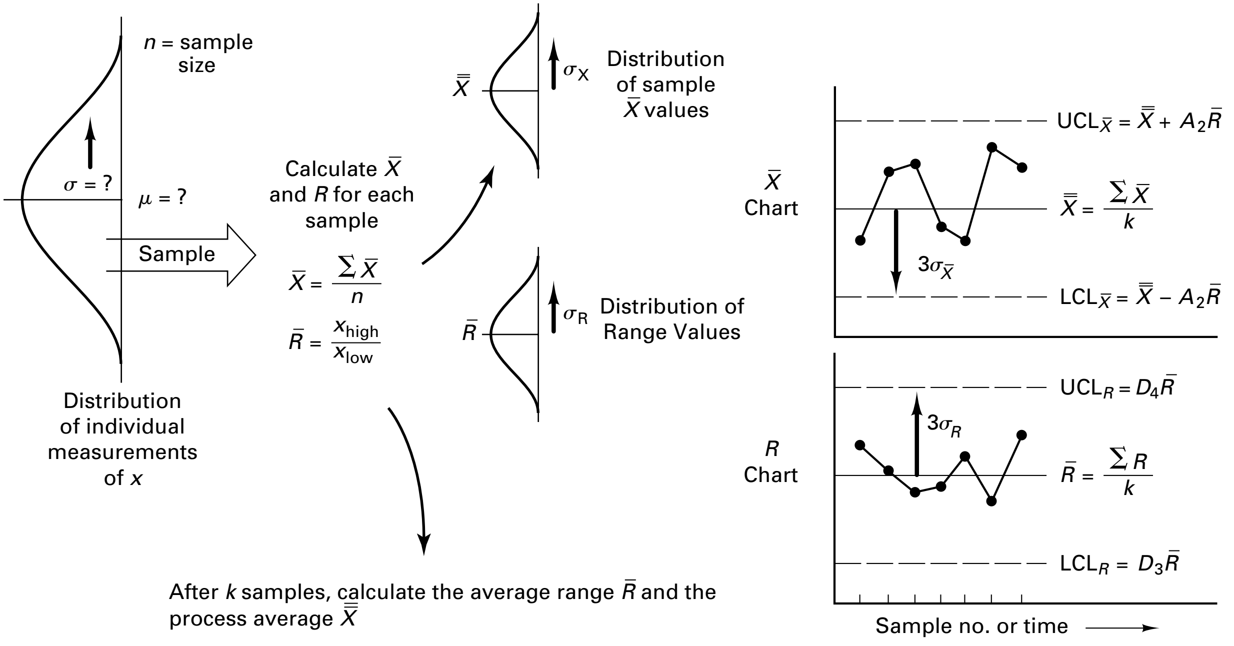
$$n = \text{sample size}$$

$$(\text{range})R = x_{\text{HIGH}} - x_{\text{LOW}} \qquad (36\text{-}5)$$

Sometimes the standard deviation is calculated:

$$(\text{sigma})\sigma = \sqrt{\frac{\sum (x_i - \overline{x})^2}{n-1}} \qquad (36\text{-}6)$$

$$n = \text{sample size}$$



After k samples, calculate the average range $\overline{R}$ and the process average $\overline{\overline{X}}$

$$\overline{R} = \frac{R_1 + R_2 + \ldots R_k}{k} \qquad \overline{\overline{X}} = \frac{\overline{X}_1 + \overline{X}_2 + \ldots \overline{X}_k}{k}$$

$$\text{UCL}_{\overline{X}} = \overline{\overline{X}} + A_2\overline{R} = \overline{\overline{X}} + 3\sigma_{\overline{X}}$$

$$\text{LCL}_{\overline{X}} = \overline{\overline{X}} - A_2\overline{R} = \overline{\overline{X}} - 3\sigma_{\overline{X}}$$

$$\text{UCL}_R = D_4\overline{R} \qquad LCL_R = D_3\overline{R}$$

$$3\sigma_{\overline{X}} = 3\frac{\sigma}{\sqrt{n}} = 3\,\frac{\overline{R}}{d_2\sqrt{n}} = A_2\overline{R}$$

Sample Size	$\overline{X}$	R Chart		Est.	σ'
(n)	A_2	D_3	D_4	d_2	c_2
2	1.88	.00	3.27	1.13	.56
3	1.02	.00	2.57	1.69	.72
4	0.73	.00	2.28	2.06	.80
5	0.58	.00	2.11	2.33	.84
6	0.48	.00	2.00	2.53	.87
7	0.42	.08	1.92	2.70	.89
8	0.37	.14	1.86	2.85	.90
9	0.34	.18	1.82	2.97	.91
10	0.31	.22	1.78	3.08	.92

FIGURE 36-13 Quality control chart calculations. On the charts, plot $\overline{X}$ and R values over time. The constants for calculating UCL and LCL values for the $\overline{X}$ and R charts are based on 3 standard deviations.

The samples are drawn over time.

Because some sample statistics tend to be normally distributed about their own mean, $\overline{X}$ values are normally distributed about $\overline{\overline{X}}$, R values are normally distributed about $\overline{R}$, and σ values are normally distributed about $\overline{\sigma}$.

Quality control charts are widely used as aids in maintaining quality and in achieving the objective of detecting trends in quality variation before defective parts are actually produced. These charts are based on the previously discussed concept that if only chance causes of variation are present, the deviation from the specified dimension or attribute will fall within predetermined limits.

When sampling inspection is used, the typical sample sizes are from 3 to about 12 units. The $\overline{X}$ chart tracks the sample averages ($\overline{X}$ values). The R chart plots the range values (R values). Figure 36-14 shows one example of $\overline{X}$ and R charts for measuring a dimension of a gap on a part called the retainers. Twenty-five samples of size 5 were taken over six days, and this sample data will be used to prepare the control charts.

The centerline of the $\overline{X}$ chart was computed prior to actual usage of the charts in control work:

$$\overline{\overline{X}} = \frac{\sum_{i=1}^{k} \overline{X}}{k} \tag{36-7}$$

where $\overline{X}$ was a sample average and k was the number of sample averages. The horizontal axis for the charts is time, thus indicating *when* the sample was taken. $\overline{\overline{X}}$ serves as an estimate for μ, the true center of the process distribution. $\overline{\overline{X}}$ is also centerline of the $\overline{X}$ chart. The upper and lower control limits are commonly based on 3 standard error units, $3\sigma_{\overline{x}}$ ($\sigma_{\overline{x}}$ is the standard deviations for the distribution of $\overline{X}$'s about $\overline{\overline{X}}$).

Thus,

$$\begin{aligned} \text{UCL}_{\overline{X}} &= \text{upper control limit on } \overline{X} \text{ chart} \\ &= \mu + 3\sigma_{\overline{x}} \text{ or} \\ &= \mu + A_2\overline{R} \\ \text{LCL}_{\overline{X}} &= \text{lower control limit, } \overline{X} \text{ chart} = \mu - 3\sigma_{\overline{X}} \\ &= \mu - A_2R \end{aligned} \tag{36-8}$$

(see Figure 36-13 for A_2 values). The upper and lower control limits are entered as dashed lines on the chart. The $\overline{X}$ chart is used to track the central tendency (aim) of the process. In this example, the samples were being taken 4 times a day. The R chart is used to track the variability or dispersion of the process. A σ chart could also be used. R is computed for each sample ($x_{\text{HIGH}} - x_{\text{LOW}}$). The value of $\overline{R}$ is calculated as:

$$\overline{R} = \frac{\sum_{i=1}^{k} R}{k}$$

where $\overline{R}$ represents the average range of k range values. The range values are normally distributed about $\overline{R}$, with standard deviation σ_R. To determine the upper and lower control limits for the charts, the following relationships are used.

$$\text{UCL}_R = \text{upper control limit, } R \text{ chart} = \overline{R} + 3\sigma_R = D_4\overline{R} = 2.11\overline{R} \text{ for } n = 5$$

$$\text{LCL}_R = \text{lower control limit} = R = 3\sigma_R = D_3\overline{R} = 0$$

where D_4 and D_3 are constants and are given in Figure 36-13. For small values of n, the distance between centerline R and LCL $_R$ is more than $3\sigma_R$, but LCL_R cannot be negative, as negative range values are not allowed, by definition. Hence, $D_3 = 0$ for values of n up to 6.

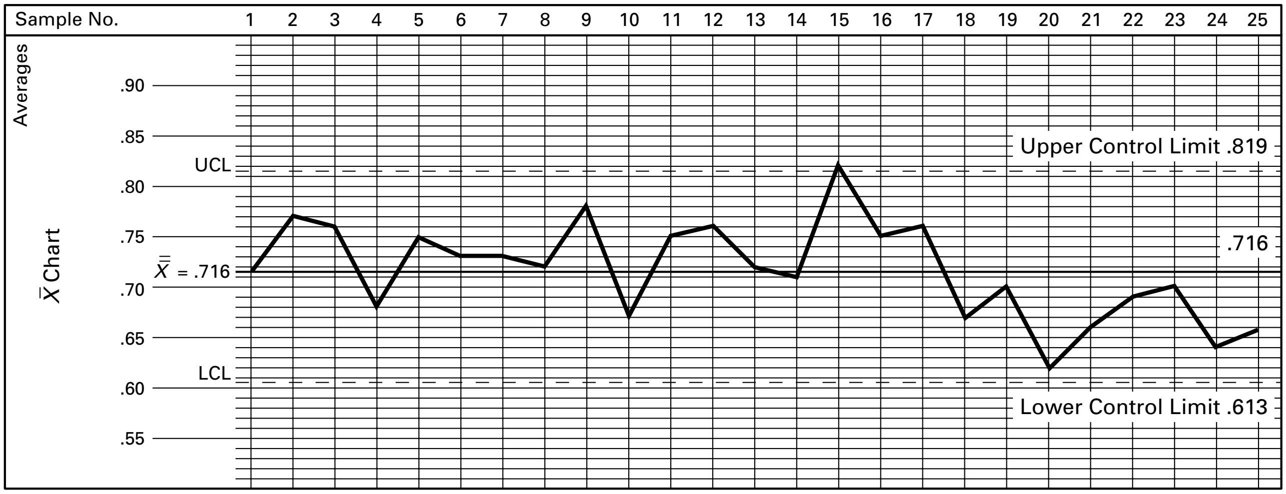
$\bar{\bar{X}} = (.70 + .77 + \ldots + .64 + .66)/25 = 17.90/25 = .716$ $\quad UCL_{\bar{X}} = .716 + (.58 \times .178) = .819$



$\bar{R} = 4.45/25 = .176$ $\quad UCL_R = 2.11 \times .178 = .376$ $\quad LCL_R = 0$

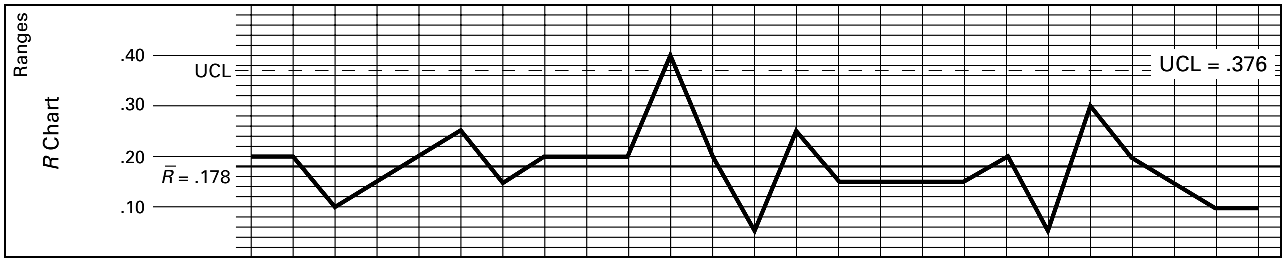


FIGURE 36-14 Example of $\bar{X}$ and R charts and the data set of 25 samples [$k = 25$ of size 5 ($n = 5$)].
(*Source : Continuing Process Critical and Process Capability Improvement, Statistical Methods Office, Ford Motor Co., 1985.)*

After control charts have been established, and the average and range values have been plotted for each sample group, the charts act as a control indicator for the process. If the process is operating under chance cause conditions, the data will appear random (will have no trends or pattern). If $\bar{X}$, R, or σ values fall outside the control limits or if nonrandom trends occur (like 7 points on one side of the central line or 6 successive increasing or decreasing points appear), an assignable cause or change may have occurred, and some action should be taken to correct the problem.

Trends in the control charts often indicate the existence of an assignable cause factor before the process actually produces a point outside the control limit. In grinding operations, wheel wear (wheel undersize) results in the parts becoming oversized and corrective action should be taken. (Redress and reset the wheel or replace it with a new wheel.) Note that defective parts can be produced even if the points on the charts indicate the process is in control. That is, it is possible for something to change in the process, causing defective parts to be made, and the sample point still to be within the control limits. Since no corrective action was suggested by the charts, a type II error was made. Subsequent operations will then involve performing additional work on products already defective. Thus the effectiveness of the SPC approach in improving quality is often deterred by the time lag between the discovery of an abnormality and the corrective action.

With regard to control charts in general, it should be kept in mind that the charts are only capable of indicating that something has happened, not what happened, and that a certain amount of detective work will be necessary to find out what has occurred to cause a break from the random, normal pattern of sample points on the charts. Keeping careful track of when and where the sample was taken will be very helpful in such investigations, but the best procedure is to have the operator take the data and run the chart. In this way, quality feedback is very rapid and the causes of defects readily found.

36.4 PROCESS CAPABILITY DETERMINATION FROM CONTROL CHART DATA

After the process is determined to be "under control," the data can be used to estimate the process capability parameters.

As an example, examine the data in Figure 36-14. These are measurements of the gaps in 125 retainers. They are supposed to have a nominal size of 0.70 mm. The population is assumed to be normal, and only chance variations are occurring. (Could you make a histogram of these 125 measurements?) The mean for all the data can be obtained by equation 36-4

$$\overline{X} = \frac{\sum_{i=1}^{125} x_i}{n}$$

where x_i is an individual measurement and the number of items was 125. The mean is a measure of the central tendency around which the individual measurements tend to group. The variability of the individual measurements about the average may be indicated by the standard deviation, σ, where

$$\sigma = \frac{\sqrt{\sum_{i=1}^{n} (x_i - \overline{X})^2}}{n} \text{ where } n = 125$$

But more commonly the sample data are used to make determinations of the process control.

A sample size of 5 was used in this example, so $n = 5$. Twenty-five groups or samples were drawn from the process, so $k = 25$. For each sample, the *sample mean* $\overline{X}$ and the *sample range R* are computed. [For large samples ($n > 12$), the standard deviation of each sample should be computed rather than the range.] Next, the average of the sample averages, $\overline{\overline{X}}$, is computed as shown in Figure 33-14. This is sometimes called the *grand average*. This is used to estimate the mean of the process, μ. The standard deviation of the process, which is a measure of the spread or variability of the process, is estimated from either the average of the sample ranges, $\overline{R}$, or the average of the sample standard deviations, $\overline{\sigma}$, using either $\overline{R}/d_2$ or $\overline{\sigma}/c_2$. The factors d_2 and c_2 depend on the sample size n and are given in the table in Figure 36-13. So μ is estimated by $\overline{\overline{X}}$ and σ is estimated by $\overline{R}/d_2$ or $\overline{\sigma}/c_2$.

The standard deviation of the distribution of the $\overline{X}$ values about $\overline{\overline{X}}$, $\sigma_{\overline{X}}$, is related to the standard deviation of the parent population, σ, by $\sigma_{\overline{X}} = \sigma/\sqrt{n}$.

Now these estimates can be used to determine the process capability of the process in the same way the histogram was used.

36.5 DETERMINING CAUSES FOR PROBLEMS IN QUALITY

The best way to quickly isolate quality problems is to make everyone an inspector. This means every worker, foreman, supervisor, engineer, manager, and so forth is responsible for making it right the first time and every time. One very helpful tool in this effort is the fishbone diagram. As shown in Figure 36-15, the fishbone diagram can be used in conjunction with the control chart to root out the causes of problems. The problem can have multiple causes, but in general, the cause will lie in the process, operators, materials, or method (i.e., the four main branches on the chart). Every time a quality problem is caused by one of these events, it is noted by the observer, and corrective action is taken. As before, experimental design procedures to be discussed later can help identify causes that affect performance.

Cause-and-effect (C&E) diagrams are also known as fishbone diagrams because of their structure. Initially developed by Kaorw Ishikowa in 1943, this diagram organizes theories about the probable cause of a problem. On the main line is a quality characteristic that is to be improved or the quality problem being investigated. Fishbone lines are drawn from the main line. These lines organize the main factors that could have caused the problem. Branching from each of these factors are even more detailed factors. Everyone taking part in making a diagram gains new knowledge of the process. When a diagram serves as a focus for the discussion, everyone knows the topic, and the conversation does not stray. The diagram is often structured around four branches: the machine tools (or processes), the operators (workers), the method, and the material being processed. Another version of the diagram is called the CEDAC, the cause-and-effect diagram with the addition of cards. The effect is often tracked with a control chart. The possible causes of the defect or problem are written on cards and inserted in slots in the charts.

The three main applications of C&E diagrams are as follows:

I. *Cause enumeration:* Every possible cause and subcause is listed.
  a. *Visual presentations* are one of the most widely used graphical techniques for QC.
  b. A better understanding of the relationships within the process yields a better understanding of the process as a whole.

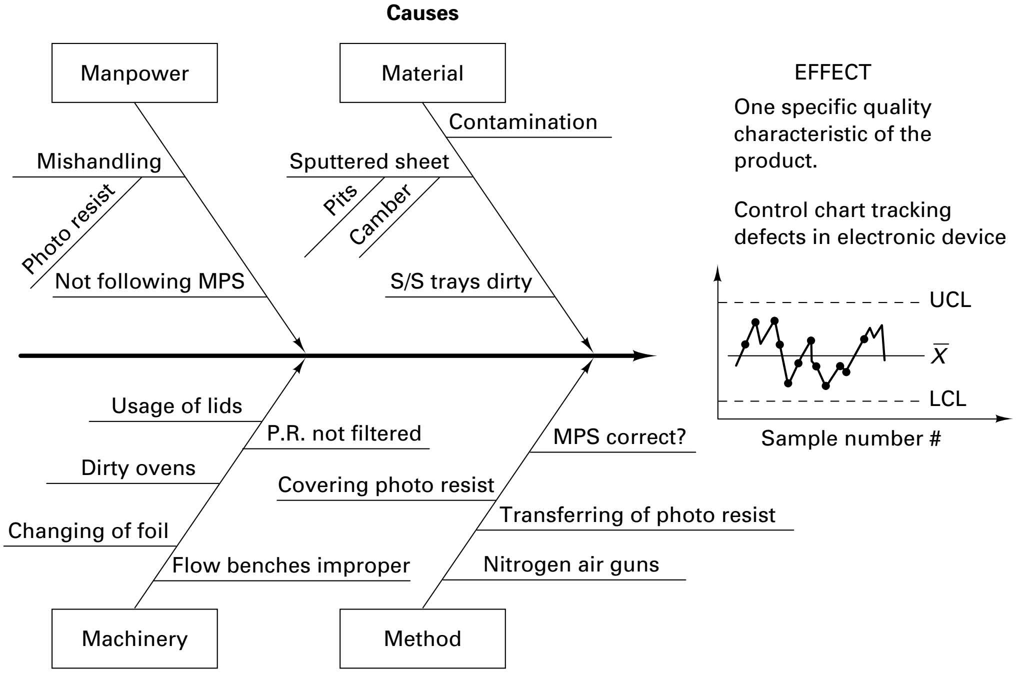

FIGURE 36-15 Example of a fishbone diagram using a control chart to show effects.

II. *Dispersion analysis* involves grouping causes under similar headings; the four M's are men, machines, materials, and methods.
  a. Each *major* cause is thoroughly analyzed.
  b. There is the possibility of not identifying the root cause (may not fall into main categories).

III. *Process analysis* is similar to creating a flow diagram.
  a. Each part of the process is listed in the sequence in which operations are performed.

In summary, data are gathered to develop the early PC studies and to prepare the initial control charts for the process. The removal of all assignable causes for variability and proper setting of the process average requires that operators and engineers work together to find the causes for variation. After the charts have been in place for some time and a large amount of data have been obtained from the process output, the PC study can be redone to obtain better estimates of the natural spread of the process during actual production. On-line or in-process methods such as SPC and off-line (Taguchi) methods are key elements in a total quality control programs.

SAMPLING ERRORS

It is important to understand that in sampling, two kinds of decision errors are always possible; see Figure 36-16. Suppose that the process is running perfectly, but the sample data indicate that something is wrong. You, the quality engineer, decide to stop the process to make adjustments. This is a type I error. Alternately, suppose that the process was not running perfectly and was making defective products. However, the sample data did not indicate that anything was wrong. You decided *not to stop* the process and set it right. This is a type II error. Both types of errors are possible in sampling. For a given sample size, reducing the chance of one type of error will increase the chance of the other. Increasing the sample size or the frequency of sampling reduces the probability of errors but increases the cost of the inspection. It is common practice in control chart work to set the upper and lower control limits at 3 standard deviations. This makes the probability of an alpha error very small and the probability of a beta error quite large. Many companies determine the size of the errors they are willing to accept according to the overall cost of making the errors plus the cost of inspection. If, for example, a type II error is very expensive in terms of product recalls or legal suits, the company may be willing to make more type I errors, to sample more, or even to go to 100% inspection on very critical items to ensure that the company is not accepting defective materials and passing them on to the customer. The inspection should take place immediately after the processing.

As mentioned earlier, in any continuing manufacturing process, variations from established standards are of two types: (1) *assignable-cause variations*, such as those due to malfunctioning equipment or personnel, to defective material, or to a worn or broken tool; and (2) *normal-chance variations*, resulting from the inherent nonuniformities that exist in materials and in machine motions and operations. Deviations due to assignable causes may vary greatly. Their magnitude and occurrence are unpredictable and thus should be prevented. However, if the assignable causes of variation are removed from a given opera-

	The process is running. It really has:	
	Changed (making defects)	Not changed
Based on the sample, you decide the process has changed	No error	Type I α error
Based on the sample, you decide the process has not changed	Type II β error	No error

Type I (α error) Saying the process has changed when it has not changed
Type II (β error) Saying the process has not changed when it has changed

FIGURE 36-16 When you look at some of the output from a process and decide about the whole (i.e., the quality of the process), you can make two kinds of errors.

tion, the magnitude and frequency of the chance variations can be predicted with great accuracy. Thus, if one can be assured that only chance variations will occur, the quality of the product will be better known, and manufacturing can proceed with assurance about the results. By using statistical process control procedures, one may detect the presence of an assignable-cause variation and after investigation to find the cause and remove it before it causes quality to become unacceptable. Also, the astute application of statistical experimental design methods (Taguchi experiments) can help to identify some assignable causes.

To sum up, PC analysis and process improvements help to get the process "under control." Control charts help to keep the process on center ($\overline{X}$ chart) with no increases in variability (R chart or σ chart).

GAGE CAPABILITY

The instrument (gage) used to measure the process will also have some inherent precision and accuracy, often referred to as gage capability. In other words, the observed variation in the component part being measured is really composed of the actual process variation plus the variation in the measured system; see Figure 36-17. The measuring system will display:

- *Bias*: poor accuracy or aim
- *Linearity*: accuracy changes over the span of measurements
- *Stability*: accuracy changes over time
- *Repeatability*: loss of precision in the gage (variability)
- *Reproducibility*: variation due to different operators

Measurements made by different operators will have different means and different variation about the mean when performing a measurement. Determining the capability of the gage is called an *R and R* study. In selecting a gage, the engineer tries to get the variation in the gage (as measured by the standard deviation) to be less than 10% of the total tolerance spread (USL − LSL). This is called the 10% rule, and the *R* and *R* study can determine the magnitude of the gage variability. Space does not permit a full discussion here of *R* and *R* studies, but detailed descriptions are found in Montgomery (2001), cited in the reference section at the end of the book. In particular, students involved in ISO9000 studies should examine the *Measurement System Analysis Reference Manual*, published by the Automotive Industry Action Group.

DESIGN OF EXPERIMENTS (DOE) AND TAGUCHI METHODS

Foreign competition has forced American manufacturers to take a second look at quality, as evidenced by the major emphasis (reemphasis) on SPC in American industry. This drive toward superior quality has led to the introduction of Taguchi methods for improvement in products, product design, and processes. Basically, SPC looks at processes and control, the latter loosely implying "improvement." DOE and Taguchi methods, however, span a much wider scope of functions and include the design aspects of products and processes, areas that were seldom, if ever, formally treated from the quality standpoint. Another threshold has been reached in quality control, witnessed by an expanding role of quality in the production of goods and services. The consumer is the central focus of attention on quality, and the methods of quality design and controls have been incorporated into all phases of production.

The Taguchi methods incorporate the following general features:

1. Quality is defined in relation to the total loss to the consumer (or society) from less-than-perfect quality of the product. The methods include placing a monetary value on quality loss. Anything less than perfect is waste.

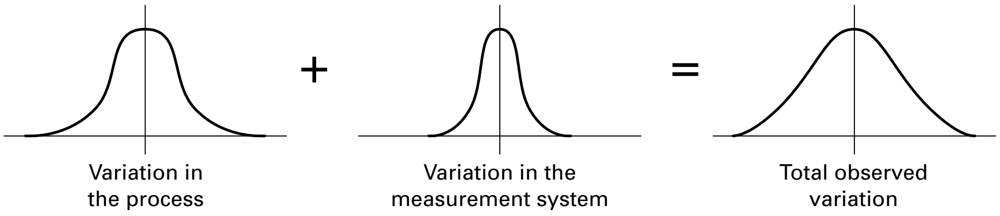

FIGURE 36-17 Gage capability (variation) contributes to the total observed variation in the measurement of a part.

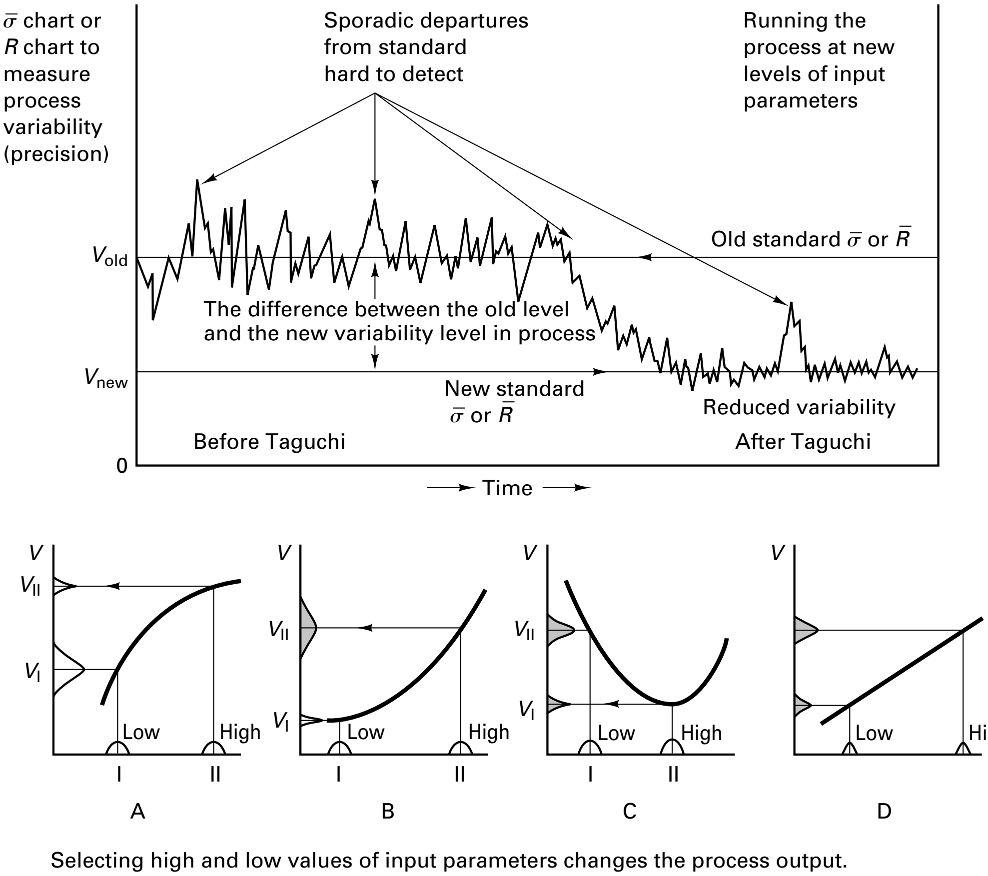
2. In a competitive society, continuous quality improvement and cost reduction are necessary for staying in business.
3. Continuous quality improvement requires continuous reduction in the variability of product performance characteristics with respect to their target values.
4. The quality and cost of a manufactured product are determined by the engineering designs of the product and its manufacturing system.
5. The variability in product and process performance characteristics can be reduced by exploiting the nonlinear (interactive) effects of the process or product parameters on the performance characteristics.
6. Statistically planned (Taguchi) experiments can be used to determine settings for processes and parameters that reduce the performance variation.
7. Design and improvement of products and processes can make them *robust*, or less sensitive to uncontrollable or difficult-to-control variations, called *noise* by Taguchi.

In the Taguchi approach, specified combinations of all of the input parameters, at various levels, that are believed to influence the quality characteristics being measured are used. These combinations should be run with the objective of selecting the best level for individual factors. For example, speed levels may be high, normal, and low; and operators may be fast or slow. For a Taguchi approach, material is often an input variable specified at different levels: normal, homogeneous, and highly variable. If a material is not controllable, it is considered a noise factor.

Designed experiments and Taguchi methods can be used as alternative approaches to making a PC study. The Taguchi approach uses a truncated experimental design (called an *orthogonal array*) to determine which process inputs have the greatest effect on process variability (i.e., precision) and which have the least. Those inputs that have the greatest influence are set at levels that minimize their effect on process variability. As shown in Figure 36-18, factors A, B, C, and D all have an effect on process variability V. By selecting a high level of A and low levels of B and C, the inherent variability of the process can be reduced. Those factors that have little effect on process variability,



Selecting high and low values of input parameters changes the process output.

FIGURE 36-18 The use of Taguchi methods can reduce the inherent process variability, as shown in the upper figure. Factors A, B, C, and D versus process variable V are shown in the lower figure.

like factor D, are used to adjust or recenter the process aim. In other words, Taguchi methods seek to minimize or dampen the effect of the causes of variability and thus to reduce the total process variability. This is also the goal of the six sigma method, which is discussed next.

The methods are, however, more than just mechanical procedures. They infuse an overriding new philosophy into manufacturing management that basically makes quality the primary issue in manufacturing. The manufacturing world is rapidly becoming aware that the consumer is the ultimate judge of quality. Continuous quality improvement toward perfect quality is the ultimate goal. Finally, it is recognized that the ultimate quality and lowest cost of a manufactured product are determined to a large extent by the engineered designs of the following:

1. The product
2. The manufacturing process technology and the sequences of processes
3. The manufacturing system (integration of the product and the process)

So, a new understanding of quality has emerged. Process variability is not fixed. It can be improved! The noise level of a process can be reduced by exploring the nonlinear effects of the product (or process) parameters on the performance characteristics.

Process capability must be also addressed in the context of machining centers and [programmable numerical control (NC)] machines. In machine tools, accuracy and precision in processing are affected by machine alignment, the setup of the workholder, the design and rigidity (accuracy) of the workholder, the accuracy of the cutting tools, the design of the product, the temperature, and the operating parameters. DOE and Taguchi methods provide a means of determining which of the input parameters are most influential in product quality when the operator is no longer there to compensate for the variability.

MOTOROLA'S SIX SIGMA

In order to meet the quality challenge of the Japanese, an American company, Motorola, developed the six sigma concept. The concept is shown in Figure 36-19 in terms of four sigma and six sigma capability. Most people do not know how sigma is determined (σ is estimated from $\overline{R}/d_2$ or σ/C_2 sample data), that a sigma is a standard deviation, or what sigma measures (sigma measures the repeatability or variability or lack of precision in a process).

In essence, the six sigma concept calls for the process to be improved to the place where there are 12 standard deviations between USL and LSL. As the variability of a process changes, so does sigma. A reduction in sigma (a reduction in spread) reflects an improvement in process or an improvement in precision (better repeatability). As the process is improved, sigma decreases. So the question is: "How do I improve the process?" This is the essence of process capability work outlined in this chapter.

Here is an example. A foundry was having a problem with cores breaking in the molds during pouring. A PC study determined that the core strength was widely variable and that it was the low-strength cores that broke when the molten metal hit them during filling. Increasing the resin content in the cores and changing the gating in the mold did not eliminate the problem, so a Taguchi study was run that revealed that core strength was highly dependent on the grain size of the sand, which was also highly variable. The sand preparation process was revised to yield more uniform-sized grains, which, when used in the core-packing process, reduced the variability in the strength characteristic and eliminated the core breakage problem.

TOTAL QUALITY CONTROL (TQC)

The phrase *total quality control* (TQC) was first used by A. V. Feigenbaum in *Industrial Quality Control* in May 1957. TQC means that all departments of a company must participate in quality control (Table 36-1). Quality control is the responsibility of workers at every level in every department, all of whom have had quality control training. It begins at the product design stages and carries through the manufacturing system, where the emphasis is on making it right the first time. It is surprising how few companies have embarked on implementing Taguchi methods in order to reduce the inherent variability

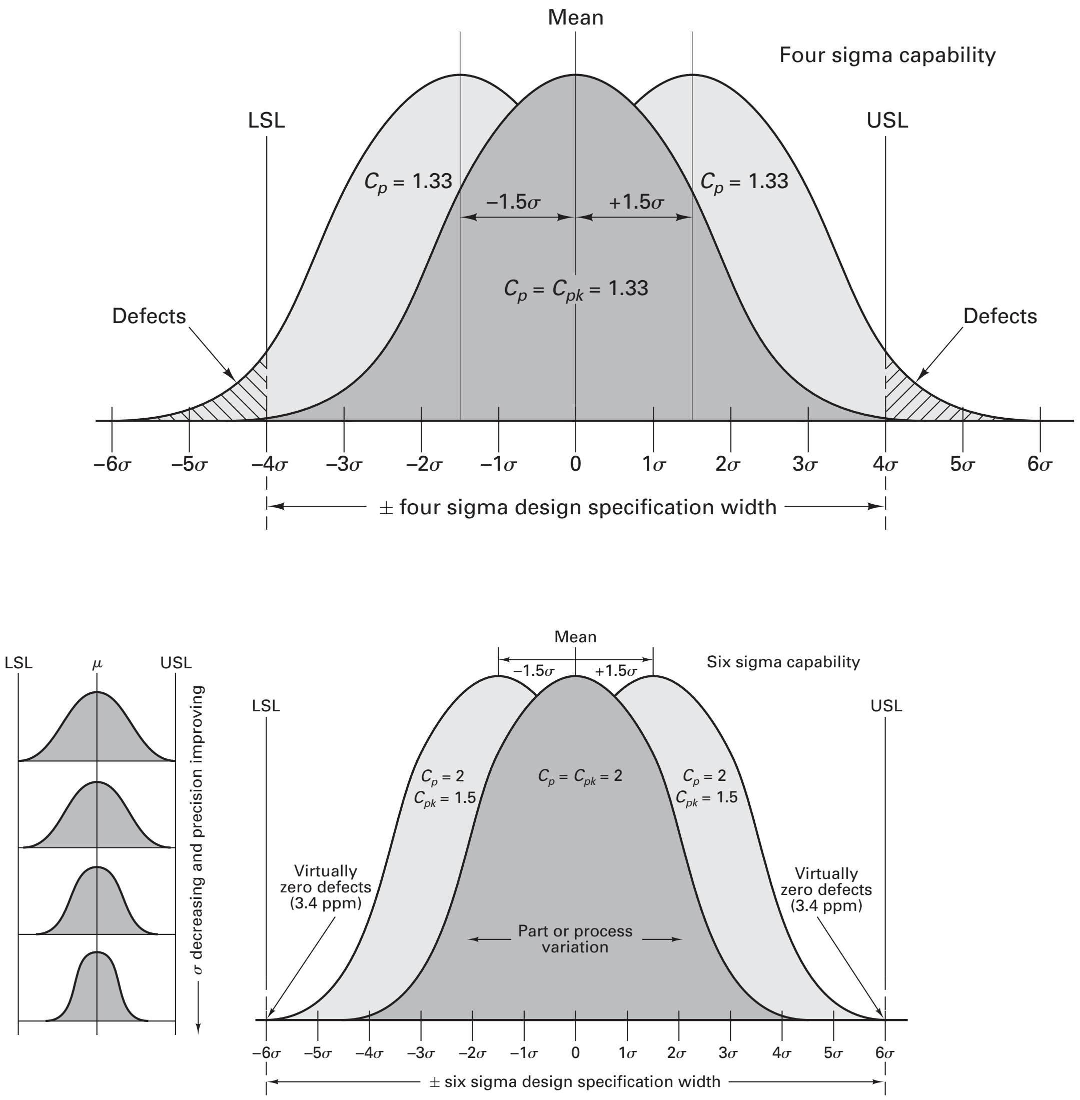


FIGURE 36-19 To move to six sigma capability from four sigma capability requires that the process capability (variability) be greatly improved (σ reduced). The curves in these figures represent histograms or curves fitted to histograms.

in their processes. This is probably because many manufacturing (mechanical) engineers have not had any coursework in this area.

Also, a change in company culture is often needed to give the responsibility for quality to the worker, along with the authority to stop the process when something goes wrong. An attitude of defect prevention and a habit of constant improvement of quality are fundamental to lean production, a system developed by Toyota. They have accomplished TQC (they call it company-wide quality control) by extensive education of the workers, giving them the analysis tools they need (control charts with cause-and-effect diagrams) to find and expose the problems. Workers are encouraged to correct their own errors, and 100% inspection (often done automatically) is the rule. Passing defective products on to the next process is not allowed. The goal is perfection. *Quality circles*, now popular in the United States, are just one of the methods used by Japanese industries to achieve perfection.

LINE STOP IN LEAN PRODUCTION

A pair of yellow and red lights hanging above the workers on the assembly line can be used to alert everyone in the area to the status of the processes. Many companies use Andon boards, which hang above the aisles. The number on the board reflects stations

TABLE 36-1 Total Quality Control: Concepts and Categories

TQC Category	TQC Concept
1. Organization	• Manufacturing engineering has responsibility for quality—quality circles
2. Goals	• Habit of improvement for everyone everywhere in the manufacturing
	• system
	• Perfection—zero defects—not a program, a goal
3. Basic principles	• Process control—defect prevention, not detection
	• Easy-to-see, quality—quality on display so customers can see and inspect processes—easy to understand quality
	• Insist on compliance with maintenance
	• Line stops when something goes wrong
	• Correct your own errors
	100% check in manufacturing and subassembly cells.
4. Facilitating concepts	• QC department acts as facilitator
	Audit suppliers
	Help in quality improvement projects
	Training workers, supervisors, suppliers
	• Small lot sizes through rapid changeover
	• Housekeeping
	• Less-than-full-capacity scheduling
	• Total preventive maintenance (TPM)
	• 8-4-8-4 two-shift scheduling
5. Techniques and aids	• Remove some inventory, expose problems, solve problems
	• Defect prevention, poka-yokes for checking 100% of parts
	• $n = 2$, for checking first and last item in lot (or $n = 3$, for large lots)
	• Analysis tools
	Cause-and-effect diagrams
	Histograms, and run charts, check sheets
	Control charts, ($\overline{X}$, R, σ)
	Scatter diagrams
	Pareto charts
	Process flow charts
	Taguchi and DOE methods

Source: Richard Schoenberger, 1983. Japanese Manufacturing Techniques.

on the line. A worker can turn on a yellow light when assistance is needed, and nearby workers will move to assist the worker having a problem. The line keeps moving, however, until the product reaches the end of the station. Only then is a red light turned on if the problem cannot be solved quickly and the line needs to be stopped. When the problem is solved and everyone is ready to go again, the red light goes off and everyone starts back to work, all in synch.

Every worker should be given the authority to stop the production line to correct quality problems. In systems using poka-yoke or automation, devices may stop the line automatically. The assembly line or manufacturing cell should be stopped immediately and started again only when the necessary corrections have been made. Although stopping the line takes time and money, it is advantageous in the long run. Problems can be found immediately, and the workers have more incentive to be attentive because they do not want to be responsible for stopping the line.

IMPLEMENTING QUALITY COMPANYWIDE

The basic idea of integration is to shift functions that were formerly done in the staff organization (called the production system) into the manufacturing system. What happens to the quality control department? The department serves as the facilitator and therefore acts to promote quality concepts throughout the plant. In addition, its staff educates and trains the workers in statistical and process control techniques and provides engineering assistance on visual and automatic inspection installations. Its most important functions will be training the entire company in quality control.

Another important function of the QC department will be to work with and audit the vendors. The vendor's quality must be raised to the level at which the buyer does not need to inspect incoming material, parts, or subassemblies. The vendor simply becomes an extension of the buyer's plant. Ultimately, each vendor will deliver to the plant perfect materials that need no incoming inspection. Note that this means the acceptable quality level (AQL) of incoming material is 0%. Perfection is the goal. For many years this country has lived with the unwritten rule that 2 or 3% defective was about as good as you could get: better quality just costs too much. For the mass-production systems, this was true. To achieve the kinds of quality that Toyota and many others have achieved, a company has to eliminate the job shop (a functional manufacturing system) and restructure the production system, integrating the quality function directly into the linked-cell manufacturing system, L-CMS.

The quality control department also performs complex or technical inspections, total performance checks (often called end item inspection), chemical analysis, nondestructive testing, X-ray analysis, destructive tests, and tests of long duration.

MAKING QUALITY VISIBLE

Visual display on quality should be placed throughout manufacturing facilities to make quality evident. These displays tell workers, managers, customers, and outside visitors what quality factors are being measured, what the current quality improvement projects are, and who has won awards for quality. Examples of visible quality are signs showing quality improvements, framed quality awards presented to or by the company, and displays of high-precision measuring equipment.

These displays have several benefits. When customers visit a plant to inspect processes, they want to see measurable standards of quality. Highly visible indicators of quality such as control charts and displays should be posted in every department. Everyone is informed on current quality goals and the progress being made. Displays and quality awards are also an effective way to show the workforce that the company is serious about quality.

SOURCE, SELF, AND SUCCESSFUL CHECKS AND POKA-YOKES

Many companies have developed an extensive QC program based on having many inspections. However, inspections can only find defects, not prevent them. Adding more inspectors and inspections merely uncovers more defects but does little to prevent them. Clearly, the least costly system is one that produces no defects. But is this possible? Yes, it can be accomplished through methods such as self and source inspection where quality control is in the hands of the operators.

Many people do not believe that the goal of zero defects is possible to reach, but many companies have achieved this goal or have reduced their defect level to virtually zero using techniques such as poka-yokes and source inspection. When you are inspecting to find defects, the components are compared with standards and defective items are removed. Sampling inspection is used when 100% inspection is not an option, but this assumes that defects are inevitable and that more rigorous inspection can reduce defects.

The truth is, to reduce the defects within a process, it must be recognized that defects are generated by the process itself and that most inspection techniques merely discover defects that already exist.

To achieve zero defects, a lean manufacturing concept must be developed where all operators are responsible for quality. You perform the following kinds of inspections:

- Successive checks, where the next operator checks the work of the previous worker
- Self-checks, where the operator checks his own work before passing it on
- Source inspection, where preventive action takes place at the error stage, to prevent errors from turning into defects

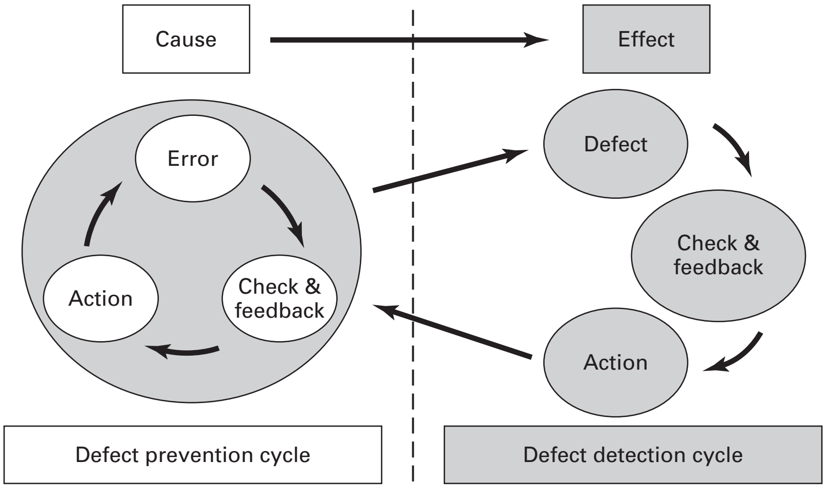

FIGURE 36-20 Source inspection involves defect prevention; that is, preventing errors from turning into defects. *(Source:* Achieving Zero Defects Mistake-Proofing—The Zero Quality Control System, *© 1999, Productivity, Inc. All rights reserved.)*

Source inspection (see Figure 36-20) involves rethinking the inspection part of the manufacturing process. First off, although it is necessary to have efficient inspection operations, they add little value in the product. Even the most efficient inspection operations are merely efficient forms of non-value-adding activity. Inspection plays a passive role in manufacturing and cannot by itself reduce defects.

Defects and *errors* are not the same thing in manufacturing. Errors can cause defects. For example, not setting the oven temperature correctly can burn the roast (too high) or cause it to be undercooked (too low). Incorrectly loading the original into the fax machine (the error) results in sending blank pages (the defect). When you discover the effect, you make corrections, but you have already spent the money to produce the defect. Table 36-2 outlines some common errors associated with manufacturing.

So *source inspection* looks for errors before they become defects. These techniques either stop the system to make corrections or automatically compensate or correct for the error condition to prevent a defective item from being made.

There are two ways to look at source inspections: vertically and horizontally. Vertical source inspections try to control upstream processes that can be the source or the cause of defects downstream. It is always necessary to examine source processes because they may have a much greater impact on quality than the processes being examined. Finding the source of a problem requires asking "Why?" at every opportunity. Here is an example.

Some steel bars were being cylindrically ground. After grinding, about 10% of the bars warped (bent longitudinally) and were rejected. The grinding process was studied extensively, and no sure solution was found. Looking upstream, a problem with the heat-treating process that preceded cylindrical grinding was detected. About 10% of the bars were not getting a complete, uniform heating prior to quench. Asking "Why?", it was found that these bars were always lying close to the door of the oven, and it was found that the door was not properly sealed, which resulted in a temperature gradient inside. Quenching of the bars induced a residual stress that was released by the grinding

TABLE 36-2 Common Errors That Can Produce Defects but Are Preventable

- Omissions in processing steps
- Errors in setting up the job in the machine
- Omission in the assembly process (missing parts)
- Inclusion of incorrect part
- Size errors due to wrong measurement
- Errors due to adjustments
- Errors in cutting-tool geometry or cutting-tool setting
- Errors in processing components (heat treating)

and caused the warping. Asking "Why?" at every opportunity uncovered the source of the problem.

Horizontal source inspections detect defect sources within the processes and then introduce corrections to keep from turning errors into defects. In metalcutting and forming, this is commonly called adaptive control (for preventing defects) or in-process quality control. One of the best ways to prevent errors from occurring is through the use of *poka-yokes*.

Poka-yoke is a Japanese word meaning "defect prevention." Poka-yoke devices and procedures are often devised mainly for preserving the safety of operations. The idea is to develop a method, mechanism, or device that will prevent the defect from occurring rather than to find the defect after it has occurred. Poka-yokes can be attached to machines to automatically check the products or parts in a process. Poka-yokes are source inspections that are usually attributes inspections. The production of a bad part is prevented by the device. Some devices may automatically shut down a machine if a defect is produced, preventing the production of an additional defective part. The poka-yoke system uses 100% inspection to guard against unavoidable human error.

Modern cars are equipped with many poka-yoke devices: you can't turn off the motor unless it is in park, you can't open a door while the car is moving, the headlights come on with the windshield wipers—all are devices to prevent you from making a mistake.

Such devices work very well when physical detection is needed, but many items can be checked only by sensory detection methods, such as the surface finish on a bearing race or the flatness of a glass plate. Variations in nonvisible conditions (air pressure, fluid velocity, temperature, electrical voltage, etc.) require detection devices where critical conditions are readily visible. For such problems a system of self-checks and successive checks can also be used.

TEAMS (AKA QUALITY CIRCLES)

Several popular programs are built upon the concept of participative management, such as quality circles, improvement teams, and task groups. These programs have been very successful in many companies but have failed miserably in others. The difference is often due to the way management implemented the program. Programs must be integrated and managed within the context of a lean manufacturing system design strategy. For example, asking an employee for a suggestion that management does not use (or cannot explain why it does not use) defeats a suggestion system. Management must learn to trust the employees' ideas and decisions and move the decision making to the factory floor.

A quality circle is usually a group of employees within the same department or factory floor area. Meetings are held to work on problems. An organization structure is usually composed of members, a team leader, a facilitator, a manufacturing engineer, and a steering committee.

Quality circles usually have the following main objectives: provide all workers with a chance to demonstrate their ideas; raise employee morale; and encourage and develop workers' knowledge, quality control techniques, and problem-solving methods. They also unify companywide QC activities, clarify managerial policies, and develop leadership and supervisory capabilities.

Quality circles have been implemented in U.S. companies with limited success when they are not part of a lean manufacturing strategy. It is possible for quality circles to work in the United States, but they must be encouraged and supported by management. Everyone must be taught the importance and benefits of integrated quality control.

SUPERIOR QUALITY IN MANUFACTURING/ASSEMBLY CELLS

In lean manufacturing subassembly and manufacturing cells, the cells are designed for a "make one–check one–move one on" (MO-CO-MOO) strategy. The part receives successive checks after each processing or assembly step. For *successive checks* to be successful, several rules should be followed. All the possible variables and attributes should not be measured, because this would eventually lead to errors and confusion in the inspection process. The part should be analyzed so that only one or two points are inspected after each step in the process. This is the heart of MO-CO-MOO. Only the most important elements just produced are inspected.

Another important rule is that the immediate feedback of a defect leads to immediate action. Since the parts are produced in an integrated manufacturing system, this will be very effective in preventing the production of more defective parts. Suppose the cell has only one or two workers and they are not in a position to directly check each other's work after each step. Here is where the decouplers can play an active role by providing automatic successive checking of the parts' critical features before proceeding to the next step. Only perfect parts are pulled from one process to the next through the decoupler.

In assembly lines, a worker may inspect each part immediately after producing it. This is called *self-checking*. There is an immediate feedback to the worker on quality. However, it would be difficult for many workers not to allow a certain degree of bias to creep into their inspection, whether they were aware of it or not, since they are inspecting their own work. Within cells operated by multiple workers, the operator of the downstream station or process can inspect the parts produced by the upstream operator. If there is a problem with the parts, the defective item is immediately passed back to the worker at the previous station. There the defect is verified and the problem corrected. Action is immediately taken to prevent any more defective parts. While this is going on, the line is shut down.

■ 36.6 SUMMARY

The designer of the product must have quality in mind during the quality design phase, seeking the least costly means to ensure the quality of the desired functional characteristics. Major factors that can be handled during the early stages of the product design cycle include temperature, humidity, power variations, and deterioration of materials and tools. Compensation for these factors is difficult or even impossible to implement after the product is in production. The distinction between superior- and poor-quality products can be seen in their variability in the face of internal and external causes. This is where Taguchi parameter design methods can be important.

The secret to successful process control is putting the control of quality in the hands of the workers. Many companies in this country are currently engaged in SQC (statistical quality control), but they are still inspecting to *find* defects. The number of defects will not be reduced merely by making the inspection stage better or faster or automated. You are simply more efficient at discovering defects. The trick is to *inspect* to *prevent* defects. How can this be done? Here are the basic ideas: Use source inspection techniques that control quality at the stage where defects originate. Use 100% inspection with immediate feedback rather than sampling. Make every worker an inspector. Minimize the time it takes to carry out corrective action. Remember that people are human and not infallible. Methods and devices can be developed to prevent them from making errors. Can you think of such a device? Does your car have a procedure that prevents you from locking the ignition keys inside the car? That is a poka-yoke.

Do not simply rely on inspection to control quality. Sorting to find defects by inspection is bad because you already paid to produce those defects.

Process improvement should drive toward defect prevention. In order to achieve the highest levels in quality, you have to implement a manufacturing system design (MSD) that has the highest objective (zero defects) built into (integrated into) the MSD.

Concentrate on making processes efficient, not simply on making the operators and operations more proficient. Continuous improvement requires that you redesign the manufacturing system continuously, reducing the time required for products to move through the system (i.e., the throughput time). This approach seems to be the American stumbling block. Industrial engineers can do operations improvement work such as buying a better machine or improving the ergonomics of a task. However, they need to do more systems improvement work. Too often fancy, complex, computerized solutions are devised to solve complex manufacturing process problems. Why not simplify the manufacturing system so that the need for complex solutions disappears?

Key Words

accuracy
control chart
control limits
fishbone diagram
histogram
nominal
parent population
poka-yoke
precision
process capability (PC)
quality control (QC)
range (R)
sample mean ($\overline{X}$)
sample size (n)
self-checking
source inspection
specification limit
standard deviation (σ)
statistical process control (SPC)
Taguchi methods
total quality control (TQC)
variability

Review Questions

1. Define a process capability study in terms of accuracy or precision.
2. What does the *nature of the process* refer to?
3. Suppose you have a "pistol-shooting" process that is accurate and precise. What might the target look like if, occasionally while shooting, a sharp gust of wind blew left to right?
4. What are the steps required to making a PC study of a process?
5. Why don't standard tables exist detailing the natural variability of a given process, such as rolling, extruding, or turning?
6. What are Taguchi or factorial experiments, and how might they be used to do a process capability study?
7. How does the Taguchi approach differ from the standard experimental method outlined in this chapter?
8. Why are Taguchi experiments so important compared to classical DOE-type experiments?
9. Here are some common, everyday processes with which you are familiar. What variable or aspect to the process might dominate the process in terms of quality, not output?
   a. Baking a cake (from scratch) or grilling a steak
   b. Mowing the lawn
   c. Washing dishes in a dishwasher
10. Explain why the diameter measurements for holes produced by the process of drilling could have a skewed rather than a normal distribution.
11. Name some common manufactured items that may receive the following:
    a. 100% inspection
    b. No final inspection
    c. Some final inspection, that is, sampling
12. What are common reasons for sampling inspection rather than 100% inspection?
13. Fill in this table with one of the four following statements: no error—the process is good; no error—the process is bad; type I or alpha error; type II or beta error.

		In reality, if we looked at everything the process made, we would know that it had:	
		changed	not changed
The sample suggested that the process had:	changed		
	not changed		

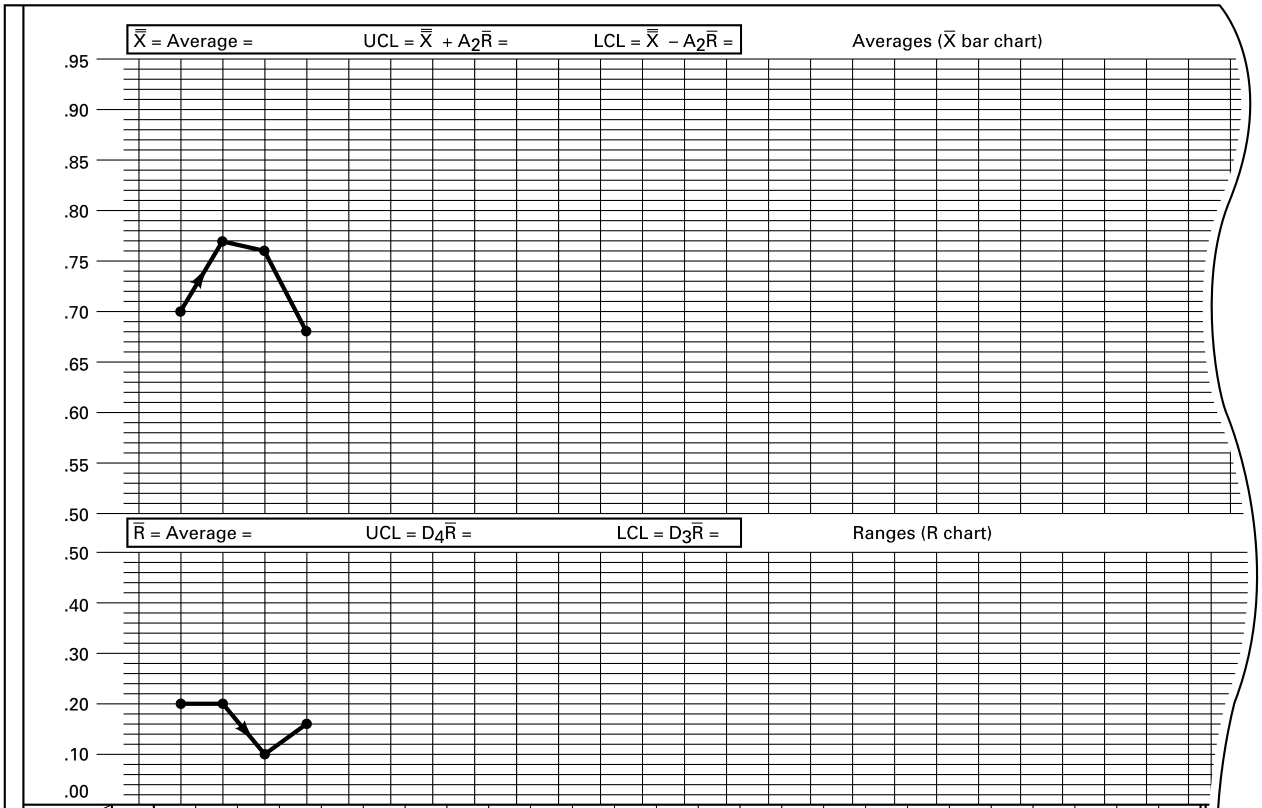
14. Explain why, when we sample, we cannot avoid making type I and type II errors?
15. Which type of error can lead to legal action from the consumer for a defective product that caused bodily injury?
16. Define and explain the difference between each of these:
    a. σ and $\sigma_{\overline{X}}$
    b. σ and $\overline{\sigma}$
    c. $\sigma_{\overline{X}}$, σ_R, and σ_σ
17. What is C_p, and why is a value of 0.80 not good? How about a value of 1.00? 1.3?
18. The designer of a component usually sets the nominal and tolerance values when designing the part. How do these decisions affect the decisions of the manufacturing engineer (MfE)?
19. What are some of the alternatives available to you when you have the situation where $6\sigma > \text{USL} - \text{LSL}$?
20. C_{pk} is also a process capability index. How does it differ from C_p?
21. In a sigma chart, are values for the samples normally distributed about $\overline{\sigma}$? Why or why not?
22. What is an assignable cause, and how is it different from a chance cause?
23. Why is the range used to measure variability when the standard deviation is really a better statistic?
24. How is the standard deviation of a distribution of sample means related to the standard deviation of the distribution from which the samples were drawn?
25. In the last two decades, the quality of automobiles has significantly improved. What do you think is the main cause for this marked quality improvement?
26. Figure 36-12 shows a bimodal check sheet indicating that the two operators performing an assembly task (in a cell) do the jobs at different rates. What would you recommend here?
27. Control charts use upper and lower control limits. Is a UCL the same as a USL?
28. In Figure 36-14, what are the USL and the LSL and why are they *not* shown on the charts?
29. What are four major branches (fishbones) on a cause-and-effect diagram?
30. How does variation in the measuring device (instrument) affect the measurements obtained on a component?
31. Explain what happed to improve the process in Figure 36-18.
32. In Table 36-1, explain these:
    a. MO-CO-MOO
    b. 8-4-8-4 scheduling
    c. $n = 2$ inspection
    d. Pareto chart
33. What is a quality circle, and how might you apply this concept to your college life?

■ Problems

1. For the items listed in the following chart, obtain a quantity of 48. Measure the indicated characteristics and determine the process mean and standard deviation. Use a sample size of 4, so that 12 samples are produced.

Item	Characteristic(s) You Can Measure
Flat washer	Weight, width, diameter of hole, outside diameter
Paper clip	Length, diameter of wire
Coin (penny, dime)	Diameter, thickness at point, weight
Your choice	Your choice

2. Perform a process capability study to determine the PC of the process that makes M&M candy. You will need to decide what characteristics you want to measure (weight, diameter, thickness, etc.), how you will measure it (use rule of 10), and what kind of M&Ms you want to inspect (how many bags of M&Ms you wish to sample). Take sample size of 4 ($n = 4$). Make a histogram of the individual data and estimate μ and σ as outlined in the chapter. If you decide to measure the weight characteristics, you can check your estimate of μ by weighing all the M&Ms together and dividing by the total number of M&Ms.
3. For the data given in Figure 36-4, compute the mean and standard deviation for the histogram and then C_p and C_{pk}, making any assumptions needed to perform the calculations.
4. For the data given in Figure 36-7, compute C_p and C_{pk}.
5. Calculate $\overline{\overline{X}}$ and $\overline{R}$ and the control limits for the $\overline{X}$ and R control charts shown in Figure 36-A. The sample mean, $\overline{X}$, and range, R, for the first few subgroups and the data for each sample are given in the bottom of the figure. There are 25 samples of size 4. Therefore $k = 25$, $n = 4$. Complete the bottom part of the table and then compute the control limits for both charts. Construct the charts plotting $\overline{\overline{X}}$ and $\overline{R}$ as solid lines and control limits as dashed lines, as shown in Figure 36-14. The first four data points have been plotted and the points



Date / Time	6/8				6/9 8	10	12	2	6/10 8	10	12	2	6/11 8	10	12	2	6/12 8	10	12	2	6/15 8	10	12	2	6/16 8
Readings 1	.65	.75	.75	.60	.70	.60	.75	.60	.65	.60	.80	.85	.70	.65	.90	.75	.75	.75	.65	.60	.50	.60	.80	.65	.65
2	.70	.85	.80	.70	.75	.75	.80	.70	.80	.70	.75	.75	.70	.70	.80	.80	.70	.70	.65	.60	.55	.80	.65	.60	.70
3	.65	.75	.80	.70	.65	.75	.65	.80	.85	.60	.90	.85	.75	.85	.80	.75	.85	.60	.85	.65	.65	.65	.75	.65	.70
4	.65	.85	.70	.75	.85	.85	.75	.75	.85	.80	.50	.65	.75	.75	.75	.80	.70	.70	.65	.60	.80	.65	.65	.60	.60
Sum	2.65	3.20	3.05	2.75																					
$\overline{X} = \frac{\text{Sum}}{\text{No. of readings}}$	.66	.80	.76	.69																					
R = Highest–Lowest	.05	.10	.10	.15	.20	.25	.15	.20																	

* For sample sizes of less than seven, there is no lower control limit for ranges.

For first subgroup:
Sum = .65 + .70 + .65 + .65 = 2.65
$\overline{X}$ = 2.65 ÷ 4 = .6625
R = .05

FIGURE 36-A

connected, but are they all correctly plotted? Replot any points that are incorrectly plotted. Plot the rest of the data on the charts and comment on your findings. (Use Figure 36-14 as a comparison.)

6. For the data given in Figure 36-A, estimate the mean and standard deviation for the process from which these samples were drawn (i.e., the parent population) and discuss the process capability in terms of C_p and C_{pk}. The USL and LSL for this dimension are 0.9 and 0.5, respectively, and the nominal is 0.7.
7. Figure 36-B contains data from a machining process that produces holes (drilling) with limits of 6.00 to 6.70 mm. The control charts for $\overline{X}$ and R using $n = 5$ and $k = 25$ are also shown in the figure. (*Note*: The numbers in the body of the table are 6.47, 6.19, 6.19, 6.29, etc.)
   1. Recheck the calculation of the mean values and the range values for the 25 samples and then check the calculations for $\overline{\overline{X}}$ and $\overline{R}$ and the control limits for the charts.
   2. Insert the centerlines for $\overline{\overline{X}}$ and $\overline{R}$ on the charts.
   3. Check the plotting of the points on the charts.
   4. Discuss the charts.
   5. Using the data to develop the process capability indexes and discuss the capability of this process.
   6. Using the data $n = 5$ and $k = 25$, develop the σ control chart and use σ to estimate σ for the process capability indexes and C_p and C_{pk}.
   7. Develop $\overline{X}$ and R charts for sample sizes of 4 (or 3) by ignoring X_5 (X_3 and X_5) or any combination of individual values. Use the charts to perform a process capability study. Did the findings change?

Product name	Cylinder	Samples	Sample size	3, 4 or 5	Period	1996, 10.15	$\overline{X}$ Control chart	R Chart

Chapter 36 CASE STUDY

Boring QC Chart Blunders

You have recently been hired by the Pippen Company as the 6 sigma Black Belt. Your new boss, Gabby Sorenson, has one of the leading textbooks in manufacturing engineering (NOT DeGarmo) and she shows you this problem. After reading the discussion and studying the figure, Gabby asked you the following questions.

1. What kind of control chart is this?
2. What do you estimate the standard deviation (a') of the parent population to be, assuming that the control limits on this chart are based on three sigma?
3. Is the dashed line in the figure labeled “mean” the mean or the average? (The mean is X and is equal to 0.00017.) What is the line really called?
4. From the information given in the discussion and in the figure, determine the values of C_p and C_{pk}.
5. What is the most glaring error in the figure (Hint: something one never does with control charts) and why is it so wrong?

Example: Maintaining accuracy in boring using control charts.

The workpiece shown in Figure CS 36 is made of gray cast iron and is bored to the tolerances indicated (5.5125/5.5115 in.).These parts were bored on a chucking machine. Each of the 19 points plotted on the vertical axis of the control chart represents the average of bore diameter measurements made on four parts (sample size). The horizontal broken lines at +0.0005 and 0.0005 represent upper and lower specified limits, respectively. The solid line X= 0.00017 in. is the estimate of the process capability based on a study of several samples bored on the machine. The upper and lower control limits are then calculated from X . We note that samples 4–9 show a definite trend toward undersized bored holes. If the operation had been continued without any changes, the successive bored holes very likely would have been out of tolerance. To avoid this situation (out of control), the boring tools were reset toward the upper control limit before parts in sample 10 and the rest were bored. *(Source: ASM International.)*

INDEX

FUNDAMENTAL MANUFACTURING PROCESSES DVD

John Wiley & Sons and the Society of Manufacturing Engineers are pleased to include a DVD based on the SME Fundamental Manufacturing Processes video series. The DVD highlights a number of the most important manufacturing processes. Each excerpt provides approximately five minutes of footage to help visualize the concepts discussed in this book. The topics covered are as follows:

MACHINING PROCESSES

1. Turning & Lathe Basics
2. Milling & Machining Center Basics
3. Basic Holemaking
4. Basics Of Grinding
5. Electrical Discharge Machining
6. Cutting Tool Materials

FORMING PROCESSES

7. Sheet Metal Shearing And Bending
8. Sheet Metal Stamping Dies & Processes
9. Casting
10. Die Casting
11. Powder Metallurgy
12. Forging

PLASTIC PROCESSES

13. Plastic Injection Molding
14. Plastic Blow Molding
15. Composite Materials & Manufacturing
16. Plastics Finishing Processes

ADDITIONAL PROCESSES

17. Introduction To Workholding
18. Computer Numerical Control
19. Measurement & Gaging
20. Gears & Gear Manufacturing
21. Heat Treating
22. Welding

The Fundamental Manufacturing Processes series features 35 full-length programs available on either DVD or VHS. For more information on the complete FTP series please visit the Society of Manufacturing Engineers at www.SME.org/videos/.

Solutions Manual by
Barney E. Klamecki

WILEY

Contents

Preface

This version of the textbook contains significant new content and, so then, does the Solution Manual. These notes are provided to explain some aspects of the new content.

The authors of the textbook prepared the new content for the book, including all new questions and problems. I prepared only the answers to the new questions and solutions for the new problems.

Many of the questions are broad, open-ended and raise real, practical concerns. The answers that I have prepared are intended to directly address the important concepts raised and provide some of the thought process leading to the answers. Where example applications of the concepts are provided these are intended to be starting points for consideration and discussion, not final, definite or unique answers.

Some internet web sites are suggested as example sites containing useful information. These are only suggestions as typical starting points for more in-depth investigation of the questions raised. I am always hesitant to refer to internet web sites since often the updating of them, and sometimes their continued existence, is problematic. Perhaps the best way to view the inclusion of a web site in the Solution Manual is as an indication of questions that are more open-ended and may require more material than is in the text for preparing answers.

For the new quantitative problems and some of the problems from previous editions of the text I have used spreadsheets to produce solutions. The intent is to provide the opportunity for users of the text to customize these problems. Problem variables and variable values can be changes with little effort. The difficulty is that to provide this capability specific software must be used since writing code that can be used on most computers is not warranted. Microsoft Excel 97 was used. In any case, the solutions are also provided in fixed form.

Some question answers were put in the form of tables so that it is possible to slightly manipulate the questions. For example, various table cells can be cleared and fill-in-the-blank questions formulated. Microsoft Word 97 was used for the Solution Manual text.

CHAPTER 1
Introduction to Materials and Processes in Manufacturing

Review Questions

1. The availability and cost of manufactured products are an important part of our cost of living and the real wealth of the nation. Thus, reducing the cost of producer and consumer goods improves the productivity while holding down inflation, thereby improving the general standard of living.

2. This is true if you consider that everyone who used the output from a process, including all the intermediate steps, is a customer. The operator of the next process is the user and customer of the proceeding process. In fact, some companies identify two customers, the external customer who buys the finished product and the internal customer, who builds the product one - i.e., the people who work in the manufacturing system. See Chapter 43

3. Job shop - an injection mold manufacturing shop, the shop at a large university that produces research equipment and apparatus. Job shops are capable of producing products with great variety, typically employing highly skilled workers.
Flow shop – automobile assembly. Flow shops are usually laid out so that specific products pass through a series of operations with no backflow. The product range is limited, production volume is large and labor skill is lower than in job shops.
Project shop – diesel-electric locomotive production facility. The end product is very large and so many machines, tools and people come to the product to produce it at a relatively fixed location.

4. In the context of manufacturing, a manufacturing system is a collection of men, machine tools, and material-moving systems, collected together to accomplish specific manufacturing or fabrication sequences, resulting in components or end products. The manufacturing system is backed up by and supported by the production system, which includes functions like control of quality, inventory, production, and manpower, as well as scheduling, planning and the like. Within the manufacturing system, there will be machine tools, which can perform jobs or

5. No. The cutting tool is the implement that does the cutting. It contains the cutting edge and is used in the machine tool. The machine tool drives the cutting tool through the work material.

6. The basic manufacturing processes are: casting or molding, forming, (heat) treating, metal removal, finishing, assembling, and inspection.

7. By casting, the desired shaped in final or near-final form, could be obtained. This greatly reduces the necessity for machining the hard-to-machine metal. Less machining

is needed when the raw material shape is close to the finished part size and shape (called near net shape casting).

8. The foam is melted and vaporized and so moves into the atmosphere around the process.

9. The cavity in the die that the work material is deformed into when the die is pressed into the workpiece. Material on the workpiece moving into the cavity, “concave,” of the die results in the raised, “convex,” part of the medal surface.

10. Trains stop at the station to load and unload people and materials. In an assembly line, products stop at the job station to take on materials or have operations performed on them.

11. False. Storage is very expensive because time costs the company money. It is expensive to keep track of stored materials, to put them into storage, to get them back from storage, to damage them as a result of excessive handling, and so on. More importantly, storage usually adds no value - very few items appreciate on the shelf.

12. For the simple, conventional paper clip, wire is cut to length and then formed in three bending operations.

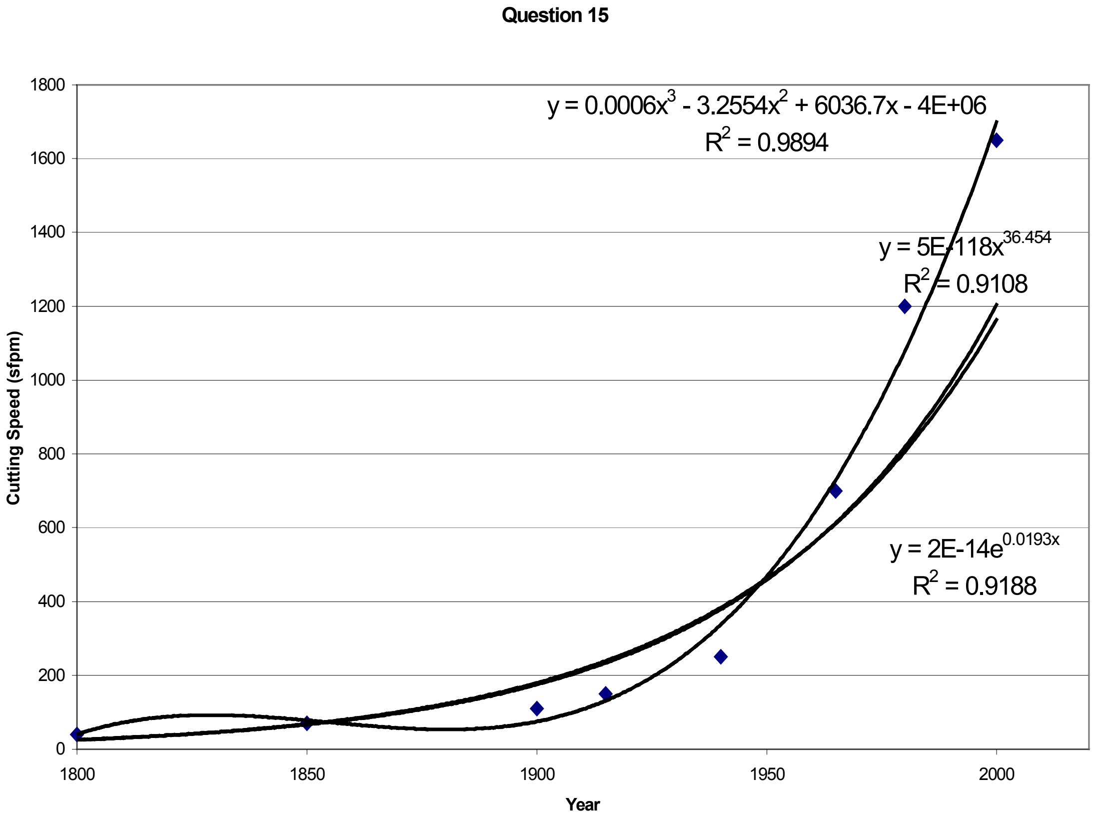
13. The university is an example of a service job shop and shows that value can be added by service processes and operations --the student enters engineering worth the minimum wage and graduates worth $15 to $20/hour. In the university job shop, the professors are the machine tool operators, the students are the workpieces, courses are the processes, tests are the inspections, books are the tooling, and department heads are the foremen.

14. Inefficient is a relative term here. If we can eliminate machining, we can save the time and the money. Machining processes are generally those which give the part its final size, shape, and surface finish and add value to the part. Because they do not produce the shape and size in bulk, but rather by localized action they may not be as efficient as forming and casting processes.

15. For the following set of data estimated from Figure 1-1

Year	**Speed**
1800	40
1850	70
1900	110
1915	150
1940	250
1965	700
1980	1200
2000	1650

fitting the data, shown as diamonds, to polynomial, power and exponential forms gives



The coefficients in the equations have little meaning since equations are a fit of cutting speed to years. The form of the equations shows a rapid rise, and an "exponential growth" conveys this idea.

16. The cost to manufacture a typical manufactured product is 20% - 30% of the selling price. For the mass produced product at the lower end of this range the manufacturing cost is \$0.20. These 20 cents includes material and processing costs. Processing includes assembly in addition to producing the components. Since the blade cost involves forming the edge in a material it is probably the highest cost part of the razor.

So, with 20 cents to cover materials, processing and assembly, and the blade the most expensive individual part an estimate of 2-3 cents is reasonable for the production of the high precision (in terms of edge) blade.

The same kind of reasoning can be used with manufacturing cost being 40% of selling cost as suggested in Problems 1 and 2.

17. Packaging is used to protest the product from the environment, to protect the product during shipping and to hold fixed numbers of products for sale.

18. Assembly of a binder type paper clip involves putting the formed wire handles in to the spring steel binder part of the clip. Assembly of bicycle wheels involves putting spokes into the wheel and hub.

If the ingredients of the club sandwich are all in their finished state then they can be assembled. If processing is necessary as in slicing meats and tomatoes and toasting bread, then the entire process is more than just assembly.

House building is usually considered construction as large parts of the effort involve manufacture of elements of the house – before they are assembled. For example, foundations are poured and let solidify before the sills for the walls are assembled to them. Houses that are simple in design and composed of large elements that are manufactured in factories can be viewed as assembly on-site. For example, assembly of entire wall sections and trusses to support roofs.

19. The physical elements of a manufacturing system are the machines, tools and inspection equipment used to produce the product. They are characterized by having measurable parameters. For example machine tools are characterized by the size of the workpiece that can be processed, in addition to a large number of other characteristics. Tools are described by their shape. Measuring and inspection instruments have measurement resolution limits. Measurable parameters extend past machine specifications to higher level (involving more than one aspect of part production) descriptions of the process such as production rates. The manufacturing system is more than the physical elements. Support and control systems, along with the physical elements, are combined in the manufacturing system.

20. The manufacturing engineer is responsible for selecting or designing and overseeing operation of the manufacturing processes. In the sense of immediate contact with processes the manufacturing engineer is often the center of "making the product." However, the decisions made by part and product designers and materials engineers have large influences on the kind of processes that can be used to make the part. How the part can be made is constrained by part design and materials used. So, all individuals who make decisions that determine manufacturing process choice should be involved in figuring out how to make the part.

21. Three general kinds of information are missing from Figure 1-6 that are contained in Figure 1-8.
1. The number and activities of the workers,
2. The measurable parameters that can be used to evaluate the operation,
3. The general view that the system in Figure 1-8 is designed for a certain product and so is more specific in design and operation than the manufacturing job shop shown in Figure 1-6.

22. This is really a discussion question to get the students to be aware of all the things involved in characterizing a process technology. The extrusion process results when the pressure applied to a material exceeds its flow strength. Sufficient energy must be applied to overcome friction, so lubrication is very important. The tooling is generally very expensive. A single die may cost $5000 and setup time can be long. The process usually produces 10 to 25 surface feet per minute of material. The critical process parameters are temperature and pressure, the material being extruded, lubrication, and extrusion rate. Some metals cannot be extruded very well. The process is constrained by

the power available and the size of the billets --i.e. the standard process is not continuous. The process operates reliably but users should always be aware of the high pressures involved in upsetting the materials. Operator skills are not critical and the process is semiautomatic. The process can do a wide variety of parts, depending only on the die design. It is hard to do hollow extrusions. Extrusion as a process is typically good to a tolerance of about 0.001 or 0.002 inches.

23. The emphasis of the question is on assembly and so can be answered relatively simply since assembly means interconnecting finished products or subassemblies. That is, automobile assembly is a series of steps in which the chassis/frame is populated with an engine, drive train, wheels/tires, seats, body panels, windows, etc. This is in contrast to manufacturing of parts such as engine blocks, crankshafts, pistons, camshafts, etc. that are then assembled into an engine, that is then used in assembling the automobile.

24. Production planning is deciding what should be done and how it should be done, what machines should be used, in what sequences, to make a part, and how these machines should be tooled, set-up, and operated. Scheduling is deciding when the production should take place, and therefore, when parts and products should be completed and ready for sale. Without these kinds of critical functions in the production system, the manufacturing system would grind to an inefficient halt.

25. How would a bumper have to be redesigned to provide the equivalent strength? What other components would have to be redesigned? What additional or different processing equipment, including finishing equipment, would be needed? Would the aluminum bumper satisfy the safety requirements (5 mph crash test) needed by the car? What are the costs savings produced by this change?

26. It is almost impossible to fabricate a low-cost item that is poorly designed and do it in an economical way. It must be designed so that it is easy to produce if it is going to be inexpensive (i.e. it has producibility). Thus, this statement is true.

27. Operations like load and unload parts from the machine, change the machine over from one part design to another (this is called set up), and change the tooling in the machine all add no value.

28. The rolls produce many feet of sheet metal that end up in many cars, so the fixed costs (like the rolls) are spread out over many sheets (feet) of metal. Thus the cost of sheet metal per car may be 50 to 100 dollars before the metal is formed into fenders and door panels.

29. Insurance, health, entertainment, sporting events, transportation, lodging, banking, communications, education, etc. are examples of service industries -- anything bought or sold in trade that cannot be dropped on your foot. Service industries worry about productivity, quality, and economic output just as much as manufacturing industries.

30. Disassembling it adds costs and value - you want the cuts of meat, not the whole animal. You are adding value to the cow when you are raising it and feeding it, so it becomes more valuable in the market. You add cost, not value when you ship the cow to the market.

31. At different levels of specification detail, hot isostatic pressing is
- a unit manufacturing process,
- a hot working process,
- a material consolidation process,
- a powder material processing technique.

32. The selling price is determined by the marketplace and what the customer will pay. The best way to improve profit is to reduce manufacturing costs per unit. This can be difficult to do when the price keeps going up.

33. The manufacturing cost for an assembled product, e.g., a car, is made up of materials (raw materials, cutting tools, purchased parts and components and their storage and handling), direct labor, indirect labor (people who work in the manufacturing system but don't work directly on the product – the car), and energy and depreciation (machines and tooling).

34. A start point for answering the question is to consider the shape of different regions of the product, Figure 1-10, and the shapes that are produced by the machining processes, Figure 1-14.
Starting with a rough cylindrical workpiece that may have been produced in a drawing or rolling operation, an overview of the machining processes starting at the top of Figure 1-14 is,
- lathe turning to produce a cylindrical workpiece,
- center drilling of end,
- a facing operation on the end of the workpiece,
- lathe turning to produce diameters and flats,
- milling to produce slot and flats,
- drilling (and perhaps reaming) of holes.

35. Product lifecycle is composed of startup, rapid growth, maturation, commodity or decline.

36. Figure 1-15 shows lifecycle phases for an existing product and includes manufacturing cost and sales volume. Before the product exists design and development costs accrue and are not shown. With product in existence use, repair and disposal costs arise.

37. To use the concepts presented in Figure 1-17 the type of components and required production rates have to be specified.
Say, two 8-hour shifts and 250 working days per year, then

Production rate of 16,000 parts/year = (16,000 parts/year)(year/250 days)(day/16 hours) = 4 parts/hour.
The lower part of Figure 1-17 shows that for part variety of 10 and 4 parts per hour production rate there is significant overlap of the system possibilities of 1) flexible manufacturing system, 2)manned and 3) unmanned cells, 4) CNC equipped job shop.

Problems

1. Solution is provided in text and is/should be
% Direct labor = [(labor cost) / (manufacturing cost)] 100%
labor cost = (20 hours)($30/hour) = $600
manufacturing cost = assumed 40% of selling price = (0.40)($16,000) = $6,400
% Direct labor = (600 / 6400) 100% = 9.4%

Production rate = (150,000 vehicles/year)(year/300 days)(day/8 hours) = 62 trucks/hour

2. Redesign of stapler:

The redesign of an existing product can involve
- redesigning individual parts to perform better,
- eliminating parts,
-- by combining existing parts into a new part
-- by replacing part function such as replacing fasteners with snap fits
- changing material

One way to formulate a problem solution is to use a table to summarize the potential for redesign.

		Possible Design Change			
Part	Function	Combine	Eliminate	Material	New design

CHAPTER 2
Properties of Materials

Review Questions

1. Metallic materials typically possess the properties of luster, high thermal conductivity, high electrical conductivity, and ductility.

2. There are several classes of nonmetallic materials and more or less specifically defined examples can be given in these classes. For example,
Polymers or plastics – polyethylene, polypropylene, epoxy.
Ceramics – aluminum oxide, silicon nitride.
Amorphous materials – glass, borosilicate glass
Organic materials – wood, oak wood
Inorganic materials – stone, granite

3. Some common physical properties of metals include:
density or weight, melting point, optical properties (such as transparency, opaqueness or color), thermal properties (such as specific heat, coefficient of thermal expansion and thermal conductivity), electrical conductivity and magnetic properties .

4. The results of standard tests apply only to the specific test conditions that were employed. Since actual service conditions rarely duplicate the conditions of laboratory testing, caution should be employed.

5. The standard units for reporting stress in the English system is pounds per square inch (psi) , and in the metric system, it is megapascals (MPa). Being the ratio of one length to another length, strain is a dimensionless number. However, it is usually reported in terms of millimeter per meter, inch per inch, or strict percentage.

6. Modulus of elasticity is a material property that describes the elastic behavior of a material. It is useful for describing the elastic response of a material and quantities related to elastic behavior. Examples are the deflection of a material subjected to loading that does not cause plastic deformation and the resilience of a material.

Resilience is the energy absorbed by a material in the elastic range. For uniaxial tension it is the area under the elastic part of the stress-strain curve and so is $(1/2)\ \sigma_Y\ \varepsilon_Y$, with σ_Y and ε_Y being the yield stress and strain at yield. Using $\sigma_Y = E\ \varepsilon_Y$ shows that resilience depends on E.

7. The elastic-to-plastic transition can be designated in a variety of ways. If the transition is a distinct one, it is known as yield point, with the highest stress preceding the plastic strain being called the upper yield point, and the lower, "runout" value is the lower yield point. If the transition is not distinct, it is DEFINED through the concept of offset yield

strength, the value of the stress associated with a specified, but tolerable, amount of plastic strain.

8. The percent elongation at fracture in a tensile test can be used as a measure of ductility. Also, the percent reduction of cross sectional area can be used. These two quantities are not directly related to each other since the cross section area changes in an unknown way in the necked region of tensile specimens loaded to fracture.

9. In many cases, material "failure" is defined as the onset of localized deformation or necking. Since additional plastic deformation after necking would occur after "failure", it would be more appropriate to measure and report the uniform elongation (or the percent elongation prior to necking) .

10. Brittleness should not be equated with a lack of strength. Brittleness is simply the absence of significant plasticity. Many brittle materials, such as glass and ceramics can be used to impart significant strength to reinforced composites.

11. Toughness is defined as the work per unit volume required to fracture a material, and can be used as one measure of a material's ability to absorb energy or impacts without cracking or breaking. Plastic deformation occurs during the measurement of toughness, whereas resilience requires the material to remain elastic.

12. True stress considers the load as being supported by the actual area of the specimen and is a true indication of the internal pressures. Engineering stress is simply a normalizing of the load, dividing it by the original cross-sectional area of the specimen, i.e. dividing it by a constant. While easy to obtain, the engineering stress has little, if any, physical significance when the actual area is different from the original.

The true, natural, or logarithmic strain is calculated by taking the natural logarithm of the current length divided by the original length, which is the sum of all of the incremental changes in length divided by the instantaneous length. It has the attractive property of being additive, i.e. the sum of the incremental strains is equal to the total strain from start to finish. Engineering strain, on the other hand, simply divides the elongation by a constant, the original length. While mathematically simple, the resultant value is not additive and has meaning only in reference to the original shape.

13. Strain hardening or work hardening is the term used to describe the phenomenon that most metals actually become stronger and harder when plastically deformed. In deformation processes, this means that further deformation will generally require greater forces than those required for the initial deformation. Moreover, the product will emerge stronger than the starting material. Prom a manufacturing perspective, this means that the material is becoming stronger as it is being converted into a more useful shape -- a double benefit. One method of measuring and reporting this behavior is through the strain hardening exponent, n, which is obtained by fitting the true stress-true strain data to the equation form:

$$\sigma = K\,\varepsilon^n$$

14. The hardness of materials has often been associated with the resistance to permanent indentation under the conditions of static or dynamic loading. Other phenomena related to hardness include the resistance to scratching, energy absorption under impact loading, wear resistance, and resistance to cutting or drilling .

15. Brinell Harness Test
(If test surface is rough, it must be made smooth usually by abrasive finishing. This is done in a series of progressively less severe steps to minimize changes in surface properties.)
Select indenter diameter to be used - larger ball for softer materials,
Select load to be applied – larger load for harder materials,
Apply load and hold for specified time,
Remove load,
Measure indentation diameter,
Calculate hardness as load over indentation surface area, or use compiled tabular measured diameter-Brinell Hardness Number data.

16. The test conditions along with the measured Rockwell Hardness Number should be reported. This is usually done by using a specific, standard, Rockwell hardness designation such as R_C60. The Rockwell Harness Number is given, 60 in this case, and the testing conditions are indicated by the “C.” The testing condition include the type of indenter, the major and minor loads and the type of test (standard or superficial with the superficial hardness tests usually indicated by “T”).

17. The various microhardness tests have been developed for applications where it is necessary to determine the hardness of a very small area of material or the hardness of thin material where one wishes to avoid any interaction with the opposing surface and support material.

18.There are a wide variety of hardness tests and they often evaluate different phenomenon: i.e. resistance to permanent or plastic deformation, scratch or wear resistance, rebound energy, and elastic deformation. All results are termed "hardness", but little correlation is expected.

19.There is often a direct correlation between penetration hardness and tensile strength. For plain carbon and low-alloy steels, the tensile strength in pounds per square inch can be estimated by multiplying the Brinell hardness number by 500. For other materials, the relationship may be different.

20.The compression test is more difficult to conduct than the standard tensile test. Test specimens must have larger cross-sectional areas to resist buckling. As deformation proceeds, the cross section of the specimen increases, producing a substantial increase in the required load. Frictional effects between the testing machine surfaces and the end surfaces of the specimen will tend to alter the results if not properly considered.

21. Dynamic loads change over time such as in impact and cyclic loading. Cyclic loading can be reversed type loading as in tension-compression or only changing magnitude as in tension-tension. Dynamic loading usually refers to relatively short term changes in load.

22. The two most common bending impact tests are the Charpy test and the Izod test. The Charpy test loads the specimen (usually notched) in three-point bending. The Izod test loads the specimen in a cantilever fashion.

23. Designers should use extreme caution when applying impact test data for design purposes because the test results apply only to standard specimens containing a standard notch loaded under one condition of impact rate. Modifications in specimen size, the size and shape of the notch, and speed of the impact can produce significant changes in the results.

24. Endurance limit / tensile strength ratios are given in Table 2-3. The table if data show that this ratio varies with material and so no universal relationship between endurance limit and tensile strength exists. A very rough estimate is that endurance limit is about one-half the tensile strength.

25. Fatigue strength is the stress that a fatigue specimen was capable of withstanding for a specified number of load cycles, and therefore refers to any point on a standard S-N plot. Endurance limit or endurance strength, on the other hand, is the limiting stress level below which the material will not fail regardless of the number of cycles of loading.

26. Several factors can drastically alter the fatigue properties of a material. One dominant factor is the presence of stress raisers, such as small surface cracks, machining marks, or gouges. Other factors include the temperature of testing, variation in the testing environment (such as humidity or corrosive atmosphere), residual stresses, and variations in the applied load during the service history.

27. For steels, the endurance limit can be approximated as 0.5 times the ultimate tensile strength as determined by a standard tensile test.

28. Initiation of a fatigue crack involves the development of high stress in a very small, local region of the material. So, any part/loading situations that give rise to high local stresses will tend to cause fatigue crack initiation and these extend all the way from microscopic inherent characteristics of the material to macroscopic part characteristics. Examples are,
- dislocation pileups in the material microstructure,
- part design features such as sharp corners and notches in keyways that cause stress concentrations,
- irregularities (surface roughness) due to manufacturing such as the “peaks-and-valleys” produced on ground surfaces.

29. Fatigue striations are the regular deformation patterns produced on fatigue surfaces as fracture progresses across the surface after a fatigue crack initiation. In fatigue, stress is

varying and the fatigue crack grows progressively or in stages when stress in high. This gives rise to the regions of crack growth called striations.

30. Engineered products frequently operate over a range of temperatures and often have to endure temperature extremes. The materials that are used in these products must exhibit the desired mechanical and physical properties over this range of temperatures. Thus, it is imperative that the designers consider both the short-range and long-range effects of temperature on the materials. This is particularly important when one realizes that the bulk of tabulated material data refers to properties and characteristics at room temperature.

31. Steels and other body-centered crystal structure metals exhibit a ductile-to-brittle transition upon cooling. If this transition occurs at temperatures above those of service, the material will be used in a brittle condition, and sudden, unexpected fractures can occur under conditions that the material would be expected to endure.

32. Material behavior under long-time exposure to elevated temperature is generally evaluated through creep testing, wherein a tensile specimen is subjected to fixed load at elevated temperature. Single tests provide data relating to the rate of elongation and the time to rupture under the specific conditions of testing. A composite of various tests can be used to evaluate the creep rate or rupture life under a variety of load and temperature conditions .

33. The stress-rupture diagram is developed by running a number of creep tests at different temperatures and different stress levels and showing all the data on a single plot. The results show changes in material behavior with changing temperature at various stress levels.

34. Terms such as machinabilty, formability and weldability convey only the general though of how easy it is to process a material and may be useful for very general qualitative comparison of materials. For example, one material may be more formable that another if it is more ductile.

The difficulty in using this general concept arises when quantitative or engineering measures are desired. Ease or difficulty of processing depends not only on material properties but also on the deformation conditions imposed in processing and on material properties at the processing conditions. For example, the performance of a manufacturing process depends on the friction acting, any lubricants and coolants used, the constraints imposed on the deformation such as by die shape in forging, etc. Further, material properties change with temperature and rate of deformation. In addition to heating materials to change there temperature before processing temperature changes during the process due to cooling and heating due to deformation. Materials are often processed in high speed operations in which strain rates are very high.

Comparing material behaviors in processing is very difficult, and dubious, since the behavior depends so critically on the processing conditions.

35. The basic premise of the fracture mechanics approach to testing and design is that all materials contain flaws or defects of some given size. Fracture mechanics then attempts to distinguish between the conditions where these defects will remain dormant and those conditions for which the defects might grow and propagate to failure.

36. The three principal quantities that fracture mechanics tries to relate are: (1) the size of the largest or most critical flaw, (2) the applied stress, and (3) the fracture toughness of the material (a material property).

37. Fracture toughness is resistance to crack growth, *K*. Crack growth rate is shown as it depends on K in Figure 2-36. Units of *K* are (N/m^2) $m^{1/2}$ or (lb/in^2) $in^{1/2}$.

Toughness or modulus of toughness is work per unit volume up to fracture and units are energy/volume = $ftlb/ft^3$ and $Joule/m^3$.

When evaluated using a tensile test the area under the tensile test curve up to fracture has units of (stress)(strain) and so (lb/in^2)(in/in) = $inlb/in^3$ and (N/m^3)(m/m) = Nm/m^3.

38. The three primary thermal properties of a material are:
(1) heat capacity or specific heat - a measure of the amount of energy that must be imparted or extracted to produce a one degree change in temperature; (2) thermal conductivity - a measure of the rate at which heat can be transported or conducted through a material; and (3) thermal expansion - a measure of the degree of expansion or contraction that will occur upon heating or cooling of the material.

39. Since density is directly related to weight any engineering application in which weight is important will be one in which density is an important material property. An example of light weight, low density, being important is an airplane. An example of heavy weigh, high density, being important is a boat anchor.

Often the minimum weight structure needed to support a loading is desired and strength-to-weight ratio is relevant. In this case the strength/density ratio of materials is important.

Problems

1. Products in which performance does not depend on resistance to mechanical loading are probably examples where performance does depend on physical properties.
a. An example is electrical wire. The intent is to conduct electricity, not to withstand appreciable loads. Another example is a camera lens.
b. Electrical conductivity and optical properties determine the major part of the performance of wires and lenses.
c. For wires the material should be ductile so it can be routed and should be a low strain hardening material so working it in installation will not cause large loads and fracture.

2. a. Bookshelves are subjected to static loading over long time.

b. In addition to static strength, bookshelf materials should be stiff and should not creep, i.e., deform over long time at relatively low stress.
c. Material secondary characteristics might include light weight (low density), easy to work and easy to finish in various ways.

3. a) A common component that is subjected to dynamic mechanical loading is a power transmission shaft.
b. The material should have a high fatigue strength (large number of cycles to failure under the expected loading situation).
c. A desirable secondary characteristics is being easy to work so as not to produce a rough surface containing sites of fatigue failure initiation.

4. a) Steels exhibit ductile-to-brittle transition with the transition temperature/temperature range dependent on carbon content and alloying additions.

b) The two steels behaviors shown in Figure 2-32 show ductile-to-brittle transition temperatures in the range of about –30°C (-22°F) to –5°C (23°F).

c) The melting temperature of nitrogen is – 210°C, 63 K, - 346°F
The boiling point of liquid nitrogen is –196°C, 77 K, -321°F.

For discussion of ductile-to-brittle transition using the data for steel presented in Section2.4, liquid nitrogen is well below the ductile-to-brittle transition for steel and so steels are not a reasonable choice for a liquid nitrogen container.

Typical transport and short time storage containers for liquid nitrogen are composed of Dewar flasks usually made of annealed borosilicate glass held in an aluminum, stainless steel, plastic or steel casing. The Dewar may be surrounded by netting to contain the glass in case of breakage. Since the liquid nitrogen does not come into contact with the casing steel casings are used.

In the event of Dewar fracture the liquid nitrogen is not contained on the surface so boiling and the formation of gas at the liquid nitrogen-casing interface probably means that a steel casing would not be subjected to stress and temperature conditions to make ductile-to-brittle transition considerations important.

Stainless steel Dewars are available.

d) There are differences in work material deformation in rolling between the longitudinal and transverse directions with respect to the rolling direction. A different deformation pattern, rolling texture, results and this leads to different microstructure and properties in different directions.

The difference in absorbed energy with rolling direction shown in Figure 2P-1 indicates that the rolling texture has an effect on energy absorbed, i.e., one of the properties affected by rolling texture is toughness.

If impact properties have been improved in steel making the causes must be in the areas of
- development of alloys that are less temperature dependent, i.e., pushing the dashed line in Figure 2-32 further to the left,
- improvement in uniformity of the microstructure so subsequent processing has less effect in changing microstructure uniformity.

The general explanation is that material properties and deformation behavior are determined by composition, structure and surrounding conditions. For fixed deformation conditions, improvement in deformation behavior is the result of improvements in structure, probably due to changing steel composition.

5. The materials are to be distinguished based on the tests described in Chapter 2, the use of readily available household items and the ability to machine the materials. The use of household items and a machine shop indicates that mechanical and physical properties listed in Chapter 2 may be qualitatively measured (comparisons rather that quantitative measurements) in addition to the tests described in Chapter 2.

One way to organize a material separation plan is to consider the applicability to material separation of each test described. The tests may be obviously useful for identifying distinguishable properties, perhaps useful or not useful depending on if the measured quantity is sufficiently different for the two materials. The materials used in this problem are described in detail further on in the text as listed in the table.

Test	1020 vs 1040 Chapter 6	430SS vs 316SS Chapter 6	6061-T6 vs AZ91 Chapter 7	Polyethylene vs Polypropylene Chapter 8
Tensile - strengths - strain hardening	No	Probably based on hardening	Probably – based on strength and hardening	Possibly – based on ductility
Compression	No	Possibly	Probably	No
Hardness	No	Possibly	Yes	No
Impact	No	Possibly	Yes	No
Fatigue	No	No	Yes	No
Toughness	No	Possibly	Yes	No

The general conclusions are
- for materials of the same general type, e.g., steels, thermoplastics, similar strengths and deformation behaviors make drawing distinctions between material difficult,
- the more different the type of material the easier it may be to distinguish between them, e.g., aluminum and magnesium are both metals but sufficiently different to make mechanical testing viable for identifying differences in properties and behavior,

- while strength properties such as yield strength may be difficult to use the changes in material behavior with continuing deformation such as strain hardening and ductility may be useful.

Distinguishing between materials based on the characteristics and properties mentioned in Chapter 2 and using readily available items can be discussed by considering the properties mentioned.

	1020 vs 1040	430SS vs 316SS	6061-T6 vs AZ91	Polyethylene vs Polypropylene
Metallic/Nonmetallic	No	No	No	No
Temperature effects	No	No	No	No
Machinability	No	Yes – effort needed to cut	Yes – effort needed to cut	No
Formability	No	Yes – amount of bending before fracture	Yes – minimum bend radius before fracture	No
Weldability	No	Yes – weld and break	Yes – weld and break	No
Heat capacity	No	No	No	No
Specific heat	No	No	Perhaps	No
Thermal conductivity	No	No	Perhaps – hold end of bars while heating other end	No
Thermal expansion – difficult to test with ordinary items	No	No	No	No
Electrical conductivity	No	No	No	No
Magnetic response	No	Yes – use a magnet	No	No
Weight – accurate electronic scales are available	No	No	Yes	Perhaps
Density	No	No	Yes	Perhaps
Melting point – only relatively small increases in temperature available	No	No	No	Yes
Boling point	No	No	No	No
Optical properties	No	No	No	No

The same general conclusion can be reached – when materials are of similar type distinguishing between them is difficult. However there are particular differences in properties that are qualitatively different and make for easy material identification, e.g., magnetic response of different classes of stainless steels. Differences in deformation behavior can lead to identifiable differences in material use and processing, such as differences in ductility leading to differences in formability.

Case Study:

Overhead Conveyor for Meat Processing

a. There are two reasonable causes of failure worth investigating, given that the hooks have sufficient load carrying capacity to support 300 pounds under typical conditions. The candidate failure inducing mechanisms might stress-corrosion cracking and/or brittle behavior at the freezer temperature.

b. First a simple experiment or analytical stress analysis to determine expected load capacity. With assurance that the hooks are capable of holding the anticipated load, the problem is use of a material that is adversely affected by the in-use environment. A recommended solution is to use stainless steel for the material. It is corrosion resistant and does not behave in a brittle manner at the use temperature. It seems that in a meat packing plant stainless steel would be the first choice for health, cleanliness and mechanical reasons.

c. Underlying materials engineering is the close relationship between structure and mechanical behavior. So, at the level of determining mechanical properties, all microstructural characteristics are important. With respect to the behavior in the use situation described and possible accelerated failure mechanisms, grain boundaries are important in stress corrosion since they are active chemical-mechanical process initiation sites.

CHAPTER 3
Nature of Metals and Alloys

Review Questions

1. Material structure determines material properties. So if material structure can be designed and produced, desirable properties can be obtained. For example, the strength of steel can be controlled by changing not only composition but also by producing useful microstructures in heat treating processes.

2. Microstructure is the structure in a polycrystalline material that is determined by the size, shape and arrangement of the grains making up the material. This is in contrast to the atomic level structure of the material.

3. An ion is an atom that has a different number of electrons than the number of electrons needed for stability. That is, a different number of electrons and protons.

Negative ions have more electrons than protons and so have a net negative charge. Positive ions have missing electrons and so contain more neutrons than electrons and so have a net positive charge.

4. Valence electrons play a large part in an atoms interactions with other atoms and in atomic level processes. The determine the kind of interatomic bonding, chemical properties, electrical properties and optical properties.

5. The three types of primary bonds are
i. ionic bond,
ii. covalent bond,
iii. metallic bond

Ionic bonds form due to the attraction between ions and so atoms that can lose or gain electrons can be bonded. In contrast atoms that assume a lower energy state by sharing electrons form covalent bonds. Metallic bonds form between atoms that readily give up electrons to a shared electron gas. Position in the table of elements is a starting place for predicting what kind of boning will occur between atoms.

6. Ionic bonds are strong primary bonds between ions. The result is that ionically bonded material are hard, brittle, have high melting point and low electrical conductivity. They are strong but not as strong as typical covalently boned materials.

7. Covalent bonds are strong and so materials are strong, hard and brittle. Depending on the number of electrons participating in the bond, covalently bonded materials show wide ranges of electrical, chemical and optical properties.

8. In metallically bonded materials there is a mobile electron cloud that produces bonding. Properties that depend on electron mobility are extreme compared to other types of materials. For example, metals have high electrical and thermal conductivities. Electron-photon interactions account for the opacity of metals.

9. Asymmetric molecules that have nonsymmetrical charge distribution form van der Waal bonds. The bonding is due to the attraction between the differently charged regions of the molecules.

10. The atomic radius is the distance between centers of atoms in a grouping of atoms, i.e., it is not defined and measured for single atoms. The distance between a particular pair of atoms is determined by the balance of attractive and repulsive forces between atoms and between the particular atoms and all their surrounding atomic neighbors. In different crystal structures the ordering of atoms is different, so interatomic force interactions are different, the compliant response of individual atoms to their surroundings is different and hence the distance between atom centers, atomic radius, is different.

11. Crystalline materials have a regular, repeating structure, a repeating elementary arrangement of atoms. Amorphous material does have a repeating, predicable arrangement of the atoms or molecules that make up the material.

12. The metallic bonding of the atoms making up a metal results in a material that is strong, ductile, has high density, high electrical and thermal conductivities and optical luster.

13. Allotropic materials are those that can exist in two or more atomic lattice structures depending on temperature and pressure conditions.

14. Compared to the simple cubic structure, the closer packing arrangement of atoms in face center cubic and body center crystal structure results in a higher packing density of atoms and so more effective electron sharing.

In contract to the existence of particular metallic structures, a more general definition of engineering metals is metals that are used in engineering applications. Simple cubic structure materials are, would be, brittle and so difficult to mechanically work into useful shapes.

15. The common metal crystal structures are body-centered cubic, face-centered cubic and hexagonal close-packed.

16. Efficiency is the amount of space in the lattice that is occupied by the atoms modeled as solid spheres.

Lattice Structure	Packing Efficiency (%)
Simple cubic	52

Body-centered cubic	68
Face-centered cubic	74
Hexagonal close-packed	74

17. When close-packed planes form in the face-centered cubic arrangement there are many possible direction of atomic plane motion resulting in higher ductility than for the hexagonal close-packed arrangement with its smaller number of easy deformation directions. Deformation or slip systems are determined by the possible planes on which deformation can occur easily and the possible directions of slip. Face-centered cubic arrangements have more active slip systems than hexagonal close-packed arrangements.

18. A grain boundary is the relatively disordered region between crystals or grains in which atomic arrangement is relatively well defined and well ordered.

19. The American Society for Testing and Materials grain size number is commonly used to specify grain size. It is defined as n in the relationship

$$N = 2^{n-1}$$

in which N is the number of grains per square inch visible at 100x magnification. Standards are specified for specimen preparation and measurement procedures.

20. Metallic crystals respond to low applied loads by simply stretching or compressing the distance between atoms. All atoms retain their basic positions, with the load serving only to disrupt the force balance of the atomic bonds in such a way as to produce elastic deformations.

21. Plastic deformation is a permanent shift of atoms resulting in a permanent change in size or shape.

22. A slip system for the plastic deformation of a metal is the specific combination of a preferred plane and a preferred direction within that plane. In general, the preferred planes are those with the highest atomic density and greatest parallel separation - the close-packed planes. The preferred directions are the close-packed directions.

23. The dominant mechanical property of the bcc crystal structure metals is high strength. The fcc metals have high ductility. The hcp metals tend to be brittle.

24. A dislocation is a line-type defect within a crystalline solid. Edge dislocations are the terminal edges of extra half-planes of atoms, and screw dislocations are the ends of partial "tears" through the crystal. Since the movement of dislocations provides the plasticity of a material, the force required to move dislocations determines the resistance to plastic deformation, or the strength of the material.

25. Other crystal imperfections can provide effective barriers to dislocation movement and be used to strengthen the metal. These include: point-type defects (such as vacancies, interstitials, or substitutional atoms), additional line-type dislocations, and surface-type

defects (such as grain boundaries) .

26. The three major types of point defects in crystalline materials are: vacancies (missing atoms), interstitials (extra atoms forced between regular atom sites), and substitutional atoms (atoms of a different variety occupying lattice sites).

27. The strain hardening of a metal is the result of the multiplication of the number of dislocations and the interaction between the various dislocations to pin or block the movements of one another.

28. Since dislocations cannot cross grain boundaries (a discontinuity to crystal structure), these boundaries serve to impede dislocation movement and make the material stronger. A material with a finer grain structure (more grain boundaries) will, therefore, tend to be stronger than one with larger grains.

29. An anisotropic property is a property that has different values in different directions.

Possible causes of anisotropy are;
- material creation as in the growth of trees and the casting of metals in which small scale structures (wood fibers, dendritic metallic microstructure) have anisotropic structures and combine in an oriented way to produce large scale anisotropic structure (grain in wood, large grains near the surface of castings),
- material processing in which symmetric microstructures are deformed into structures with distinctive shapes. For example, rolling of a metal that has ideally spherical grains produces elongated grains along the rolling direction. The resulting product has anisotropic mechanical properties, such as different strength and ductility along the rolling direction and perpendicular to the rolling direction..

30. Brittle fractures occur without the prior warning of plastic deformation and propagate rapidly through the metal with little energy absorption. Ductile fractures generally occur after the available plastic deformation has been exceeded.

31. Plastic deformation increases the internal energy of a material through both the creation of numerous additional dislocations and the increased surface area of the distorted grain boundaries. Given the opportunity, the metal will seek to reduce its energy through the creation of a new crystal structure, i.e. recrystallize.

32. Recrystallization is often used to restore ductility to a metal and enable further deformation to be performed. Without recrystallization, further deformation would result in fracture.
NOTE: If the deformation is performed at temperatures above the recrystallization temperature, deformation and recrystallization can take place simultaneously and large deformations are possible .

33. The major distinguishing factor between hot and cold working is whether the deformation is produced at a temperature that is above or below the recrystallization

temperature of the metal. In cold working, no recrystallization occurs and the metal retains its strain hardened condition. When hot working is performed, recrystallization produces a new grain structure and no strain hardening is possible.

34. When an alloy addition is made to a base metal, several possibilities can occur. The two materials can be insoluble and refuse to combine or interact. If there is solubility, the alloy can dissolve in the base metal to produce a solid solution of either the substitutional or interstitial variety. A final possibility is that the two can react to produce an intermetallic compound - a combination with definite atomic proportions and definite geometric relationships.

35. Intermetallic compounds tend to be hard, brittle, high-strength materials .

36. The charge carriers in metals are the valence electrons. The general concept becomes slightly cloudy since in metals the electron sea or electron cloud is composed of electrons that are in essence shared by all the atoms. In a sense the valence electrons belong to all the atoms and are not valence electrons in the sense of the valence electron of an atom.

37. Electrical resistance in a metal depends largely on two factors - the number of lattice imperfections and the temperature . Vacancies, interstitials, substitutional atoms, dislocations, and grain boundaries all act as disruptions to the regularity of a crystalline lattice. Thermal energy causes the atoms to vibrate about their equilibrium positions and interferes with electron transport.

38. Intrinsic semiconductors are ones that occur naturally. Extrinsic semiconductors have chemistries that have been modified by "doping" to enhance or alter their conductivity.

Problems:

None

Case Study:

Window Frame Materials and Design

Wood (such as kiln-dried Ponderosa pine) is easily shaped, can be painted or finished in a wide spectrum of finishes, and has low thermal conductivity (keeping the winter cold and summer heat out). Unfortunately, the material has a definite grain structure, which may lead to cracking or splintering. The material requires special impregnation and coating to improve its ability to resist degradation. Wood requires regular surface maintenance (such as painting or sealing) to minimize moisture absorption and rot. While its dimensions are relatively insensitive to changes in temperature, they can change significantly with changes in humidity or moisture content, leading to possible warping or twisting. The shrinking, swelling and cracking tendencies make it extremely difficult to provide a durable surface protection. Finally, wood is a combustible material.

Aluminum can be extruded into the complex channels used for window frames, is durable, non-corrosive, and can be color anodized or finished into a variety of surfaces. The properties are consistent and predictable and do not change over time, or with variations in temperature (over the range where windows would operate). The material does not absorb moisture, swell, shrink, split, crack or rust. Maintenance is extremely low, but the material has a high thermal conductivity. If the same piece is exposed to a cold exterior and warm, moist interior (as in winter weather), the material will try to achieve thermal uniformity. The inside surfaces will "sweat" with condensation, and thermal efficiency of the window will be poor. Compared with alternatives, however, aluminum is stronger and more rigid (23 times stiffer than vinyl) . From a safety perspective, aluminum is noncombustible and does not emit any toxic fumes when heated to high temperature.

Vinyl windows offer a range of color, and the color is integral to the material. There is no need for any surface finishing and the appearance requires no periodic maintenance. In addition, the thermal conductivity is low, giving the window good thermal efficiency. Unfortunately, polymers have poor dimensional stability, generally shrinking over time, and often deteriorate with prolonged exposure to ultraviolet light (becoming brittle) . Since windows will see prolonged exposure to sunlight, the long term durability and stability may come into question. The thermal expansion of vinyl is considerably greater than either aluminum or wood, and the resulting dimensional changes may cause distortion of the windows. In addition, the properties of vinyl will vary over the temperature range that the product will see. When heated, vinyl loses strength, and when cold, it becomes more brittle and less impact resistant. The material is combustible and may emit toxic fumes when exposed to high temperatures.

It would appear that aluminum is a superior structural material, whose primary detriment is its high thermal conductivity. If a design could be developed to insert some form of conductivity barrier between the outside and inside surfaces, the resulting window would offer the best of all worlds. Several companies currently offer such a design, linking the inside and outside extrusions with a high-strength polymeric link. Being totally internal, this polymer is not subject to sunlight deterioration, and does not significantly impair the structural performance of the window.

CHAPTER 4
Equilibrium Phase Diagrams and the Iron-Carbon System

Review Questions

1. A phase is a portion of a substance possessing a well-defined structure, uniform composition, and distinct boundaries or interfaces.

2. In a glass of soda with ice, the soda is continuous and the ice is discontinuous. Helium in a balloon is a gaseous phase, and coffee with cream is a single-phase solution.

3. An equilibrium phase diagram is a graphical mapping of the natural tendencies of a material system (assuming that equilibrium has been attained) as a function of such variables as pressure, temperature, and composition.

4. The three primary variables considered in equilibrium phase diagrams are: temperature, pressure and composition.

5. A pressure-temperature phase diagram is not that useful for many engineering applications because most processes are conducted at atmospheric pressure. Most variations occur in temperature and composition.

6. A cooling curve is a temperature versus time plot of the cooling history when a fixed-composition material is heated and subsequently cooled by removing heat at a uniformly slow rate.

7. Transitions in a material's structure are indicated by characteristic points on the cooling curve. These characteristic points may take the form of an isothermal hold, abrupt change in slope, or localized aberration to the continuity of the curve.

8. Solubility limits denote the conditions at which a solution becomes completely saturated, i.e. any additional solute must go into a second phase. Solubility limits are generally determined through use of inspection techniques such as X-ray analysis (detects where a new crystal structure or lattice spacing appears) or microscopy (detects the presence of the second phase), that can be used to identify the composition where the transition from one to two-phase occurs.

9. In general, as the temperature of a system is increased, the maximum amount of a substance that can be held in solution also increases.

10. Complete solubility implies complete solubility in both liquid and solid states. The two types of atoms have to be able to exist in the same crystalline structure. Atom “size” and valence electron structure have to be similar.

Partial solubility results when there is a saturation limit for one type of material in another and this saturation limit depends on temperature. So, as temperature is lowered and solubility decreases a two phase material forms from the initially one phase material.

Insolubility means that the materials are so different in nature (atomic size, valence electron structure, etc.) that they are totally insoluble in each other.

11. Upon crossing the liquidus line during cooling, the first solid begins to form in the material. Upon crossing the solidus line, solidification is complete, i.e. there is no longer any liquid present. Upon crossing a solvus line, a single phase material begins to precipitate a second phase, since the solubility limit is now being exceeded.

12. The three pieces of information that can be obtained from each point in an equilibrium phase diagram are: the phases present, the composition (or chemistry) of each phase, and the amount of each phase present.

13. A tie-line is an isothermal line drawn through any point in the two phase region of a phase diagram, terminating at the boundaries of the single phase regions on either side. It is used in the two-phase regions of an equilibrium phase diagram.

14. The end points of the tie-line correspond to the compositions of the two phases present.

15. The relative amounts of the component phases in a two-phase mixture can be computed through use of the lever law. The tie-line is separated into two segments by dividing it at the chemistry of the alloy in question. The fraction of the total length of the tie-line that lies opposite to a given phase corresponds to the fractional amount of that particular phase.

16. Cored structures refer to materials that have microscopic level variations in chemical composition.

Cored structures form because as the metal solidifies through the freezing range the chemical composition constantly changes. If cooling rate is rapid, material diffusion rate is too slow to produce uniform chemistry. Different regions of the solid material have different chemical characteristics determined by the temperature at which the regions solidified.

17. Three-phase reactions appear as horizontal lines in binary (two-component) phase diagrams. These lines have a distinctive V intersecting from above, or an inverted~ V intersecting from below. The intersection of the V and the horizontal line denotes the three-phase reaction, which is usually written in the form of cooling, i.e. the phases present above the line going to those present below.

18. A eutectic reaction has the general form of Liquid ---> Solid 1 + Solid 2. In essence, a liquid solidifies to form two distinctly different solids of differing chemistries.

19. Eutectic alloys are attractive for casting and as filler metals in soldering and brazing because they generally have the lowest melting point of all alloys in a given system and solidify into a relatively high-strength structure.

20. A stoichiometric intermetallic compound is a single-phase solid that forms when two elements react to form a compound of fixed atomic ratio. The compound cannot tolerate any deviation from that fixed ratio, so it appears as a single vertical line in a phase diagram, breaking the diagram into recognizable sub areas . Non-stoichiometric intermetallic compounds are single phases that appear in the central regions of a phase diagram, that can tolerate chemical variations, and thus have an observed width. They appear as a region and not a line.

21. In general, intermetallic compounds tend to be hard, brittle materials .

22. If an intermetallic compound can be uniformly distributed throughout a structure in the form of small particles in a ductile matrix, the effect can be considerable strengthening of the material. If the intermetallic should become the continuous phase (as in a grain boundary coating) or be present in large quantities, the material will be characteristically brittle.

23. The four single phases in the iron-carbon equilibrium phase diagram are: ferrite (alpha), which is the room-temperature body-centered cubic structure; austenite (gamma), the elevated temperature face-centered cubic phase; delta-ferrite (delta), the high-temperature body-centered cubic phase; and cementite (Fe_3C), the iron-carbon intermetallic compound that occurs at 6.67 wt. percent carbon.

24. The point of maximum carbon solubility in iron, 2.11 weight percent, forms an arbitrary division between steels and cast irons. Cast irons contain greater than 2.11% carbon and experience a eutectic reaction upon cooling.

25. Some of the key characteristics of austenite are its high formability (characteristic of the fcc crystal structure) and its high solubility of carbon (a good starting point for heat treatment) .

26. The most important three-phase reaction in the iron-carbon diagram when considering steels is certainly the eutectoid reaction. Under equilibrium conditions, austenite of 0.77 weight percent carbon and the fcc crystal structure transforms into ferrite of the bcc crystal structure, capable of holding only 0.02% carbon and cementite or iron carbide with 6.67% carbon. In essence, iron changes crystal structure and the rejected carbon goes to form the iron carbide intermetallic.

27. The fcc crystal structure of austenite is capable of dissolving as much as 2.11% carbon at elevated temperature. In contrast, the bcc crystal structure of ferrite can hold only 0.02% carbon at its maximum solubility and 0.007% at room temperature .

28. Pearlite is the name given to the structure formed when austenite undergoes the eutectoid reaction under equilibrium (or near-equilibrium) conditions. It is a lamellar structure composed of alternating plates of ferrite and cementite, but has its own characteristic set of properties, since it always forms from the same chemistry at the same temperature.

29. Steels having less than the eutectoid amount of carbon (less than 0.77% carbon) are called hypoeutectoid steels. Their structure consists of regions of ferrite that formed before the eutectoid reaction (primary or proeutectoid ferrite) and pearlite that formed as the remaining austenite underwent the eutectoid transformation. Steels with greater than 0.77% carbon are called hypereutectoid steels and have structures consisting of primary cementite and pearlite.

30. The general composition of cast irons is 2.0 to 4.0% carbon, 0.5 to 3.0% silicon, less than 1.0% manganese, and less than 0.2% sulfur. In addition, nickel, copper, chromium and molybdenum may be added as alloys. Silicon is the major new addition. It partially substitutes for carbon, and promotes the formation of graphite as the high-carbon phase.

31. Silicon content of cast iron is 0.5% to 3.0%. Silicon partially substitutes for carbon and promotes the formation of graphite as the high-carbon phase.

32. Cast irons often contain graphite as the high-carbon phase instead of the cementite (or iron carbide) commonly found in steels. Graphite formation is promoted by slow cooling, high carbon and silicon contents, heavy section sizes, inoculation practices, and alloy additions of Ni and Cu. Cementite is favored by fast cooling, low carbon and silicon levels, thin sections, and alloy additions of Mn, Cr, and Mo.

33. The microstructure of gray cast iron consists of three-dimensional graphite flakes dispersed in a matrix of ferrite, pearlite, or other iron-based structure.

34. Since the graphite flakes in gray cast iron have no appreciable strength, efforts to increase the strength of this material must focus on improving the strength of the iron-based matrix structure.

35. Gray cast irons possess excellent compressive strengths, excellent machinability, good wear resistance, and outstanding vibration damping characteristics. In addition, the silicon provides good corrosion resistance and the high fluidity desired for castings. Low cost is an additional asset.

36. Gray cast iron contains graphite flakes and so exhibits low ductility. The graphite component produces stress concentrations, crack initiation sites and the resulting brittleness.

37. White cast iron is very hard, but very brittle. It finds application where extreme wear resistance is required.

38. Malleable iron is essentially heat-treated white cast iron where a long time thermal treatment changes the carbon-rich phase from cementite to irregular graphite spheroids. The more favorable graphite shape removes the internal notches of gray cast iron and imparts the increased ductility and fracture resistance .

39. The graphite is in the form of smooth, approximately spherical particles.

The graphite shape formation is controlled by material additions to the cast iron and cooling rate. In contrast to controlling graphite particle shape by complicated heat treatment as in the malleable cast irons.

Since the graphite flakes do not act as strong fracture initiation sites due to their shape, material ductility increases.

40. Increased cost of ductile cast iron compared to gray cast iron is due to
- increased cost of material additions needed to form spherical graphite,
- more sophisticated furnaces and control systems to assure the formation of desired graphite structure.

41. Compacted graphite cast iron is characterized by a graphite structure intermediate to the flake graphite of gray cast iron and the nodular graphite of ductile iron. It forms directly upon solidification, and possesses some of the desirable properties and characteristics of each.

Problems:

1.Since the topic is producing and processing engineering materials, the phase diagram will be a temperature-composition diagram and the temperature range is over the solid and liquid material state range.

i. The two components selected can be completely soluble in each other in both liquid and solid states. The general form of the equilibrium diagram is shown in Figure 4-6.

ii. The two components can be completely insoluble in each other in liquid and solid phases and the general form of the equilibrium or phase diagram is shown in Figure 4-7.

iii. For materials that are partially soluble the general equilibrium diagram is shown in Figure 4-8 and is extended to include a three phase reaction for some materials. The diagram then contains a V-shaped line meeting another line such as at composition of 61.9% tin and temperature of 183^o C in Figure 4-5. General cases are shown in Figure 4-9. The cusp/inflection of the liquidus line indicates a very particular, well defined state and solidification process.

The identification is then
a. Single phase

i For completely soluble materials there will be a liquid solution for temperature-composition states above the liquidus line. A solid solution exists at states below the solidus line.
ii. For insoluble materials there will be no single phase regions on the diagram.
ii For the point of contact between the V-shaped line with the solidus line single phase material exists above and below the contact point and two phase material to the left and right of the point.

b. Three phase reaction
i. Reactions between two completely soluble materials will not result in a three phase state.
ii. The is no interaction between insoluble materials and so two such materials will not form three phases.
iii. Three phase reactions occur for partially soluble materials at the point of contact between the V-shape line and the solidus line. The liquid phase meets two-phase regions at this point.

c. Intermetallic compound
i. Completely soluble material form solutions not compounds.
ii. Ideal completely insoluble materials do not interact and so will not form compounds.
iii. Stoichiometric intermetallic compounds exist in a fixed atomic ration and so are represented by vertical lines on equilibrium diagrams, Figure 4-9. Nonstoichiometric intermetallic compounds are shown as regions of compositions. These regions are usually narrow.

2. A way to approach looking for applications of particular material is to identify material characteristics that point to particular kinds of use and so to look for products in that use area.

a. Gray cast iron has low alloy content and is easily produced resulting in a low cost material and the possibility of casting complex shapes. The microstructure is composed of dispersed graphite flakes in a metal matrix. This leads to brittleness, ease of machining, high damping capacity and low tensile strength but high compressive strength.

Application in situations with large size, compressive loading and required damping are indicated, e.g., machine tool structures.

b. White cast iron behavior is determined to a large extent by the high iron carbide content. White cast iron is hard and brittle.

Applications in which minimal wear rate is required and the loading is compressive are typical, e.g., machine tool ways.

c. Malleable cast iron has higher ductility than gray or white cast irons because the form of the graphite is nodular, not flake-like. To produce this microstructure high cooling rates are required.

The ductility of malleable cast iron means higher tensile strength, greater impact strength and easier further processing (e.g., machining) than for the more brittle cast irons. The required fast cooling rate implies the production of relatively small castings to assure fast cooling and acceptable temperature gradients.

Applications are small parts that require significant further processing and are used in relatively high tensile stress situations, e.g., rigging components such as pulley supports.

d. Ductile cast iron has the same type of graphite shape as malleable cast iron, but the microstructure is formed by alloying additions rather than the involved heat treatment needed to produce malleable cast iron. The desirable mechanical properties and ease of processing of malleable cast iron are also characteristic of ductile cast iron. The need to carefully control alloying and production of ductile cast iron leads to a higher cost material than malleable cast iron.

Applications are then similar to those for malleable cast iron in which higher cost can be justified, e.g., jigs and fixtures.

e. Compacted graphite cast iron has graphite microstructure between those of gray cast iron and ductile cast iron. The newly developed, easier to control production process makes for a less costly material that still possesses reasonable strength, ductility and machinability. Compacted graphite cast iron has higher thermal conductivity than ductile cast iron.

Applications are in newer applications in which the increased mechanical properties of ductile cast iron are desirable along with high thermal conductivity. Cast iron internal combustion engine components are starting to be the major uses of compacted graphite cast iron

Case Study:

The Blacksmith Anvils

1. The anvil will be subjected to the shock of direct and indirect hammer blows during the forging of metals. The surfaces must be resistant to wear, deformation and chipping, and good energy absorption or damping characteristics would be an added plus, acting to reduce noise and vibration. The anvil must have sufficient mass to absorb the blows, and not tip or move when the blows are offset from the base. The material must resist damage when red-hot metal is placed in contact with its surfaces for brief to moderate periods of time. Since heat retention in the workpiece is desirable, heat transfer to and through the anvil should be minimized. Corrosion resistance to a normal shop atmosphere would also be desirable. While the dimensional requirements can be somewhat lenient, the working surface should be flat and reasonably smooth.

2. Features influencing the method of fabrication include the cited yield strength, elongation and hardness, and somewhat limited production quantity. In addition, the somewhat massive size (both weight and thickness) can be quite restrictive. The width is probably about 4-inches or greater. Other than a single mirror plane, there is no

significant symmetry or uniformity of cross section. Handling should be minimized because of the size and weight.

Because of the size (both length and thickness), complexity of shape, and limited production quantity, some form of expendable-mold casting appears to be the most attractive process. Forging would be another alternative, but the size and quantity could be quite limiting.

3. Because of the need for impact resistance, cast irons would most likely come from either the malleable or ductile families, but the section thickness may present problems for the production of malleable. Cast steels would also be quite attractive, but the higher melting temperatures, lower fluidity, and high shrinkage could present problems. Alloyed material may be necessary for the desired heat treatment response.

4. Production alternatives include casting the entire piece from a single material, or casting the base of one material (including the horn) and welding or otherwise attaching a plate of stronger material to the top. Because of the desire to replicate the 1870's design, a single material is probably preferred .

While any of the materials discussed in section 3 would be workable alternatives, ductile cast iron might be the most attractive. It would most likely be cast in some form of sand mold, possibly one with higher strength than green sand. After casting, heat treatment would likely be necessary to establish the desired properties. A normalizing or annealing treatment would produce the desired properties with a very stable structure. The working surfaces and mounting base would be subjected to some form of surface grinding. If needed, a deep surface hardening treatment, such as flame hardening, could be used on the critical surfaces to increase the hardness.

CHAPTER 5
Heat Treatment

Review Questions

1. Heat treatment is the controlled heating and cooling of metals for the purpose of altering their properties. Its importance as a manufacturing process stems from the extent to which properties can be altered.

2. Heat treatment changes material structure at the microscopic level and so can change both physical and mechanical properties.

3. While the term "heat treatment" applies only to processes where the heating and cooling are done for the specific purpose of altering properties, heating and cooling often occur as incidental phases of other manufacturing processes, such as hot forming and welding. Material properties will be altered as the material responds in the same way it would if an intentional heat treatment had been performed. Properties can be significantly altered by the heating and cooling.

4. Processing heat treatments are slow cool, rather long time, treatments designed to prepare a material for fabrication. Some possible goals of these treatments are: improve machining characteristics, reduce forming forces, or restore ductility for further fabrication .

5. Since most processing heat treatments involve rather slow cooling or extended time at elevated temperature, the conditions tend to approximate equilibrium, and equilibrium phase diagrams can be used as a tool to understand and determine process details .

6. The A_1, A_3 and A_{cm} lines are used to describe transitions on iron carbon phase diagrams. The A_1 line designates the eutectoid line. A_3 designates the boundary between austenite and ferrite+austenite regions. A_{cm} separates the austenite and austenite+cementite regions.

7. Annealing operations may be performed for a number of reasons, among them: to reduce strength or hardness, remove residual stresses, improve toughness, restore ductility, refine grain size, reduce segregation, or alter the electrical or magnetic properties of a material.

8. Full anneals can produce extremely soft and ductile structures, but they are time consuming and require considerable energy to maintain the elevated temperatures required during the soaking and furnace cooling. In addition, the furnace temperature is changed during the treatment, so the furnace must be reheated to start another cycle.

9 . If hypereutectoid steels were slow cooled from the all-austenite region, they would spend considerable time in the austenite plus cementite condition, and the hard, brittle cementite that forms would tend to produce a continuous network along the grain boundaries. A small amount of cementite in a continuous network can make the entire material brittle.

10. The major difference of normalizing compared to full annealing is the use of an air cool in place of the long time, controlled furnace cool. This reduces processing time, furnace time, and fuel and energy use. However, the furnace cool of a full anneal imposes identical cooling conditions at all locations within the metal and produces identical properties. With normalizing, the cooling will be different at various locations. Properties will vary between surface and interior, and different thickness regions will have different properties.

11. Process heat treatments that do not require the reaustenitization of the steel include: the process anneal, designed to promote recrystallization and restore ductility; the stress-relief anneal, designed to remove residual stresses; and spheroidization, a process to produce a structure that enhances the machinability or formability of high-carbon steels.

12. Process anneals are performed on low-carbon steels with carbon contents below 0.25% carbon. Spheroidization is employed on high-carbon steels with carbon contents greater than 0.6%C.

13. The recrystallization process and its kinetics is a function of the particular metal, the degree of prior straining, and the time provided for completion. In general, the more a metal has been strained the more energy has been stored, and the lower the recrystallization temperature or the shorter the time.

14. The six major mechanisms available to increase the strength of a metal are: solid solution strengthening, strain hardening, grain size refinement, precipitation hardening, dispersion hardening, and phase transformation hardening. All techniques are not applicable to every metal.

15. The most effective strengthening mechanism for the nonferrous metals is precipitation hardening.

16. Precipitation hardening begins with a solution treatment to create an elevated-temperature single-phase solid solution, followed by a rapid quench to produce a supersaturated solid solution, and then a controlled reheat to age the material (cause the material to move toward the formation of the stable two-phase structure).

17. Precipitation hardening metals are either naturally aging (ages at room temperature) or artificially aging (requires elevated temperature to produce aging). Considerable flexibility and control is offered by artificial aging, since the properties can be altered and controlled by controlling the time and temperature of elevated temperature aging. Dropping the temperature terminates diffusion and retains the structure and properties

present at that time. NOTE: Subsequent heating, however, will continue the aging process.

18. In a coherent precipitate, the crystallographic planes of the parent structure are continuous through the precipitate cluster, and the solute aggregate tends to distort the lattice to a substantial surrounding region. In contrast, second-phase particles have their own crystal structure and distinct interphase boundaries .

19. Overaging is the decrease in hardness and strength of precipitation or age hardened materials. Overaging occurs when the solute atoms form large enough clusters that coherency of the solute atom clustering is lost. The large effects of coherent clusters on hindering dislocation motion are lost. The large noncoherent clusters than act as a dispersion hardening mechanism.

20. In constructing the IT or T-T-T diagram, thin specimens of a metal are heated to form uniform, single-phase austenite, and are then instantly quenched to a temperature where austenite is not the stable phase. The samples are then held at this constant temperature for variable periods of time and the kinetics of the structure change are determined. Such instantaneous changes in temperature followed by isothermal holds are quite unrealistic for manufactured items, which usually undergo some form of continuous cooling as heat is extracted from surfaces and fed to the surfaces from the hot interior.

21. For steels below the A_1 temperature, the stable phases predicted by the equilibrium phase diagram are ferrite and cementite .

22.According to the T-T-T diagram, some of the non-equilibrium structures that may be present in heat-treated steels are:
bainite, martensite, tempered martensite, and retained austenite.

23. Martensite forms from austenite by an instantaneous change in crystal structure with no diffusion. The fcc austenite transforms to the body-centered structure which is distorted into a tetragonal shape to accommodate the additional carbon. The degree of distortion is proportional to the amount of trapped carbon .

24. The major factor determining the strength and hardness of steel in the martensitic structure is the amount of carbon present in the steel.

25. Retained austenite is austenite which remains in a metastable state at temperatures where the equilibrium phase diagram predicts that it should no longer exist. It can be responsible for low strength or hardness, dimensional instability or cracking, or brittleness (by transforming to untempered martensite at some later time) .

26. As formed, martensite lacks sufficient toughness and ductility to be useful as an engineering material. Tempering is the controlled decomposition of the single-phase supersaturated solid solution toward the formation of the stable ferrite and cementite structure. Ductility and toughness improve at the expense of strength and hardness.

27. Both heat treatments begin by replacing the original structure with an elevated-temperature, single-phase solid solution (redissolving any second phases) . A quench then produces a supersaturated solid solution. A more moderate reheating then permits diffusion to move the material toward formation of the stable two-phase configuration. When age hardening, the quenched material is weaker and more ductile, and aging increases the strength at the expense of ductility. With the quench-and-temper process, the quenched structure is strong, but lacks ductility. Tempering increases ductility at the expense of strength.

28. The C-C-T diagram, continuous-cooling-transformation diagram, shows the phase and composition of steels on cooling as functions of temperature and time.

The C-C-T diagram is more useful than the T-T-T diagram since it describes more realistic heat treatment conditions. The T-T-T diagram assumes instantaneous cooling and complete isothermal transformations that are not the actual situations.

29. In the Jominy end-quench hardenability test, a standard steel specimen is subjected to a standardized quench. Since the thermal conductivity of steel is essentially constant for the range of carbon and low-alloy steels, the cooling rate varies with the distance from the quenched end - from rapid quench to an approximate air-cool.

30. The quench in the Jominy test is standardized by specifying the quench medium (water), quenchant temperature (75 F), internal nozzle diameter (1/2 inch), water pressure, and the gap between the nozzle and the specimen.

31. The concept of "equivalent cooling rates" is based on the assumption that identical results will be obtained if a material undergoes identical cooling history. If the cooling rate is known for a given location within a part, the properties at that location can be predicted as those at the equivalent cooling rate location of a Jominy test bar (well-documented in many reference texts) .

32. Hardenability is a measure of the depth to which full hardness can be obtained when heat-treating a steel. It is primarily dependent upon the types and amounts of alloy elements in the steel.

33. The depth of hardening can be increased by increasing either the severity of the quench or the hardenability of the steel. Quench changes may be limited by cracking or warping problems, however. Hardenability is increased by increasing the amount of alloy additions.

34. The three stages of liquid quenching are: the vapor-jacket stage, the second stage in which the quenchant extracts heat by boiling, and the third stage where the mechanism of heat transfer is limited to conduction and convection.

35. As a quench medium, water offers a high heat of vaporization, and second-stage cooling down to 212^0F. It is cheap, readily available, easily stored, nontoxic, nonflammable, smokeless, and easy to filter and pump. On the negative side, the bubbles tend to cling, it is an oxidizing medium, and is corrosive. In addition, the rapid rates of cooling often induce distortion and cracking.

36. Oil quenches are generally less likely to produce quench cracks than water or brine for several reasons. The rate of heat extraction into boiling oil is slower than in boiling water. The major difference, however, is due to the fact that the boiling points of oils are sufficiently high that the transition to the third-stage of quenching occurs before the martensite start temperature. Slower cooling through the martensite transformation leads to a milder temperature gradient and a reduced likelihood of cracking.

37. Polymer or synthetic quenches cool more rapidly than oils but slower than water or brine. They can be tailored by varying the concentrations of the quench components to provide extremely uniform and reproducible results. They are less corrosive than water or brine, are cheaper and less of a fire hazard compared to oils, and tend to minimize distortion.

38. Some undesirable design features in parts that are to be heat treated include: nonuniform sections or thicknesses, sharp interior corners, and sharp exterior corners.

39. When steel is quenched, the elevated temperature face-centered cubic structure changes to the body-centered configuration, and expands When aluminum is quenched, it cools and thermally contracts. In most cases, the residual stresses formed by cooling tend to be opposite for the two materials.

40. Residual stresses can be undesirable because, in service, they add algebraically to the stresses applied to the part. Loads well within the design limit may couple with unfavorable residual stresses to produce failure. By themselves, residual stresses may produce unwanted distortion or cracking.

41. Quench cracking is due to temperature gradients. Differences in temperature between different regions produce stresses and possibly different phases. The mechanical and structural mismatches are large enough to cause fracture.

42. Two methods of producing strong structures while minimizing residual stresses and the likelihood of cracking are austempering and martempering. A rapid cool is used to reduce the temperature of the material to just above the martensite start. The temperature is then allowed to become uniform prior to either further cooling to martensite (martemper) or isothermal transformation to bainite (austemper) .

43. In thermomechanical processing, mechanical deformation and heat treatment are intimately combined into a single process.

44. Selective heating techniques for surface hardening include:

flame hardening, induction hardening, laser beam hardening, electron beam hardening, and lead-pot or salt bath immersion.

45. Laser beam surface hardening operates at high speeds, produces little distortion, induces compressive residual stresses on the surface, and can be used to harden selected surface areas while leaving the remaining surfaces unaffected. Computer control and automation can be readily used and conventional mirrors and optics can be used to shape and manipulate the beam.

46. Carburizing is the elevated temperature surface treatment in which carbon is caused to diffuse into steel. The carbon may be in a solid, liquid or gaseous environment around the part being treated.

The intent of carburizing is to alter material composition and structure in selected regions of the part. In order to control the distribution of carbon in the part further heat treatment after the initial diffusion process may be required. Rapid cooling is used to fix the carbon in the high temperature state. Slow cooling is used to produce further, controlled diffusion of the carbon into the part.

47. Compared to conventional nitriding or carburizing, ionitriding offers shorter cycle times, reduced consumption of gases, significantly reduced energy costs, reduced space requirements and the possibility of total automation. Product quality is improved and the process is applicable to a wider range of materials.

48. Batch furnaces may be preferred to continuous furnaces when the productions runs are small and the details of the thermal processing vary from lot to lot. Continuous furnaces are best for large production runs of the same or similar parts that undergo the same thermal process.

49. Artificial atmospheres are often used during heat treatment operations to suppress undesirable reactions such as scale formation or tarnishing, prevent decarburization, or supply carbon or nitrogen for surface modification.

50. In a fluidized-bed furnace, a bed of dry, inert particles is heated and fluidized by a stream of flowing gas. Parts introduced into the fluidized media become engulfed and are heated by radiant heating. Temperature and atmosphere can be altered quickly, heat transfer rate and thermal efficiency are high, and fuel consumption is low. Due to high flexibility, one furnace can be used for multiple applications.

51. While heat treatment consumes large amounts of energy, its use may actually be an energy conservation measure because it enables the manufacture of a higher-quality, more durable, product. In addition, higher strengths may permit the use of less material to produce a comparable product.

Problems:

1. While this is essentially a library-research project, it is hoped that the student will note such features as the following:
Flame and induction hardening are performed on materials that have the capability of possessing both the desired substrate properties and the desired surface properties. Carburizing alters the surface chemistry and achieves the desired hardness through subsequent heat treatment. This treatment can take the form of a direct quench from the carburizing treatment, a quench from a reheat to a lower temperature, 'or dual surface and substrate treatments. Nitriding also modifies the surface chemistry, but the nitrided layer cannot sustain subsequent heat treatment. Therefore, the substrate is fully heat-treated prior to nitriding, and the hard surface is formed after the heat treatment .The additional information can be found in numerous references, such as Metals Handbook, or the references cited under the "Heat Treatment" and "Surfaces and Finishes" sections of the Selected References for Additional Study.

2. At the time of preparation a internet search for “boriding” gave the following sites in the first 15 sites listed and the information gleaned from them is presented in the table below.
www.thomasregister.com/olc/metlab/bori.htm
www. concentric.net/~ctkang/boride.shtml
www.staff.ncl.ac.uk/s.j.bull/SENotes.html
www.mrs.org/publications/jmr/jmra/1989/novdec

	Boriding / Boronizing	
1	Process description	parts are packed in a boron containing material and heated in a furnace in - vaporized boron reacts with the work material forming hard boron compounds
2	Materials	typically steels, but many alloying additions react with boron
3	Equipment	only a controlled atmosphere furnace
4	Processing conditions	boron gas atmosphere, up to 980^{o}C, 1800^{o}F, hours
5	Hardened depth	10 - 100 µm, 0.0003 - 0.003 in
6	Hardness	1600 – 4000 HV depending on boron compound formed
7	Further processing	may be followed by tempering
8	Distortion/Stress	as with any surface layer production or modification process mismatches in microstructure or deformation state result in stress gradients and distortion
9	Selective area hardening	conceivable to shield areas of part with only small diffusion of boron under shield parallel to surface

3. While the basic information on these processes has been summarized in the text, this problem encourages the students to dig deeper in a library-research mode. One will learn, for example, that there are actually several means of spheroidizing a high-carbon steel. These are different processes with the same objective and utilize the same name. It is important that users understand the entire process, and all of the intricacies, such as the different effects of full anneal and normalizing on subsequent machining (as discussed in the text) .
Useful references again are Metals Handbook and those listed in the "Heat Treatment" section of the Selected References for Additional Study.

4.The effectiveness of quenching usually means the length of time needed to bring the workpiece temperature to a desired temperature. The shorter this time the more effective the quench. In the typical quenchant vaporization – quenchant boiling – conduction heat transfer processes that occur when the work is immersed in the quenchant. The initial vaporization process has the lowest rate of heat transfer out of the workpiece. If the vaporization phase can be minimized the effectiveness of quenching will be increased. With use of a hot oil the quenchant is brought to the boiling stage of quenching faster than with a cold oil and so quenching is more effective.

Case Study:

A Flying Chip from a Sledgehammer

The hammerhead chipped because of the formation of untempered martensite. Untempered martensite of 0.6% carbon would have a hardness of about Rockwell C 65 and would be extremely hard and brittle, quite likely to crack upon impact.

The procedure used to grind off the mushroom would likely involve removing the handle to permit hand grinding of the head. This would then be periodically dipped into a container of water when it gets too hot to hold. Considering the size and mass of a 15-pound sledge hammer head, and the thermal conductivity of steel, it is quite possible that the temperatures in the grinding region could be sufficient to reaustenitize ($>1333^0$F) the metal before the operator would feel uncomfortably high temperatures in the gripped region (especially if he were wearing some type of protective leather-palmed glove) . Upon water quench, the austenite would transform to untempered martensite. Subsequent grinding might bring about some degree of tempering, but this is not assured and all of the untempered martensite may not be affected.

Possible solutions to the problem include: (1) alteration of the grinding procedure to prevent the generation of such excessive temperatures, or (2) a required furnace retempering of the entire head prior to reassembly and reuse, and (3) mandatory use of safety goggles when using the sledge hammers.

CHAPTER 6
Ferrous Metals and Alloys

Review Questions

1. Many of the properties and characteristics of engineering materials depend not only on the material itself, but also on the manner of production and the details of processing. Aspects of prior processing can significantly influence both further processing and the final properties of the product.

2. A ferrous material is one that is based on the element iron (i.e. iron is the major chemical constituent of the material).

3. When iron ore is reduced to metallic iron, other elements are usually present in the product. All of the phosphorus and most of the manganese in the ore will also reduce and will enter the iron. The oxides of silicon and sulfur will be partially reduced and these elements will also become part of the metal.

4. Pig iron is a high-carbon, high-silicon material with a chemistry in the range of 3.0 to 4.5% carbon, 1.0 to 3.0% silicon, 0.15 to 2.5% manganese, 0.05 to 0.1% sulfur, and 0.1 to 2.0% phosphorus. In the conversion into steel, the pig iron is subjected to an oxidation process that substantially decreases the amount of carbon, silicon, manganese, phosphorus, and sulfur.

5. Ladle metallurgy refers to a variety of processes designed to provide final purification and fine tune both the chemistry and temperature of the melt. Alloy additions can be made, carbon can be further reduced, dissolved gases can be reduced or removed, and steps can be taken to control subsequent grain size, limit inclusion content, reduce sulfur, and control the shape of any included sulfides. Stirring, degassing, reheating, and various injection procedures can be performed to increase the cleanliness of the steel and provide tighter control of the chemistry and properties.

6. By extracting molten steel from the bottom of a ladle, slag and floating matter are not transferred to the solidified product .

7. Solidification shrinkage is the term applied to the often substantial change in dimensions that occurs when a liquid changes to solid. The more efficient arrangement of atoms results in an increase in density and a decrease in volume.

8. Continuous casting virtually eliminates the problems of piping and mold spatter. In addition, it eliminates the pouring into molds, stripping the molds from the solidified metal, and the handling and reheating of the ingots prior to rolling. Cost, energy and

scrap are all significantly reduced. The products have improved surfaces, more uniform chemical composition, and fewer oxide inclusions.

9. Dissolved oxygen in molten steel can be removed by adding aluminum, ferromanganese or ferrosilicon to the molten steel. In this deoxidation process the added materials react with the dissolved oxygen to form solid metallic oxides.

10. Gases can be removed from molten steel by vacuum degassing, vacuum arc remelting, vacuum induction melting and electroslag remelting.

11. Electroslag remelting can be used to produce extremely clean, gas-free metal. The nonmetallic impurities are collected in the flux blanket, leaving beneath a newly solidified structure with improved quality.

12. A plain carbon steel is an alloy of iron and carbon, containing manganese, phosphorus, sulfur, and silicon in normal, but small, quantities.

13. A low-carbon steel is one that has less than 0.20% carbon.

Medium-carbon steel contains 0.20% to 0.50% carbon.

High-carbon steels contain more than 0.50% carbon.

14. Medium-carbon steels are used in high volumes because they offer the best overall balance of engineering properties. The high fatigue and toughness properties of the low carbon steels are effectively compromised with the strength and hardness of the higher carbon contents.

15. Plain-carbon steels are the lowest-cost steel material. Because of the low cost, they should be given first consideration for many applications.

16. The most common alloy elements added to steel include:
chromium, nickel, molybdenum, vanadium, tungsten, cobalt, boron, and copper, as well as manganese, phosphorus, sulfur, and silicon in amounts greater than normally present.

17. Alloy elements are added to steel for a variety of reasons, among them: to improve the strength and hardenability, or to produce special properties, such as corrosion resistance or stability at high or low temperatures.

18. Alloy elements that are particularly effective in increasing the hardenability of steel in order of decreasing effectiveness are: manganese, molybdenum, chromium, silicon, and nickel. Vanadium and boron are also used in small, but effective quantities .

19. Chromium, vanadium, molybdenum, and tungsten can all be used to impart strength and wear resistance through the formation of stable second-phase carbides.

20. The last two digits in the AISI-SAE designation system for steel indicates the approximate carbon content of the steel in hundredths of weight percent. This is useful information since many engineering properties are directly tied to the carbon content.

21. Letters are added between the second and third digits in the steel designation and at end of the numerical designation.

The letter in the center of the numerical designation indicates an addition to the base metal or the process used to produce the steel. Examples are B and L indicating addition of boron or lead and E signifying steel produced in an electric furnace.

The letter added at the end of the numerical designation indicates the hardenability of the steel.

22. In selecting a steel, it is important to keep use and fabrication in mind. For example, a product that is to be assembled by welding would benefit from a lower carbon content as such would reduce the likelihood of cracking. Additional strength, if desired, would be better obtained through selection of additional alloy elements rather than an increase in the carbon content of the steel.

23. There is a fundamental difference in the way strength is obtained in the HSLA and constructional alloy steels. The high strength/low alloy (HSLA) types rely largely on the chemical composition to develop the desired mechanical properties in the as-rolled or normalized condition. In contrast, the constructional alloys generally develop the desired properties through the use of nonequilibrium heat treatment.

24. Microalloyed steels are steels that contain small amounts of alloying elements like niobium, vanadium, titanium, zirconium, boron, rare earth elements, or combinations thereof and are used as substitutes for heat-treated steels. Attractive strength and hardness is obtained without interfering with the material processing (weldability, machinability and formability) .

25. Microalloyed steels require less cold work to attain a desired level of strength, so the remaining ductility can be greater than with alternative materials. Hot formed products can often be used in the air cooled condition to provide properties comparable to quenched-and-tempered alloys . Machinability, fatigue life, and wear resistance can be superior to alternative materials. Energy savings can be substantial, straightening or stress relieving after heat treatment can be eliminated, and quench cracking is not a problem. Weight can often be reduced in parts, since the strength is increased.

26. Dual phase steels contain ferrite and high-carbon martensite.

27. Dual phase steels are more formable (ductile) than high strength low alloy steels. They are attractive than HSLA steels for making products that require a large amount of deformation in their production, e.g., parts with small radius bends.

28. Free machining steels are basically carbon steels that have been modified by an alloy addition to enhance machinability. Sulfur, lead,. bismuth, selenium, tellurium, and phosphorus have all been added to enhance machinability.

29.When free-machining steels are selected, the ductility and impact properties are somewhat lower than with the unmodified steels

30. Bake-hardenable steels are aging resistant during normal storage, but begin to age during forming, and continue to age while exposed to heat during the paint baking operation. Since strengthening occurs after forming, the forming characteristics are good, coupled with improved product properties.

31. Precoated steel sheets can often be used to offset the high cost of finishing products on a piece-by-piece basis -- a costly and time-consuming approach. Caution must be exercised to protect the coating during fabrication, but this is usually far less than the cost for finishing the individual pieces.

32. The amorphous metals have attracted considerable attention for use in magnetic applications. Since the material has no grains or grain boundaries, the magnetic domains can move freely in response to magnetic fields, the properties are the same in all directions, and corrosion resistance is improved. The high magnetic strength and low hysteresis losses offer the possibility of smaller, lighter weight magnets.

33. Maraging steels are used when super-high strength is the dominant requirement, and acceptable toughness is also needed. Yield strengths are often in excess of 250 ksi with elongations in excess of 11%.

34. The elevated temperature limit for plain-carbon steels is about 250^o or 500^oF

35. Recycling of a material is easier if the material can be easily collected and reprocessed with no major complications.

Steel is widely used so it available for recycling. Steel is magnetic so it can be separated easily from other materials.

Except for high quality, special application steels requiring tight composition controls, steel is easily reprocessed from scrap steel.

36. The corrosion resistance of stainless steels is the result of a strongly adherent chromium oxide that forms on the surface when the amount of chromium dissolved in the metal exceeds 12%.

37. The ferritic stainless steels are the cheapest of the various families. If their properties are adequate, they should be given first consideration when a stainless steel is required.

38. Martensitic stainless steels frequently contain significant amounts of carbon since

they are used in the quenched and tempered structure. The carbon is dissolved in the austenite at elevated temperature and then trapped into the body-centered structure by quenching. Different amounts of carbon provide different levels of strength, as in the plain-carbon and alloy steels .

39. Stainless steels are stainless when there is at least 12% chromium in atomic form that can react with oxygen at the surface. When martensitic stainless steels are slow cooled or annealed the chromium in the steel reacts with other elements and so is not available to react with oxygen at the part surface. The steel is then not stainless since the protective surface reaction layer is not present. The annealed material is subject to red rust corrosion.

Martensitic stainless steels can be made stainless by a quench and temper process. In this type of process reaction between chromium and other alloying additions are limited.

40. Austenitic stainless steels are nonmagnetic and offer superior corrosion resistance to a host of media. Formability is outstanding, and they respond well to strengthening by cold work.

41. Duplex stainless steels have a chemistry and processing designed to produce a microstructure that is a combination of ferrite and austenite, and properties that are often superior to either the straight ferritic or austenitic varieties.

42. Sensitization of a stainless steel is the loss of corrosion resistance that occurs when the local concentration of chromium drops below 12%. This is usually caused by the formation of chromium carbides along grain boundaries. Methods of prevention include: keep the carbon content low, tie up the carbon with an alternative element, and rapidly cool the material through the carbide-forming temperature range.

43. Tool steels are metals designed to provide wear resistance and toughness combined with high strength. They are basically high-carbon steels where the alloy chemistry provides the desired balance of toughness and wear resistance.

44. While the AISI-SAE designation system for plain-carbon and alloy steels is based on material chemistry, the AISI-SAE system for tool steels identifies materials by a letter indicating the primary feature, such as quenching medium, primary application, special characteristic, or specific industry, followed by a number that simply designates the specific member within the family .

45. Air-hardenable tool steels can be hardened by less severe quenches, permitting tighter tolerances through heat treatment and reduced tendency to crack or warp. Applications involving large amounts of costly or precision machining are particularly attractive .

46. Hot-work tool steels generally use additions of the carbide-forming alloys, such as chromium, tungsten, and molybdenum .

47. If alloy cast irons are to be heat treated, the alloy elements are often selected to improve hardenability. If the cast iron is not to undergo heat treatment, the alloy elements are often selected to alter the properties through affecting the formation of graphite or cementite, modifying the morphology of the carbon-rich phase, or simply strengthening the matrix material. Other reasons for an alloy addition might include improving the wear resistance or providing some degree of enhanced corrosion resistance.

Problems:

No problems

Case Study:

Interior Tub of a Top-Loading Washing Machine

1. The present product is currently performing in an adequate manner and has established itself as somewhat of an industry standard. The material is relatively inexpensive, and readily available, but the necessary surface treatment requires considerable energy and handling with the coating, drying and firing, often of multiple layers. The deep drawing of the material will most likely require intermediate anneals, which will further increase manufacturing cost. While both of the above areas include significant possibilities for problems and involve additional cost, it is likely that the coating process would be the most problematic and most costly.

2. The conversion to stainless steel would enhance customer attractiveness, but also eliminate the need for a coating operation. Unfortunately, the stainless is a more costly material, would require more force to deform, and, depending on the particular type, may have poorer formability. Because of the higher forming forces, equipment and tooling would have to be stronger and would therefore be more costly.

3. Because of the superior formability, some form of austenitic stainless steel would be preferred. This part requires conversion from flat sheet to a deep drawn shape, a procedure that will likely require multiple stages of forming. In addition, the austenitic stainlesses offer superior corrosion resistance, and the product will come into contact with a wide spectrum of water qualities, laundry products, and additives, such as chlorine bleach. There is no need for the high strength of the heat-treated martensitic grades, and the less expensive ferritic alloys lack the superior formability of the face-centered cubic structured austenitic material. Because of the spectrum of possibilities, no attempt is made to select a specific alloy.

4. The austenitic stainless steels strengthen considerably when cold worked, and this can be a useful means of achieving the desired strength. However, it is doubtful that the additional strength of cold working is necessary, and the residual stresses imparted by the

deformation may be detrimental in the form of stress-corrosion problems during service .

If the strengthening of cold work is deemed desirable, the effects of the residual stresses could be reduced by taking the material through the recovery stage of the recrystallization process. This reduces the residual stresses while retaining the mechanical properties set by the cold working.

If intermediate anneals are required during the deformation sequence, the effects of prior cold work will not be carried to the finished product. In addition, one consequence of partial cold rolling of the starting material will be to reduce the; ductility of a material being used for an application that requires extensive deformation. It is unlikely, therefore, that the use of prior cold rolling would be appropriate or desirable for this product.

5. It is possible that a surface passivation treatment would be beneficial for this product, but the inherent properties of the stainless should be adequate.

CHAPTER 7
Nonferrous Metals and Alloys

Review Questions

1. Nonferrous metals often possess certain properties not usually associated with ferrous metals, among them being: corrosion resistance, ease of fabrication, high electrical and thermal conductivity, light weight, strength at elevated temperatures and color.

2. The nonferrous alloys are generally inferior to steel in terms of strength and elastic modulus, and possibly weldability.

3. Alloys with low melting points are often easy to cast, using sand molds, permanent molds, or dies.

4. The wide use of copper and copper alloys is largely due to the high electrical and thermal conductivity, high ductility, and corrosion resistance .

5. The relatively low strength and high ductility make copper quite attractive far forming operations. By cold-working, the tensile strength can be raised from about 30,000 psi to over 65,000 psi., with a concurrent drop in elongation from 60% to about 5%. The low recrystallization temperature is attractive when additional cold working is desired.

6. A primary limitation of capper is its high density --heavier than iron. Strength-to-weight comparisons place it below most engineering metals. In addition, some significant problems can occur when the metal is used at elevated temperature.

7. Commercially pure copper is classified as
- electrolytic tough pitch, ETP, copper if it contains 0.02% - 0.05% oxygen,
- oxygen-free high-conductivity, OFHC, copper if it contains much less than 0.02% oxygen.

These two types of copper differ primarily in oxygen content. This difference implies difference in conductivity and differences in production to control oxygen content.

8. The copper-zinc alpha brasses are quite ductile and formable, achieve good strength through cold working and have good corrosion resistance and high electrical and thermal conductivities. Both strength and ductility increase with zinc content up to about 36% zinc. In addition, variations in chemistry can be used to produce changes in color and various platings are easy to apply.

9. Brasses are susceptible to stress corrosion cracking. Stress corrosion requires a hostile environment and stress. The stress acting is a combination of stress due to loading in

service and residual stresses created during processing. To reduce the net stress acting in service, residual stress can be removed or reduced by a stress relief process.

10. The term "bronze" can be particularly confusing. While the term frequently refers to copper-tin alloys, it can be used to describe any copper alloy where the major alloy addition is neither zinc nor nickel.

11. The copper-nickel alloys are particularly well known far their high thermal conductivity and high-temperature strength, coupled with good corrosion resistance.

12. Copper-beryllium alloys can be age hardened to produce the highest strengths of the copper-based metals. In addition to having strengths similar to steel, the alloys are nonsparking, nonmagnetic, and have high electrical and thermal conductivity. Its use has been drastically limited, however, by concerns over the toxicity of the beryllium.

13. Aluminum and its alloys have achieved popularity due to their light weight, high electrical and thermal conductivity, good corrosion resistance, and workability.

14. A given volume of aluminum is about one-third the weight of the same volume of steel. The specific gravity of aluminum is about 2.7 while for steel specific gravity is about 7.9.

In manufacturing operations both cost per unit weight and cost per unit volume are useful quantities. The cost of many metal raw materials and structural shapes that will be converted into finished parts are quoted as cost per weight.

The cost of the finished part includes manufacturing costs and material costs. If the volume of a particular part will be the same whether it is made of aluminum or steel, the relevant material cost for the part is cost per unit volume of material.

15. The electrical conductivity of pure aluminum is approximately 62% that of copper for the same size wire and 200% that of copper on an equal weight basis.

16. Aluminum alloys are inferior to steel in the area of elastic modulus. In addition, the wear, creep, and fatigue properties are generally rather poor.

17. The observed corrosion resistance of aluminum alloys is again the result of a tight, adherent oxide coating, similar to that found in stainless steels.

18. Wrought means “worked” and the wrought aluminum alloys are designed to have properties that are desirable for making worked or formed parts. Mechanical properties that are desirable for making formed parts include low yield strength, high ductility, high toughness, high strain hardening rate if high strength is desired in the finished part.

Cast or casting alloys are designed to have properties desirable for making cast parts. For example, casting alloys have low melting temperature, high fluidity when molten and desirable as-solidified structures and properties.

19. While the four digit number of an aluminum alloy only designates chemistry, the temper designation or suffix denotes the condition or nature of the prior processing history of the material. This can be used to provide a good indication of the structure and properties of the alloy.

20. The high-strength, aircraft-quality" aluminum alloys generally receive their strengthening through an age hardening treatment.

21. Alcad is a composite with a thin layer of corrosion resistant aluminum bonded to a higher strength corer material. The result is a corrosion resistant and high strength material.

22. The aluminum alloys used for permanent mold casting must be designed to have lower coefficients of thermal expansion because the molds offer restraint to the dimensional changes that occur upon cooling. Die casting alloys require high degrees of fluidity and "castability" because they are often cast into thin sections. In addition, many are designed to have rather high as-cast strength under rapid cooling conditions.

23. The aluminum-lithium alloys offer higher strength, greater stiffness and lighter weight than most of the commercial aluminum alloys, coupled with the relative ease of fabrication of aluminum alloys.

24. Magnesium and magnesium alloys can be characterized by poor wear, creep, fatigue, and corrosion resistance properties. The modulus of elasticity is low and the alloys possess limited ductility .

25. The use of magnesium is generally restricted to applications where light weight is very important. Magnesium alloys are best suited for applications where lightness is the primary consideration and strength is a secondary requirement.

26. Classification of metals typically involves specifying the composition (alloying), heat treatment and sometime other characteristics such as addition of base metals and method of production (Question 21 in Chapter 6).

Magnesium alloys classification uses
- one or two prefix letters to specify the two largest alloying additions,
-, two or three numerals that specify the percentages of the two main alloying metals,
- sometimes a suffix letter to denote a base alloy variation,
- sometimes a suffix letter to designate material temper.

27. The forming behavior of magnesium alloys is poor at room temperature, but most conventional processes can be performed when the material is heated to between 450 and 7000P.

28. Magnesium is flammable or explosive when it is in a finely-divided form, such as powder or chips. A critical feature here is the ratio of surface area to volume. In addition, magnesium is flammable when heated above 800^{o}F in the presence of oxygen.

29. The primary application of pure zinc is the galvanizing of iron and steel. The principal use of the zinc-based alloys is in die-casting operations. They are low in cost, have low melting points, do not affect steel dies adversely, and can possess good strength and dimensional stability.

30. Zinc-aluminum casting alloys are designed to have higher strength, hardness and wear resistance and lower melting and casting costs than zinc casting alloys.

31. Titanium and its alloys are strong, lightweight, corrosion resistant, and offer strengths similar to steel at temperatures up to 9000F.

32. The attractive mechanical properties of titanium and titanium alloys are generally retained at temperatures up to 900^{0}F.

33. The nickel-based Monel alloys probably offer better corrosion resistance to more media than any other commercial alloy.

34. Nickel, iron and nickel, or cobalt forms the base metal for the superalloys.

35. when the operating temperature exceeds the limits of the superalloys, exotic materials must be employed, such as TD-nickel or the refractory metals.

36. The refractory metals consist of: niobium, molybdenum, tantalum, rhenium and tungsten.

37. While the eutectic lead-tin alloy offers the lowest melting temperature of the lead-tin solders, the high cost of tin has prompted many users to specify solders with a lower-than-optimum tin content.

38. Beryllium has low density (less than aluminum) and high stiffness (greater than steel) and so parts with high stiffness-to-weight ratio can be design and produced.

39. Graphite possesses the unique property of actually increasing in strength as the temperature is increased. This makes the material attractive for elevated temperature applications, such as electrodes in furnaces.

Problems:

No problems

Case Study:

Nonsparking Wrench

Many safety tools have been made from the copper-2% beryllium alloy, since its age-hardened properties approach and often exceed those of many heat-treated alloy steels. This is fine for small tools where the cost of the material and the weight of the copper alloy (greater than that of steel) are not objectionable. However, with the proposed pipe wrench, both cost and weight may pose serious problems to the acceptance of the tool.

The copper-2% beryllium alloy will likely have to be used in the actual jaws of the wrench, as it is one of the few nonferrous materials that can provide the necessary strength, wear resistance, and fracture resistance for this use. However, the handle, adjuster ring, and moving L-shaped upper jaw will likely have lower mechanical property requirements that could be met by some of the other age-hardenable, higher-strength nonferrous materials. Aluminum alloys, such as 6061, 2014, 2024, 7075, 7079 and others could be forged and heat-treated to produce the handle and jaw components, and copper-beryllium inserts can be installed in the jaws. Alternately, an age-hardenable aluminum casting alloy could be selected and these components could be fabricated by sand, permanent mold, or even die casting. One problem with the use of the aluminum alloy with a copper insert would be the presence of a galvanic corrosion cell (dissimilar metals), which could be aggravated by some of the environments in which tools are typically stored. Since replaceable inserts would be desirable, and the method of assembly would likely involve a removable fastener, electrical contact between the components would be virtually assured. The possible severity of this problem would have to be monitored.

Alternative solutions would not be as attractive. Manufacture of the handle from a less expensive copper-base alloy would reduce cost and significantly reduce the galvanic corrosion problems, but the weight of such a wrench may be objectionable. Smaller wrenches in the series might be made in this manner. Magnesium alloys offer light weight, but lack the necessary strength and rigidity. Titanium alloys are difficult to fabricate (too reactive to easily cast and generally require isothermal forging) . Nickel-base alloys would offer no cost advantage to the copper-beryllium.

Unless the galvanic corrosion problems become excessive in the jaws, the most attractive solution would appear to be a to use copper-beryllium inserts in cast or forged aluminum components. All parts would probably require strengthening through age hardening treatments.

CHAPTER 8
Nonmetallic Materials: Plastics, Elastomers, Ceramics, and Composites

Review Questions

1. Some of the naturally occurring nonmetallic engineering materials are: wood, stone, clay, and leather.

2. The term "nonmetallic engineering material" now includes plastics, elastomers, ceramics and composites.

3 . The term "plastics" refers to engineered organic materials, composed of hydrogen, oxygen, carbon and nitrogen, in the form of large molecules that are built up by joining smaller molecules. They are natural or synthetic resins, or their compounds, that can be molded, extruded, cast, or used as thin films or coatings.

4. Considering a macroscopic piece of plastic/polymer there are two types of bonds within it. Within the molecules themselves the bonding is covalent. This is the primary bonding in the material.

Between the molecules much weaker van der Waals bonds act.

5. A saturated molecule is one to which no additional atoms can be added. If the molecule is a pure hydrocarbon, it contains the maximum number of hydrogen atoms. An unsaturated hydrocarbon does not contain the maximum number of hydrogen atoms.

6. An isomer is one structural form of a given kind and number of atoms that can form in different ways. That is, isomers are different structural arrangements of a given number and kind of atoms and an isomer is one instance of the possible isomers.

7. Polymerization can take place by either addition or condensation. In addition, a number of small molecules unite to form a large molecule with repeated units. Condensation polymerization results in the formation of a polymer and a small by-product molecule .

8. The repeated molecular unit in a polymer molecule is a mer. The degree of polymerization is the average numbers of these units (mers) in the polymer molecule.

9. The terms thermoplastic and thermosetting refer to a material's response to elevated temperature. Thermoplastic materials soften with increasing temperature and become harder or stronger when cooled. The cycle can be repeated as often as desired and no chemical change is involved. In the thermosetting materials, elevated temperatures tend to promote an irreversible condensation reaction. Once set, additional heatings do not

produce softening. Instead, the materials maintain their mechanical properties up to the temperature at which they char or burn .

10. Crystallization of a polymer means that the polymeric molecules align into a repeating, orderly structure. Crystallization occurs in only individual regions of the polymer, not over the entire, macroscopic piece of material.

11. The strength of the thermoplastic materials can be altered by mechanisms that restrict or alter the intermolecular slippage. These mechanisms include: longer chains, polymers with large side groupings, branched polymers, cross-linking, and crystallization.

12. The deformation of thermosetting material requires the simultaneous breaking of numerous primary bonds. Therefore, these materials are strong, but brittle.

13. .Upon subsequent heating, the thermosetting polymers maintain their mechanical properties up to the temperature at which they char or burn.

14. While thermoplastic materials are easily molded, the temperature of the mold must be cycled to permit the molded product to cool and strengthen prior to ejection. In contrast, the mold used to process thermosetting polymers can operate at a fixed temperature, but the molding time is often longer because of the need to complete the curing or "setting" of the resins.

15. Attractive engineering properties of plastics include:
light weight, corrosion resistance, electrical resistance, low thermal conductivity, the variety of optical characteristics, formability, surface finish, low cost, and low energy content.

16. The inferior properties of plastics generally relate to mechanical strength. Yield strength, impact strength, dimensional stability, property retention at elevated temperature, sensitivity to humidity, and degradation under certain forms of radiation are all limiting or undesirable properties.

17. Environmental conditions that may adversely affect the performance of plastics include: elevated temperature, humidity, and ultraviolet and particulate radiation.

18. Additive agents are frequently added to plastics to improve their properties, reduce their cost, improve their moldability, and impart color.

19. Filler materials are added to molded plastic to: improve strength, stiffness, or toughness; reduce shrinkage; reduce weight; or provide cost-saving bulk.

20. Common filler materials for plastics are wood flour, cloth fibers and particles, glass fibers, mica and inorganic materials such as talc and clay. They are intended primarily to improve mechanical properties of the polymeric material and in some cases to reduce cost by including a low cost volume fraction in the higher cost plastic.

21. Stabilizers or antioxidants are added to plastics to reduce long term degradation of the polymer due to factors such as heat and radiation.

22. Oriented plastics are intended to have increased strength in a particular direction.

23. The "true engineering plastics" offer improved thermal properties, first-rate impact and stress resistance, high rigidity, superior electrical characteristics, excellent processing properties, and little dimensional change with temperature or humidity. They offer a balanced set of engineering properties.

24. Plastics have replaced glass in containers and flat glass. PVC competes with copper and brass in pipe and plumbing fittings. Plastics have replaced ceramics in sewer pipe and lavatory facilities. New automotive uses include engine components and fuel tanks and fittings.

25. With the amount of a particular type of plastic that is recycled being an indicator of ease of recycling, polyethylene terephthalate (PET) and high density polyethylene are the easiest to recycle.

26. Mixed plastics contain multiple types of resins, fillers and colors, and may mix thermoplastics and thermosets. Most, however, have the same physical properties, making separation extremely difficult.

27. Elastomers are a class of linear polymers that display an exceptionally large amount of elastic deformation when a force is applied, frequently stretching to several times their original length. In these materials, the long polymer chain is in the form of a coil, which elastically uncoils and recoils in response to loads.

28. By cross-linking the molecules, it is possible to prevent viscous deformation, while retaining the large elastic response. The elasticity or rigidity of the product can be determined by controlling the number of cross-links. Small amounts of cross-linking produces soft, flexible material. Additional cross-linking makes the material harder, stiffer, and more brittle. Thus the properties of an elastomer can be tailored through control of the amount of cross-linking.

29. Natural rubber is an organic material and so its strength is very sensitive to temperature and its structure is degraded by solvents such as petroleum based oil, gasoline and naphtha and radiation energy.

30. The outstanding physical properties of ceramics include their ability to: withstand high temperatures, provide a variety of electrical properties, and resist wear.

31. The crystal structures of ceramic materials are frequently more complex than those for metals because atoms that differ greatly in size must be accommodated within the same structure and interstitial sites become extremely important. In addition, charge

neutrality must be maintained throughout the structure of ionic materials. Covalent materials can only have a limited number of nearest neighbors - forcing inefficient packing and low density.

32. Amorphous or noncrystalline ceramics are often called glasses, and said to be in a glassy state or have a glass structure.

33. The refractory ceramics are materials that are designed to provide acceptable mechanical and chemical properties while at high temperatures .

34. The dominant property of the ceramic abrasives is their high hardness.

35. Glass products are formed by heating the feed stock or initial workpiece and then mechanically shaping it at the elevated temperature. Examples of forming techniques are mechanical forming using paddles and blowing of hollow shapes.

Machinable ceramics have been developed but these are typically called ceramics, not glasses.

36. Cermets are combinations of metals and ceramics that are bonded together in the same manner in which powder metallurgy parts are produced. They combine the high refractory characteristics of ceramics and the toughness and thermal shock resistance of metals.

37. Ceramic materials generally do not exhibit their potentially high tensile strength because small pores or flaws act as stress concentrators and their effect cannot be reduced by plastic flow.

38. The mechanical properties of ceramics generally show a wider statistical spread than the properties of metals since the size, number, shape and location of the flaws is likely to differ from part to part, inducing failure at very different applied loads.

39. Even if all of the flaws or defects could be eliminated from the structural ceramics, the materials would still fail by brittle fracture with little, if any, prior warning. Thermal shock may be a problem, cost would be high, joining to other materials is difficult, and machining limitations favor net-shape processing .

40. The structural ceramic materials include: silicon nitride, silicon carbide, partially stabilized zirconia, transformation-toughened zirconia, alumina, sialons, boron carbide, boron nitride, titanium diboride, and ceramic composites.

41. Sialon is stronger than steel, extremely hard, and light as aluminum. It has good resistance to corrosion, wear and thermal shock, is an electrical insulator, and retains good tensile and compression strength up to 2550^{o}F. In addition, its thermal expansion is quite low compared to steel or polymers. When overloaded, however, it will fail by brittle fracture.

42. Some of the ceramic materials currently being used as cutting tools include: silicon carbide, cobalt-bonded tungsten carbide, silicon nitride, cubic boron nitride, and polycrystalline diamond. The ceramic cutting tools offer low wear rates, low friction, high rates of cutting, and long tool life.

43. A composite material is a heterogeneous solid consisting of two or more components that are mechanically or metallurgically bonded together. Each of the components retains its identity, structure and properties, yet by combining the components, unique properties are imparted to the composite.

44. The properties of composite materials generally depend upon: the properties of the individual materials; the relative amounts of the components; the size, shape and distribution of the discontinuous components; the degree of bonding between the components; and the orientation of the various components.

45. The three principal geometries of composite materials are: laminar or layer-type, particulate, and fiber-reinforced.

46. A bimetallic strip consists of two metals with different coefficients of thermal expansion bonded together as a laminate. Changes in temperature produce a change in shape.

47. The attractive aspect of the strengthening that is induced in the dispersion-strengthened particulate composites is the stability and retention that is observed at elevated temperatures. The particles are selected to be insoluble in the matrix material, their effect persists to temperatures much higher than for the naturally-occurring two-phase materials.

48. Due to their unique geometry, the properties of particulate composites are usually isotropic. This is usually not true for the laminar, whose properties differ perpendicular and within the plane of the laminate. Fiber-reinforced composites, may or may not be isotropic depending on the length and randomness of the orientation of the fibers.

49. In a fiber-reinforced composite, the matrix supports and transmits loads to the fibers, and provides the ductility and toughness. The fibers, on the other hand, provide strength by carrying most of the load.

50. Common fibers used in fiber reinforced composites are nylon, rayon, Kevlar, glass and graphite. Since the matrix protects the fibers from fracture initiation and growth conditions in use, brittle materials can be used as the strength producing components of composites.

51. In a fiber-reinforced composite, the fibers can be in a variety of orientations: short, random fibers; unidirectional fibers; woven fabric layers; and complex 3-dimensional weaves.

52. Tbe properties of fiber-reinforced composites depend strongly upon: the properties of the fiber material, the volume fraction of fibers, the aspect ratio of the fibers, the orientation of the fibers, the degree of bonding between the fiber and the matrix, and the properties of the matrix.

53. Compared to metals, the metal-matrix composites offer higher stiffness and strength and a lower coefficient of thermal expansion. Compared to the organic matrix materials, they offer higher heat resistance as well as improved electrical and thermal conductivity .

54. In a ceramic matrix composite, the fibers add directional strength, increase fracture toughness, and improve thermal shock resistance.

55. Current limitations to the extensive use of composite materials in engineering applications include: the high cost of the material, the intensity of labor required for fabrication, and the lack of trained designers, established design guidelines, information about fabrication costs, and methods of quality control and inspection. In addition, it is often difficult to predict interfacial bond strength, strength of the composite, response to impacts and probable modes of failure. There is concern about heat resistance, sensitivity to various environments, and instability of properties. Repair, maintenance, and assembly are difficult or require special procedures.

56. Composites are quite attractive for aerospace applications because they offer high strength, light weight, high stiffness, and good fatigue resistance.

Problems:

1. a). Some of the desirable features for a submarine material are high strength (to withstand water pressure), fracture resistance (to withstand possible impacts), corrosion resistance (to both fresh and salt water), and the ability to be fabricated into a leak-tight assembly (possibly using techniques like welding) . Possible materials would include high-strength steels, titanium alloys, and possibly nickel-based alloys.

b) For aerospace applications, concerns focus on areas such as: light weight, strength-to-weight ratio, fatigue resistance, and ease of fabrication and ability to fabricate in small production quantities .

c) Engineers are constantly pushing the limits of engineering materials. Some current targets that are presently unattainable include: (1) reuseable rocket engines that, can withstand temperatures in excess of 4000^0F, stresses and severe vibrations, and (2) light weight wing skin materials for hypersonic aircraft that will withstand temperatures in excess of 1800^0F, and be resistant to fracture, fatigue and corrosion.

Since these applications both require elevated-temperature properties, they will likely be addressed through ceramic materials, the family of intermetallic compounds, or even the high-temperature metals (although these are sufficiently heavy as to be inappropriate for the airplane use) . Any use of polymers would be highly unlikely at the specified temperatures.

2. This is an open-ended problem, but numerous examples can be considered, such as: (1) window frames (wood, metal, vinyl); (2) lavatory basins (metal, cast polymer, ceramic whiteware); and (3) window cranks for autos or mobile homes (die cast plastic or die-cast zinc) .

3. Coated cutting tool preparation is described in Section 22.2.

The performance of the coating is in machining, in contrast to performance in mechanical and chemical tests related to expected performance in machining, e.g., hardness, hot hardness (e.g., Figure 22-3, Table 22-1), corrosion. Using the information available in Chapter 22 enables a comparison of performance in terms of tool wear/tool life in machining.

	Deposition conditions	Performance
TiC	chemical vapor deposition 1000°C 1800°F initial heating in inert atmosphere	cutting speed – up to 1200 sfpm, Fig 22-1 n = 0.33, page 537
TiN	chemical vapor deposition preferred – as above - or physical vapor deposition (reactive sputtering, reactive ion plating, arc evaporation) 200-485°C, 400-900°F in vacuum	cutting speed – up to 1200 sfpm, Fig 22-1 n = 0.35, page 537
Al_2O_3	alumina compacts made by compaction and sintering 267 – 286 MPa, ~40,000psi ~ 1000°C, 1800°F alumina coatings	cutting speed – up to 1200 sfpm, Fig 22-1 n = 0.40

Maximum useful cutting speeds are about the same for all materials. Based on the value of n which is the exponent in the Taylor Tool Life equation aluminum oxide cutters will have the longest tool life followed by titanium nitride and then titanium carbide.

Mechanical properties will enter in determining tool performance in specific machining operations. For example, the brittle aluminum oxide tool is expected to perform poorly in interrupted cutting such as milling due to varying cutting forces and temperature cycling.

4. Ceramics are hard, strong, brittle materials. Oxides are chemically stable. These materials have low thermal conductivity. Ceramic parts are made in high temperature compaction followed by sintering and finishing processes, Section 8.4. Residual voids in the part, coupled with the inherently brittle ceramic materials, usually results in brittle materials.

a. With respect to part manufacture these material characteristics have important implications. Compaction of a ceramic part before sintering requires application of high pressure. This implies difficulties for production of large parts since this implies the need for high pressure, high load, high stiffness machinery. Compaction requires high strength dies and formed parts have to be removed from the die so complex shaped parts may not be feasible to manufacture. Mechanical manufacturing processes such as forming and machining produce a part by controlled deformation of the work material. The brittleness of typical ceramics means that they will fracture during production processes except in processes in which very little deformation is needed to produce the part. In many finishing operations such as machining brittle materials fracture leaving rough surfaces subject to fracture initiation at the sharp nonuniformites in the surface. (There is recent development of ductile regime machining/grinding in which small depths of cut are used and ductile workpiece deformation is produced.) The low thermal conductivity of ceramics means that extreme temperature gradients can arise in high speed deformation processes. Relatively low processing speeds may be required, e.g., low grinding speed, low depth of cut. Further, the low thermal conductivity of ceramic parts will present problems when these parts mate with metallic or other material parts with high thermal conductivity. The chemical stability of ceramics implies that joining processes will be difficult.

These kind of arguments lead to the conclusion that the primary limitations to the production of a ceramic engine are that only relatively small, simple shape parts that require little finishing can be easily produced, Figure 8-7. Small ceramic parts are finding their way into traditional internal combustion engines, e.g., valve guides, turbocharger impellers.

b. To make the small, simple shape parts most of the technical ceramics materials (in contrast to the fine ceramics and glasses) can be used, given that the part will be made. That is, if a ceramic part can be realistically produced in the face of limitations such as those described above, most common ceramics that can be sintered can be used.

c. As discussed in part a above, part design and production processes in which little deformation is needed to produce relatively small, simple shape parts are expected to be successful when manufacturing ceramic parts. This implies net final shape compaction and sintering followed by finishing processes that remove only small amounts of material. The hardness of ceramics also indicates small material removal finishing operations using hard tools, e.g., grinding, lapping polishing.

d. For the manufacture of ceramic parts

- with respect to material properties materials that exhibit as much plastic deformation as possible are desirable. This will lead to being able to process the materials in conventional processes that typically impose significant deformation on the workpiece.
- with respect to processes, processes that do not impose large scale deformation will be useful since they will avoid the fracture associated with deforming brittle materials.

Case Study:

Two-Wheel Dolly Handles

There is considerable variability to this problem, but concerns should address the durability, impact resistance when dropped on the handles, and the ability to withstand high localized stresses (such as at the bolt holes) without cracking or fracture. Since the product may be used on outdoor loading docks in mid-winter, critical properties must be present at low temperatures -- a possible problem for polymeric materials.

A number of alternatives are possible, including such techniques as the injection molding of polymeric material containing chopped fibers, and others. Since the design was made for casting, one might expect incorporation of pattern-removal draft, and a preference for uniform thickness or section size.

CHAPTER 9
Material Selection

Review Questions

1. Exceeding product requirements will usually involve using different materials and possibly different manufacturing processes to produce the product. Changes (higher quality materials and operations to work them) in materials and processes may result in higher costs. Using different materials and processes may also require the acquisition of new knowledge, understanding and experience – the development of new knowledge bases for materials and processes.

2. In a manufacturing environment, the selection and use of engineering materials should be a matter of constant reevaluation. New materials are continually being developed. Others may no longer be available. Prices are subject to change and fluctuation. Concerns regarding environmental pollution, recycling, and worker health and safety impose new constraints. The desire for weight reduction, energy savings, or improved corrosion resistance may require a material change. Increased competition, the demand for improved quality and serviceability, and negative customer feedback may all prompt review and evaluation. Finally, the climate of product liability demands constant concern for engineering materials.

3. Recent shifts in the materials used in automobiles show increased use of lighter weight materials and high-strength steels, as well as plastics and composites. Early automobiles made extensive use of wood, and some early fenders were made of leather .

4. The development, substitution and use of materials in aerospace applications are generally driven by the need for improved strength-to-weight ratio and high temperature resistance. Some of the newer materials used for improved strength with light weight are high strength, light weight metal alloys such as aluminum-lithium alloys, metal-matrix composites, polymer-matrix composites, carbon fiber composites. The refractory superalloys and newer titanium alloys are being used where maintaining strength at high service temperatures in important.

5. There is a distinct interdependence between engineering materials and the processes used to produce the desired shape and properties. A change in materials will often require a change in manufacturing processes; and improvements in processes may lead to a reevaluation of materials.

6. At a very high level of description, engineering design is specifying what material to use and how to distribute it in space to provide a specified function(s). Design should also include manufacturing considerations – how to produce the part or product.

In more detail, design is detailed specification of

- what to produce based on quantitative performance measures,
- the required material and geometric properties,
- the material(s) to use,
- and the related issues of manufacturing process selection.

Design is often specific to a part of the overall product production activity, e.g., part design, process design, manufacturing system design. All of these kinds of activities are related and should be integrated in the product production enterprise.

7. The three usual phases of product design are: conceptual design, functional design and production design. Consideration of material is of almost no concern in the first phase; is of importance in the second phase in that suitable materials must be available and selected; and in the third phase, the exact materials to be used must be related to the production processes and to the tolerances required and the cost.

8. If one does not require that prototype products be manufactured from the same materials that will be used in production and by the same manufacturing techniques, it is possible to produce a perfectly functioning prototype that cannot be manufactured economically in the desired volume or one that is substantially different from what the production units will be like. By using the same material and process, the prototype will provide a true assessment of the performance and manufacturability of the product.

9. New materials should be evaluated very carefully to assure that all of their characteristics are well established. Numerous product failures have resulted from new materials being substituted before their long-term properties were fully known. when changing a process, it is important that the effect of the process on the properties of the material be known and acceptable .

10. The "case-history" approach has several pitfalls. First, minor variations in service requirements may well require different materials or different manufacturing operations. In addition, this approach precludes the use of new technology, new materials, and other manufacturing advances that may have occurred since the formulation of the previous solution.

11. The most frequent problem that arises when seeking to improve an existing product is to lose sight of one of the original design requirements and recommend a change that in some way compromises the total performance of the product.

12. A thorough job of defining needs is the first step in any materials selection, and all factors and possible service conditions should be considered. Many failures and product liability claims have resulted from simple engineering oversights or failure to consider all types of reasonable product use.

13. Dimensioned sketches show the desired end result shape. Since the shape is explicitly specified and the means of producing it are not specified, the specified shape has numerous implications. These implications extend from possible redesign of the part by

making it a combination of simpler shapes to the part shape determining possible manufacturing processes, e.g., prismatic and cylindrical parts will be made using different types of processes, perhaps milling and lathe turning.

Dimensioned sketches probably specify shape, dimensions and perhaps tolerances. Part performance determining characteristics such as required surface finish (surface shape) may not be specified. Surface finish requirements will determine the kind of processes that can produce the required surface and the possible need for more than one process as in turning and then grinding a shaft.

Overall shape also may be inadequate for specifying part characteristics for parts used in assemblies. When parts have to mate with other parts dimensional and geometric (shape) characteristics are important. The natural variations in them when large numbers of parts are being made become important. Part accuracy and precision and the allowable variations in them during manufacture are probably not shown on a dimensioned sketch.

14. Material properties change with temperature and so specifying the required mechanical properties for a design/part/product has to include changes in properties that result from
- the temperature in use,
- variations in temperature as thermal cycling can cause stress cycling if the part is constrained.

Also, the rates of many chemical, physical and mechanical processes vary with temperature. For example, the effective strength of a part changes with corrosion and corrosion rate varies with temperature.

15. The compatibility of a product to its service environment is absolutely necessary for its success. Some considerations should include: highest, lowest, and normal operating temperatures, and the nature of any temperature changes; possible corrosive environments; desired lifetime; and the anticipated level of maintenance or service.

16. In design many manufacturing concerns arise and should be considered as part of the design process, for example,
- part production quantity and required production rate as this affects the type of machine tools that can be used,
- part quality since different manufacturing processes have different capabilities,
- part test and inspection requirements as these are included in most manufacturing operations,
- part mating requirement for assembly,
- part disassembly requirements related to repair, disposal, recycling,
- part section changes since they affect part handling in sequences of processes and in assembly,
- use of standard sizes for part features since this may enable use of standard size tooling,
- material selection criteria that include ease of manufacture, e.g. use of easy to machine, machinable, or easy to form, formable, materials.

17. Although there is a tendency to want to jump to "the answer", it is important that all factors be listed and all service conditions and uses be considered. Many failures and product liability claims have resulted from simple engineering oversights or the designer not anticipating reasonable use for a product or conditions outside of the specific function for which he designed it.

18. All factors have to be considered since each and every one can have an effect on performance and so on the quality of the product. In addition, interactions between design factors, between service conditions and between all design factors and in-use conditions should be considered, e.g., the interactions of stress due to static and dynamic loading and environment of sea-based structures since stress corrosion cracking is an important issue.

19. "Absolute" requirements are those for which no compromise or substitution can be permitted. "Relative" requirements are those which can be compromised to some extent.

20. Handbook-type data is obtained through the use of standardized materials characterization tests. The conditions of these tests may not match with those of the proposed application. Significant variation in factors such as temperature, rates of loading, and surface finish can lead to major changes in material performance. In addition, the handbook values often represent an average, and the actual material properties will vary on either side of that value.

21. While cost is indeed an important consideration, it may be desirable to first demonstrate that the material or materials meet all of the necessary requirements. If more than one candidate emerges, then cost becomes a factor. If only one is satisfactory, then one must determine if its cost is acceptable.

22. Barbell weights should be evaluated on a cost per pound basis. Parts with fixed size, like door knobs should be evaluated on a cost per cubic inch basis. There are numerous other examples.

23. Product failures can provide valuable information. By identifying the cause of the failure, the engineer can determine the necessary changes that would be required to prevent future occurrences. Failures of similar parts in similar applications can provide additional information.

24. In selecting a material, one should consider the possible fabrication processes and the suitability of the various candidate materials to each process. All processes are not compatible with all materials. The goal is to arrive at the best combination of material and manufacturing process for the particular product .

25. In general, decisions about a material or process to be used influence the other. Processing options for materials depend on the material selected. In an extreme case, the specification of a material may result in not being able to process it with available equipment. For example, if a highly temperature resistant material has to be used for a part there is no choice but to obtain the machines and tooling capable of processing the

material or finding a source for part manufacture. The only way rational manufacturing planning can be done is if this is realized at the part design stage.

Conversely, if available manufacturing machines have to be used, only materials that can be processed are feasible options.

Further, if the processes to be used changes material characteristics the extent of the effects on different materials has to be considered in material selection. For example, a residually stressed surface layer is produced in machining. Some metals are more strain hardening than others and so the level of residual stress produced will be different.

Since part or product cost depends on both material and processing costs, specification of a material determines part of the manufacturing cost.

26. Since a wide range of knowledge is needed in all aspects of
- material properties and behavior,
- the capabilities of manufacturing processes,
- and the effects of processing on material structure, properties and performance,
multiple individuals will probably be involved in material and process selection.

27. Material substitution problem example:
The replacement steel automobile body panels with new high strength, low alloy steel resulted in thinner, lighter body panels of essentially the same strength. However, the less corrosion resistant, thinner HSLA steel panels rusted through more quickly.
Initial replacement of cast iron engine blocks with aluminum block resulted in lighter engines but with less damping. Vibration became a problem, subsequently solved.

28. Product liability cases have resulted from a number of reasons, most commonly: failure to know and use the latest information about the material used, failure to foresee and take into account reasonable uses for the product, use of materials about which insufficient data is known, inadequate quality control, and material selection made by unqualified people.

Problems:

1. Based on the chart below, material Y has the highest rating number. However, because it does not have satisfactory weldability and this is an "absolute" requirement, it should not be selected. Material Z should be used.

Material Characteristic
1. Corrosion
2. Weldability
3. Brazability
4. Strength
5. Toughness

6. Stiffness
7. Stability
8. Fatigue
9.As-welded Strength
10. Tensile Strength
11. Cost
R = Material Rating Number

	Go – No Go			**Relative Rating Number**								**R**
	1	2	3	4	5	6	7	8	9	10	11	
X		S				3x1	3x4	2x5		3x4		**37**
Y		U				3x1	5x4	3x5		5x4		**58**
Z		S				3x1	3x4	5x5		2x4		**48**

2. The problem specifies performance and durability as factors to be considered. Chalk trays have few performance requirements and so the Rating Chart is simple. Durability is also not a complex issue. The manufacture of the tray is considered in the next part of the discussion.

With the simple performance and durability concerns it is reasonable to simplify the Rating Chart by making all requirements Go – No Go except for cost. Or, to use weighting factors for all with the probable result that cost will be the overriding factor and then the Rating Chart can be redone as No – No Go except for cost. This Go – No Go versus weighting is somewhat analogous to the distinction of Variable and Attribute testing discussed in Chapter 10.

Material	Go – No Go Screening				Weight	Rating
	Cross section shape	Paintable Finishing	Ease of Cleaning	Can be cut to length, joined	Cost 1 = low 5 = high	
Wood	S	S	S	S	2	
Aluminum	S	*	S	S	2** 4**	
Plastic	S	S	S	S	1	

S = Satisfactory, U = Unsatisfactory,
* limited range of anodized colors and this is reflected in cost
** cost for metallic finish
*** cost for anodized colors

With only the cost criterion distinguishing the choices available funds and subjective appearance and look-and-fell will determine choice.

The “continuous cross section” in the problem statement indicates the same cross section along the tray length. Two issues arise; the cross section shapes that need to be produced and the desirability (production rate and manufacturing cost) of producing parts in a continuous manner.

Wooden trays can be made by machining long pieces of work material in a shaping operation. Cutters can be ground to the desired shape, mounted on the shaper arbor and the long workpieces fed past the cutter. A series of cutting heads or machines will probably be required to sequentially change the initial, perhaps rectangular, cross section to the final cross section shape. Molders are similar machines used to produce wooden moldings. Cutting speeds (speed of the cutting edge through the work material) for wood are high as is the feed speed, the rate at which the workpiece moves past the cutter.

The machining process produces a finished surface that in sophisticated, well run operations may be smooth enough to paint of finish with some other coating. If the surface is not sufficiently smooth subsequent abrasive finishing may be required. In addition to the finished surface shavings or chips are produced. This is a low value by-product even if it is used in other reconstitutes wood products such as flake board. And, the chips may have to be further processed for some products such as oriented strand board.

In contrast to wood that cannot be easily formed, aluminum ductility enables it to be formed in extrusion and rolling processes (Chapter 18), perhaps at elevated temperature. Both processes are continuous in the sense that long sections of product can be formed from standard size and shape feedstock. Since complex, hollow shapes can be extruded, extrusion is a logical choice for chalk tray production. Long sections can be cut to length. Joining sections such as at a corner is not a problem since the tray is not a load bearing structure and so load transference is not needed. Smooth corner joints with the sections simply butted up against each other is a adequate.

Long shaped sheet metal parts can be continuously produced in roll forming, Chapter 19. Depending on the cross section shape required and the tray section thickness roll forming may be feasible. Qualitatively, thick sheet deformed to a tight bend radius will fracture on the outside of the bend and wrinkle on the inside surface of the bend. Steel rain gutters are roll formed (usually on-site) since the initial sheet workpiece is thin.

High forces are needed to extrude aluminum through a complex geometry die and so strong, stiff machines and tooling is required. If plastic trays will suffice they can be produced from potential less expensive plastic in a less complicated plastic extrusion machine, Chapter 20. Plastic rain gutters are extruded.

3. This is considered in the Case Study in Chapter 3

4. The explanation given for the better performance of newer turbine blades is in terms of typical polycrystalline cast material versus single crystal turbine blades. So, the materials used must have adequate high-temperature, high-stress properties and behavior. The material-manufacturing process pair must be capable of producing large single crystal products.

At the time of preparation of this solutions manual
a search for jet & engine & turbine & blade & casting produced

www.cmse.ed.ac.uk/AdvMat45/SuperEng.pdf that presents overviews of
- the pressure, temperature operating environment in jet engines,
- the failure modes of engine components,
- jet engine design,
- material strengths as a function of temperature

leading to the development of Ni-based superalloys up to the current alloys and their characteristics. Explanation of mechanical behavior in terms of composition and microstructure are presented.

Microstructures are shown – equiaxed crystal structure, directionally solidifies, single crystal. The advantages and use of coatings is covered.

The production of single crystal blades by using a "spiral selector" that allows the nucleation and growth if only one crystal is illustrated.

www.msm.cam.ac.uk/phase-trans/2001/slides.IB/photo.html provides an explanation of creep behavior in terms of the grain boundaries in a metal part and shows photographs of turbine blades with the same composition but produced by
- casting,
- directional solidification,
- directionally solidified using a spiral mold section that allows production of a single crystal blade.

The general conclusions that can be drawn are that
- the inherent strength of material is determined by their composition and structure,
- high strength materials have been designed and developed using fundamental engineering science knowledge about composition and composition-structure relations,
- in product design the in-use conditions have to be considered when specifying required strength of materials,
- in-use conditions may lead to various failure mechanisms,

--- in jet engines, high temperature results in lowering material strength and also creep and corrosion arising as important types of failure.

More specifically,
- loading applied at elevated temperatures makes material strength and deformation behavior more dependent on grain boundary behavior (strength decreases, creep and corrosion),
- one way to increase material high temperature performance is to produce alloys and microstructures that limit grain boundary effects such as diffusion along grain boundaries and grain boundary sliding,
- another way to limit grain boundary effects is to control the size of grains and the orientation of the boundaries - directional solidification,

- another possibility is to eliminate grain boundaries, - single crystals.

In order to produce desired product behavior by using engineered materials (composition and structure), special, new manufacturing processes may have to be developed. In the case of single crystal jet engine turbine blades a process was developed in which
- the fundamental concept is to make only one crystal available for growth,
- and to set crystal growth conditions so that growth of one crystal occurs without the nucleation of other crystals.

One example of a process to do this is shown.

An example of Nondestructive Evaluation (X-ray) is shown at
www.sv.vt.edu/xray_ct.html

Case Study:

Material Selection

This is an open-ended and extremely variable problem that is designed to get the student to question why parts are made from a particular material and how they could be fabricated to their final shape. In addition, they are asked to consider the need for property modification via heat treatment and/or surface treatment, and should begin to recognize the need to properly integrate these operations in the manufacturing sequence. The specific answers received will depend not only upon the specific product or products chosen but also upon the background and perception of the student.

CHAPTER 10
Measurement and Inspection

Review Questions

1.In order for parts to be interchangeable, they must be manufactured to the same standards of measurement. Simply put, everybody's definition of an inch or a centimeter must be the same identical measurement. In addition, certain sizes and shapes (like threads on a shaft or teeth on a thread) are standardized. Thus, all spark plugs for automobile engines have a standard diameter size and thread shape to fit into everyone's sockets. Standardization is fundamental to interchangeability and interchangeability is fundamental to repetitive part manufacture and mass production.

2. The least expensive time to make a change in the design is before the part is being made. Putting the manufacturing engineering requirements into the design phase helps insure that the part can be economically fabricated.

3. Attributes inspection trys to determine if the part is good or bad. Variables inspection requires a measurement be made to determine how good or how bad and thus, more information about part quality is obtained. If your car has an oil pressure gage, you always know what the oil pressure is (variables), but if it only has a warning light, you only know whether the pressure is good (no light) or bad (light comes on).

4. Warning lights (usually red) readily alert the driver to a bad situation, whereas the driver may completely ignore a low gage reading. The driver may not even know what a bad reading is or that a dangerous condition exists, or worse, what the gage is actually informing him or her about. Most cars today have both kinds of inspection devices to keep the driver informed. Sometimes the decision to change is based on economics as attributes gages are usually less expensive than variables types.

5. The four basic measures are: length, time, mass, and temperature .

6. Referring to Figure 10-1, the Pascal is a measure of pressure in SI units. Pressure is the force per unit area and its dimensions are newtons per square meter (N/ m^2) in SI units or psi in English units. This unit is named after Blaise Pascal (1623-1662), a French mathematician and scientist who developed the following principal - a pressure applied in any portion of the surface of a confined fluid is transmitted undiminished to all points within the fluid - Pascal's principal.

7. The grades of gage blocks are laboratory, precision, and working - in decreasing level of accuracy. The blocks come in sets so that they can be "wrung" together into any length needed from 0.1001 to over 25 inches in increments of 0.0001 inch.

8. The surface tension of an ultrathin film of oil between the very smooth, flat, block faces keeps the blocks locked together. Because they are so smooth and in such intimate contact, they can actually weld together via diffusion if left in contact for prolonged periods of time.

9. The allowance determines the desired basic fit between mating parts. Tolerance takes into account deviations from a desired dimension and fit, and are necessary in order to make manufacturing practicable and economical .

10. (a) Sliding fit would be too loose and wring fit, too tight - therefore, snug fit, hand assembled. (b) Obviously, a sliding fit as the speed is very low. (c) Free fit with liberal allowance as speeds are high and so are pressures.

11.

Hole Basis	Shaft Basis	Fit Description	Example
H11/c11	C11/h11	Loose-running	door hinges
H9/d9	D9/h9	Free-running	pulley held on shaft by set screw
H8/f7	F8/h7	Close-running	keyed gear on shaft
H7/g6	G7/h6	Sliding	folding knife pivot
H7/h6	H7/h6	Locational-clearance	flat electrical cable connectors
H7/k6	K7/h6	Locational-transition	tapered shank drill – lathe tailstock
H7/n6	N7/h6	Locational-transition	locating pins between cylinder and crankcase on single cylinder engines
H7/p6	P7/h6	Locational-interference	ball bearing inner race on shaft
H7/s6	S7/h6	Medium-drive	cast iron drive gear on shaft
H7/u6	U7/h6	Force	steel drive gear on shaft

12. A shrink fit is permanent, but can be disassembled by proper heating and/or cooling of the members. The word shrink implies that one element is heated (to expand it) and the other is cooled (to shrink it). Then the elements are joined to form a shrink fit. A weld is absolutely permanent -- cannot be disassembled without ruining the parts.

13. To determine the aim of a process, one needs measures of accuracy. To determine

the variability in a process, one needs measures of precision. Accuracy is measured by distribution means and precision is measured by variances or standard deviations (square roots of variances) . A process capability study is usually performed by taking samples of the output from the process and measuring them for the desired characteristic.

14. Interferometry is an example of an optical inspection.

15. The factors should include the rule-of-ten, linearity, repeat accuracy, stability, resolution and magnification, the type of device, the kind of information desired (attributes or variables), the size of the items to be measured, the rate at which they must be measured, and the economics of buying, installing, and using the device.

16. Determining repeat accuracy is easy. Just step on the scale and step of f numerous times and take readings. Determining linearity requires that you have a set of standard weights which you can load on and off -- say 10, 50, 90, 130 etc. pounds -- and plot linear loads versus readings. Generally, scales and other measuring devices are nonlinear at the ends of the scale and linear in the central area.

17. Variable with student. The experiment should show that magnification amplifies the measurement while resolution refers to the limit of detection.

18. Magnification of the output of a measuring device beyond the limits of its resolving capability is of no value. Magnification of a photographic negative beyond the size of the silver halide grains results in grainy photographs. Every measuring device has a limit to its resolving capability. All the magnification in the world will not change that limit.

19. Parallax is the apparent change in the position of an object when it is viewed from a different direction, i.e. the position from which the object is viewed has an effect on the apparent position of the object. Tennis linesmen want to maintain their position so that the apparent position of the ball does not change due to the linesman moving his/her position. The linesman looks right down the line and tries not to move his/her head. A spectator with a different viewing angle than the line judge will see an apparently different ball position.

20. The measuring instrument should be an order of magnitude (10 times) more precise than the object being measured. This rule actually refers to the gage capability. Gage capability is determined by gage R&R studies. See Statistical Quality Design and Control by Devor, et al.

21. The 25 divisions of the moveable vernier plate are equal in length to the 24 divisions on the main scale. Thus each division on the vernier equals 1/25 of .6 or .024 inches. Each division on the main scale is equal to 1/24 of an inch or .6 or 0.025 inches. Thus each division on the vernier is 0.025 - 0.024 = 0.001 inches less than each division on the main scale.

22. The micrometer is sensitive to the closing pressure and the lack of pressure control. Errors in analogue devices are also made by misreading the barrel by a factor of 0.025.

23. They are both about the same order of magnitude in terms of their precision and repeatability, but the micrometer has a limited size range and, thus, must be purchased in sets (quite expensive), whereas a vernier can measure a wide range of sizes with one device. The micrometer is more rugged and better suited for the industrial setting (shop floor). It is also less sensitive to dirt and it is easier to teach someone how to read it.

24. The device tends to lift itself off the surface if too much torque is applied.

25. The equation for thermal expansion is
$\Delta l = \alpha \Delta T$
where Δl is the change in length for a given change in temperature ΔT and α is the coefficient of thermal expansion ($11 \times 10^{-6}/{}^0C$)
and 1 is the length of the bar (2 feet). $20\ {}^0F = 6.67^0C$ and 2 ft = 24 inches.
Therefore:

$$\Delta l = 11 \times 10^{-6} \times 24 \times 6.67 = 0.017768 \text{ in.}$$

which is well within the measuring capability of a supermicrometer. However, don't forget that the supermicrometer will also expand (or contract) with this temperature change, so if you tried this experiment, you would not get this reading unless only the steel bar expanded, not the supermicrometer itself. You can detect a change in length of a bar with a supermicrometer simply due to heating with your hands.

26. Optical means are used so that nothing touches and thus distorts a delicate part.

27. Parts can be measured directly using the micrometer dials or compared with a profile or template drawn directly on the screen. The images on the screen can also be directly measured by a ruler and these dimensions then divided by the magnification being used -- usually 10 to 20X. The projector magnification should be checked, however, when this technique is used by projecting a known standard onto the screen.

28. Because of the large distance and the accuracy and precision needed, a laser interferometer would probably be most suitable.

29. The laser scanner is more precise and likely to be faster with less image processing.

30. The CMM is a mechanical device with precise X - Y - Z movements for precision 3D measurements. Usually a probe is used to touch the surfaces of parts being measured and the dimensions are read on digital displays and computer terminals.

31. The principle of the sine (definition of sine) is that the sine of an angle in a right triangle is the ratio of the length of the side of the triangle opposite the angle to the length of the triangle hypotenuse.

32. The not-go member is usually made shorter than the go member because it undergoes less wear.

33. In using a dial gage, one must be sure that the axis of the spindle is parallel with the dimension being measured. Dial indicators also suffer from friction in the gears, so multiple readings are highly recommended.

34. The gage is designed so that if it errors, it will reject a good part rather than accept a bad part. The gage has a tolerance added for manufacturing and a tolerance added for wear.

35. The go ring should slip over the shaft. If it does not, the shaft is too large. The not-go ring should not slip over the shaft. If it does, the shaft is too small.

36. Air gages will detect both linear size deviation and out-of-round conditions of holes. They are fast and there is virtually no wear on the gage or part.

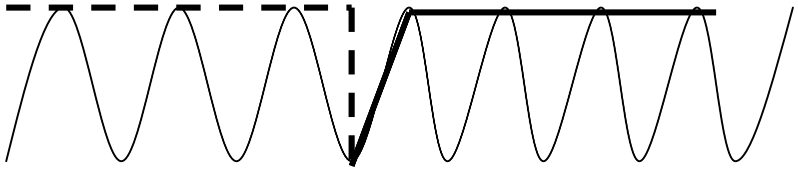
37. Monochromatic light waves will interfere with each other (producing light and dark bands) if they get out of phase. Thus, a dark band indicates that the two beams have cancelled each other out. Light from a single source can be shifted out of phase by having it travel different distances.

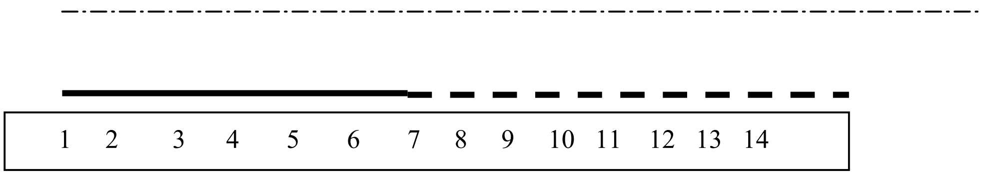
38. An optical flat is made from glass or quartz, is transparent, and the two faces are flat and parallel to a high degree of accuracy. A toolmaker's flat is made of steel, with the two faces very flat, but they do not have to be exactly parallel .

39. The microinch roughness, either arithmetic average roughness or root mean square roughness, is a single number that describes an extended line. So, different profile patterns can have the same average height value just as different populations of measurements can have the same average value.

For example, consider the three surface profiles shown (wavy, dashed line, solid line) which each have the same maximum height of roughness = 1 unit, the same number of height measurements = 14 and the height measurements made at the maximum height points of the wavy profile and labeled 1-14.

The reference line for calculation of R_a is at the mid-height of the profiles = ½ and so the 14 height measurements are all = ½.





The R_a value for all the profiles is $R_a = (14)(1/2) / 14 = ½$

40. Because identical roughness values can be very different in appearance, surface-finish blocks enable a designer to better relate a desired surface, obtained by a specific process, to the measured value that must be specified.

41. The spherical radius of the tip of a diamond stylus limits the resolution. Suppose you have a smooth plate with small holes on it. In your hand you have a needle and are trying to locate the holes. Let's assume the holes are square, round, and triangular in shape. The needle will allow you to detect the location of the holes, but not identify their shape when the holes are about the same size as the tip of the needle or smaller. Thus, there is a big difference between being able to detect the presence of a flaw and being able to resolve its geometry .

42. As the surface finish improves (surface gets smoother and AA or rms values get smaller), the tolerance generally improves
--gets smaller. Improving the surface finish and tolerance usually means identifying better, more precise processes, so the cost goes up accordingly. The exception is finishing processes which are used to improve the surface finish without strong regard to the tolerance.

43. Devices that use light scattering correlated to surface roughness lose their validity when surface roughness gets much above 40 - 50 mm. AA.

Problems:

1. Reading 1.436 in.

Inches are numbered in sequence over the full range of the bar. Every fourth graduation between the inch lines is numbered and equals one-tenth of an inch or 0.100". Each bar graduation is one twenty-fifth of an inch or 0.025".

The vernier plate is graduated in 25 parts, each representing 0.001". Every fifth line is numbered - 5, 10, 15, 20, 25 - for easy counting.

To read the gage, first count how many inches, tenths (0.100") and twenty-fifths (0.025") lie between the zero line on the bar and the zero line on the vernier plate and add them.

Then count the number of graduations on the vernier plate from its zero line to the line that coincides with a line on the bar.

Multiply the number of vernier plate graduations you counted times 0.001" and add this figure to the number of inches, tenths and twenty-fifths you counted on the bar. This is your total reading. The vernier plate zero line is the one inch (1.000") plus four tenths (0.400") plus one twenty-fifth (0.025") beyond the zero line on the bar, or 1.425". The 11th graduation on the vernier plate coincides with a line on the bar (as indicated by stars). 11 x .001" (.011") is therefore added to the 1.425 bar reading, and the total reading is 1.436".

2. Reading 41.68 mm

Each bar graduation is 0.5 mm. Every twentieth graduation is numbered in sequence - 10 mm, 20 mm, 30 mm, 40 mm, etc. - over the full range of the bar. This provides for direct reading in millimeters .

The vernier plate is graduated in 25 parts, each representing
0.02 mm. Every fifth line is numbered in sequence -0.10 mm,
0.20 mm, 0.30 mm, 0.40 mm, 0.50 mm - providing for direct reading
in hundredths of a millimeter.

To read the gage, first count how many mm lie between the zero line on the bar and the zero line on the vernier plate.

Then find the graduation on the vernier plate that coincides with a line on the bar and note its value in hundredths of a mm.

Add the vernier plate reading in hundredths of a mm to the number of mm you counted on the bar. This is your total reading. The vernier plate zero line is 41.5 mm beyond the zero line on the bar, and the 0.18 mm graduation on the vernier plate coincides with a line on the bar (as indicated by stars.) 0.18 is therefore added to the 41.5 mm bar reading, and the total reading is 41.68 mm.

3.

41.68 mm = 1.6409 inches
1.6409 - 1.436 = 0.2049 inches

4. Same as in 8th edition

$\sin \theta = 3.250 / 5.000 = 0.65$
$\theta = 40.54$ degrees

5. The error due to the gage blocks will be covered up by the dial indicator error

+0.000,008 or -0.000,004 for gage blocks versus
+0.001 or -0.001 for dial indicator

The error will be 3.249 to 3.251 due to leveling of the part with the dial gage.
= 40.53 to 40.55
Error ~.02 degrees, due to dial indicator not the gage blocks.

6. A 0.359 B 0.242 C 0.376

7. A 0.2991 B 0.3001

8. Metric vernier micrometers are used like those graduated in hundredths of a millimeter (0.01 mm), except that an additional reading in two-hundredths of a millimeter (0.002 mm) is obtained from a vernier scale on the sleeve.

The vernier consists of five divisions each of which equals one fifth of a thimble division - 1/5 of 0.01 mm or 0.002 mm.

To read the micrometer, obtain a reading to 0.01 mm. Then see which line on the vernier coincides with a line on the thimble. If it is the line marked 2, add 0.002 mm; if it is the line marked 4, add 0.004 mm, etc.

The left side micrometer reads 5.500 mm

The 5 mm sleeve graduation is visible 5.000 mm

The 0.5mm line on the sleeve is visible.	0.500 mm
Line 0 on the thimble coincides with the reading line on the sleeve	0.000 mm
The 0 line on the vernier coincide with lines on the thimble.........	<u>0.000 mm</u>
The micrometer reading is	5.500 mm

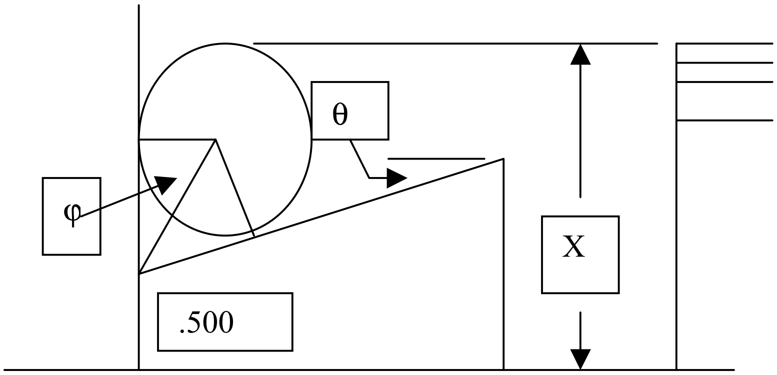
The right side micrometer reads 5.508 mm

The 5 mm sleeve graduation is visible 5.000 mm The 0.5mm lines on the sleeve is visible. . . . . 0.500 mm
Line 0 on the thimble lies below the reading line on the sleeve, indicating that a vernier reading must be added.

Line 8 on the vernier coincides with a line on the thimble............ <u>0.008 mm</u>.
The micrometer reading is.......... 5.508 mm

9. Height difference = 5 x 0.000,001,6 x 2 = 0.000,116 inches.

10. The probe is used to find the stack of gage blocks that exactly matches the height of the ball sitting on the part.



The angle θ is 17.354 degrees, from

$\tan \theta = (1.125 - 0.800) / 2.000 = 0.3125$

$X =$ height of gage blocks $= 0.500 + d + r$

$X = 0.500 + .5 \cot \varphi + 0.500$

$\cot \varphi = X - 0.500 - 0.500 / 0.500$

$90^{o} = 2 \varphi + \theta$

$\varphi = (90^{o} - \theta) / 2 = 36.3^{o}$

$X = 1.68$

11. The lower vernier reading is the inch scale and
0 on vernier is less than 1 on beam and past the 4 on beam => .4 inch
0 on vernier is 3 divisions past 4 on beam => (3/4)(.100 in) = 0.075 inch
vernier and beam graduations are given as lining up at 14 on vernier =>0.014 inch
Reading = .400 + .075 + .014 = 0.489 inch

For the top, metric, scale
0 on vernier indicates 12 mm
vernier and beam graduations are said to line up at 0.38 mm (0.41-0.42 may look better) => 0.38 mm
Reading = 12 + .38 = 12.38 mm

Case Study:

Machining Accuracy Over the Last Century

1. There are fundamentally different machining processes. For example large chip producing machining processes such as milling, grinding and lapping are all considered machining processes.

To estimate a limit in machining precision there are at least two approaches that can be followed. One is to extrapolate the data shown in the chart. Extrapolation is always dangerous and the issue is how far to extrapolate data.

Considering the "Precision machining" line on the chart the 1990 precision is about 0.3 μm = 12 μin. If this line is extended for 20 years a precision of about 0.07 is forecast. With the long extrapolation this value may be a reasonable limit.

2. Nanoprocessing is working with material either to produce nanometer scale features or working with material bodies that are nanometer size. Current computer hard disk substrates (before the magnetic and protective layers are applied) have surface roughness at the few nanometer level.

3. Industrial precision depends on the industry. Computer chip and disk drive industries routinely work at nanometer and less precision.

4. Without knowing the measurements made, a reasonable guess is that the vertical axis should be label "precision."

5. Most of the processing of materials at the nanometer level is concerned with producing nanometer level individual particles. These are formed in processes ranging from chemical synthesis to combustion.

CHAPTER 11
Nondestructive Inspection and Testing

Review Questions

1. Destructive testing has to be done on a statistical basis for two general reasons.
i. Since testing involves making the part tested not useful, not all parts can be tested. (In reality, unless absolutely necessary testing of all parts is undesirable even if the testing is not destructive.) So, in order to obtain information about the entire population of parts from a subset of tested, and no longer useful, parts statistical techniques are needed.
ii. Often the behavior of interest in part testing is due to characteristics specific to a particular part, e.g., a flaw that exceeds a certain size and so serves as a fatigue failure initiation site. In such cases and even with nondestructive testing a number of tests are again required to obtain information about a large number of parts from a tested sample of parts.

2. In a proof test, a product is subjected to loads of a determined magnitude, generally equal to or greater than the designed capacity. If the part remains intact, then there is reason to believe that it will perform adequately in the absence of abuse or loads in excess of its rated level.

3. Hardness tests can be used to provide reasonable assurance that the proper material and heat treatment were employed in a given part. The tests can be performed quickly, possibly on every product, and the associated mark can easily be concealed or removed .

4. Nondestructive testing is the examination of a product in a manner that will not render it useless for future service. The testing can be performed directly on production items or even parts in service. The entire production lot can be inspected, different tests can be applied to the same item, and the same test can be repeated on the same specimen if desired. Little or no specimen preparation is required and the equipment is often portable.

5. Some possible objectives of nondestructive testing include: the detection of internal or surface flaws, the measurement of dimensions, the determination of a material's structure or chemistry, or the evaluation of a material's mechanical or physical properties.

6. When selecting a nondestructive testing method, one should consider the advantages and limitations of the various techniques. Some can be performed on only certain types of materials. Each is limited in the type, size, and orientation of the flaws that it can detect. Various degrees of accessibility may be required and there may be geometric restrictions as to part size or complexity. Availability of equipment, the cost of operation, the need for a skilled operator, and the availability of a permanent record are other considerations.

7. By ensuring product reliability and customer satisfaction, nondestructive testing can actually be an asset, expanding sales and profitability. In addition, it can be used to assist product development and process control, further reducing costs.

8. Visual inspection should be a primary means of inspection because,
- it is very discerning, especially with training and experience,
- the brain is a powerful tool for interpreting images,
- aids for optical inspection are readily available, e.g., magnifying instruments and cameras,
- quantitative image analysis techniques and tools are available,
- surfaces are often important regions in determining quality and performance of manufactured parts.

9. Visual inspections are limited to the accessible surfaces of a product, so no information is provided relating to the interior structure or soundness.

10. Liquid penetrant testing can be used to detect any type of open surface defect in metals and other nonporous materials. Cracks, laps, seams, lack of bonding, pinholes, gouges, and tool marks can all be detected.

11. Materials must be ferromagnetic in order to be examined by the magnetic particle technique. Nonferrous metals, ceramics and polymers cannot be inspected .

12. The relative orientation of a flaw and magnetic field is quite important in determining whether the flaw will be detected, since the flaw must produce a significant disturbance to the magnetic field. If a steel bar is placed inside an energized coil, a magnetic field is produced that aligns with the axis of the bar. Defects perpendicular to this axis can be easily revealed, but a flaw parallel to the axis could go relatively unnoticed. By passing a current through the bar, a circumferential magnetic field is produced that will detect axial flaws, but not those in a radial orientation.

13. Testing where one listens for the characteristic "ring" to a product, is limited to the detection of large defects because the wavelength of audible sound is rather large compared to the size of most defects.

14. The coupling medium in ultrasonic inspection is used to improve the transmission of energy, ultrasonic vibrations, into and out of the test piece. The coupling medium couples the transducer and test piece and test piece and received with respect to the incident and transmitted or reflected ultrasonic signals.

15. Three types of ultrasonic inspections are: (1) pulse-echo, where inspection is made from one side or surface; (2) through-transmission, where the sending and receiving transducers are on opposite sides of the piece, and (3) resonance testing, where thickness can be determined from a single side.

16. X-rays, gamma rays and neutron beams can all be used to provide radiographic

inspection of manufactured products .

17. A penetrameter is a standard test piece that provided a reference for the image densities on a radiograph. Penetrameters are made of the same or similar material as the specimen and contain structural features of known dimensions. The image of the penetrameter then permits direct comparison with the features in the image of the product.

18. The limitations of radiographic inspection techniques have to do with incident radiation being scattered by part characteristics other than those of interest and with high cost.

With regard to part characteristics, incident radiation is scattered in all directions due to the material itself and so contrast between characteristics of interest and the overall material background is lost. This may require image enhancement to make the images useful.

19. Since the materials examined by eddy-current inspection must be good electrical conductors, it is unlikely that the technique would be useful to examine ceramic or polymeric materials.

20. Eddy current testing uses the change in magnetic permeability and electrical conductivity as the basis for producing a measurable output and so any part characteristic that depends on these quantities can be identified. Eddy current testing can be used to detect surface and near surface flaws, differences in metal chemical composition and heat treatment , hardness, case hardness depth and residual stress. Other testing techniques can be used to measure these characteristics individually, eddy current testing can be used to measure all of them.

21. Acoustic emission is not a means of detecting an existing, but static defect in a product, but a means of detecting a dynamic change, such as the formation or growth of a crack or defect or the onset of plastic deformation. The sound waves emitted during this dynamic event are detected and interpreted.

22. By using multiple sensors and timing techniques similar to those used to locate earthquakes, acoustic emission can be used to physically locate the flaw or defect emitting the sound.

23. Various thermal methods can be used to reveal the presence of defects. Parts can be heated and means used to detect abnormal temperature distributions, indicative of faults or flaws. The presence of "hot spots" on an operating component can be an indication of defects. Thermal anomalies can also provide an indication of poor bonding in composite materials.

24. Evaluations of resistivity from one sample to another can be used for alloy identification, flaw detection, or the assurance of proper processing - such as heat

treatment, the amount of cold work, weld integrity, or the depth of case hardening .

25. Computed tomography provided a cross-sectional view of the object along the axis of inspection. By multiple scanning, full 3-dimensional representations of the interior of a product can be generated .

26. Since surface regions of materials often serve as initiation sites for failure, e.g., the high stress, irregular surface profile regions of machined shafts, surface region characterization is important. Chemical composition of surface layers can be important in determining part performance since it affects part structure and properties.

Some surface region chemical composition characterization techniques are Auger electron spectroscopy (AES), energy-dispersive X-ray analysis (EDX), electron spectroscopy for chemical analysis (ESCA), and secondary-ion mass spectroscoopy (SIMS).

27. The basis of inspection was once the rejection of any product shown to contain a flaw or defect. With the rapid advances in inspection capability, it is now possible to detect "defects" in almost every product, including those that perform adequately. The basis of discrimination should be the separation of products with critical flaws that could lead to failure, from products where the flaws will remain dormant throughout the lifetime of the product, i.e. allowable flaws.

Problems:

1. X-ray radiography is a poor means of detecting cracks in a product, for the crack or void size must be sufficiently large as to produce a difference in transmitted intensity. Only if the orientation of a crack were parallel to the X-ray beam would there likely be sufficient differences to detect the flaw. Otherwise, the X-ray would indicate a given and constant thickness of material and reveal none of the existing cracks.

Crack detection would be better performed by ultrasonic inspection, penetrant testing, and magnetic particle inspection. These have limitations as to the location, depth and orientation, but are generally superior for detecting cracks than X-ray radiography .

For a permanent record, the electronic signals received at the transducers in ultrasonic inspection, and displayed on some form of screen, can also be recorded on magnetic tape or some other form of storage medium. The surfaces of parts examined by penetrant inspection or magnetic particle techniques can be photographed or recorded on some form of video recorder.

2. A major limitation to each of the following is:

- Visual inspection: Depends upon the skill of an inspector and is limited to surface flaws.

- Liquid penetrant inspection: Can only detect flaws that are open to the surface.
- Magnetic particle inspection: Orientation of the flaw and field affects sensitivity, limited to ferromagnetic materials, detects only surface and near-surface flaws.
- Ultrasonic inspection: Difficult to use with complex shape parts, trained technicians are required, and the area of inspection is small.
- Radiography: Costly, must observe radiation precautions, defects must be larger than a minimum size, must generally process film to get results.
- Eddy current testing: Reference standards are needed for comparison and trained operators are required, materials must be conductive, depth is limited.
- Acoustic emission monitoring: Only growing flaws can be detected, experience is required, and there is no indication of the size or shape of the defect.

3. Consideration of various inspection techniques means will they work, in contract to selecting the best measurement scheme.

Techniques for detection of surface flaw and internal flaws can be separated based on the penetration of the probe into the material. This will depend on the king of probe used and the transparency of the material to it.

a. The most obvious properties of ceramics that will affect choice of measurement technique are low electrical conductivity and absence of ferromagnetism. Some ceramics are transparent to light but overall most structural ceramics are not optically transparent.

b. Polymers are also poor electrical conductors, nonmagnetic and have low density. Different polymers are transparent and opaque.

c. Fiber composite regions that might be of interest are the fibers, the matrix and the fiber-matrix interface. The usefulness of the means of inspection will depend on the region of interest.

The general purpose nondestructive inspection methods (e.g., not leak testing) described in the chapter can be screened using the general Go – No Go concept used in Chapter 9 for materials screening.

Surface Flaws				
	Ceramics	Polymers	Composites polymer matrix	Composites metal matrix
Visual	yes	yes	yes	yes
Liquid Penetrant	yes	yes	yes	yes
Magnetic Particle	no	no	no	probably

Ultrasonic*	yes	yes	yes	yes
Radiography	no	no	no	no
Eddy Current	no	no	no	yes
Acoustic Emission	no – AE are produced by deformation processes and while ongoing deformation depends on existing flaw state to some extent, use of AE seems not feasible			
Thermal Methods	yes – but relatively low high heat capacity and low thermal conductivity of polymers makes thermal methods less useful			
Strain Sensing	yes	yes	yes	yes
Electrical Resistivity	no	no for typical polymers, with conductive polymers a very special case		yes
Surface Topography	yes	yes	yes	yes

* using surface waves,

Subsurface Flaws				
	Ceramics	Polymers	Composites polymer matrix	Composites metal matrix
Visual	no except for transparent materials			
Liquid Penetrant	yes for near surface flaws			
Magnetic Particle	near surface	no	no	near surface
Ultrasonic*	yes			
Radiography	yes, effectiveness depends on material density			
Eddy Current	no	no	no	near surface
Acoustic Emission	no – AE are produced by deformation processes and while ongoing deformation depends on existing flaw state to some extent, use of AE seems not feasible			
Thermal Methods	near surface			
Strain Sensing	no unless accurate mechanical models available for relating measured surface strains to internal stress fields that depend on flaws			
Electrical Resistivity	no	no	no	near surface
Surface Topography	no			

* through transmitted mode

4. High density powder metallurgy parts can be treated as conventional parts from the viewpoint of both inspection and secondary processing. As the density decreases (i.e. the volume fraction of voids increases), the material is less capable of transmitting sound, current, and magnetic field -- the essence of the various probing techniques. Moreover, the voids are actually "defects" and are often detected. when the numbers become great,

the signals become quite garbled, and the presence of additional, more-significant, defects may be difficult, or impossible.

5.Quality control is covered in Chapter 12, Total Quality Control in Section 12.4. The question posed in the problem can be addresses in general terms without recourse to the details provided in Chapter 12.

The facile answer is - just as 100% inspection has an error rate so too do the processes used in total quality control and so it is not clear which is superior. The more complete answer is that if the combination of processes in total quality control systems reduces the defect rate to a lower level than in 100% inspection a superior system exists. In essence, the whole (total quality control) performing better than the sum of its parts, or perhaps better than any particular part (inspection).

A more detailed, quantitative answer can be developed using the concepts presented in Chapter 12 and actual inspection and quality control system data.

6. When both sides of the part are accessible easy-to-use, accurate, inexpensive mechanical measuring instruments can be used – rules, rules and calipers, vernier and micrometer calipers and even dial indicators, depth gages and height gages can be used. Large enough flat surface areas have to be accessible.

Optical instruments such as microscopes, optical comparators and vision systems can be used if edge-on views are practical.

Even though designed for more complicated measuring tasks, coordinate measuring machines can be used to measure part thickness if the two sides are accessible.

In general, when both sides of the part are accessible to mechanical or optical instruments and the part shape is compatible with the size of the probe (the micrometer anvil size for example) many, simple measurement techniques are available.

When only one side of the part is accessible suitable thickness measurement instruments are more limited. The pulse-echo technique described in the problem is a possibility as is the resonance testing method described on page 238.

The theoretical “ability to measure from only one side” is usually not the actual case. The part will probably be resting on a surface and so thickness measurements using various physical phenomena can be envisioned, although they may be impractical due to cost, safety or other concerns. Electrical resistance between the support surface and a electrode on the accessible part surface can be used to measure thickness. A heat source applied to the part surface and temperature measurements at the part surface and support surface along with thermal conductivity data could be used to measure thickness. Similarly, measuring the heat flux needed to maintain a constant temperature difference could be used to deduce thickness.

7. The expression given in Problem 7 can be used

$$t = 2d / V$$

$$d = 2\,(\,0.003\text{ m}\,) / 5000\text{ m/s} = 1.2\ \mu\text{s}$$

8. Wavelength $= \lambda = V / f$

For parts a. Ultrasonic waves, and c. Acoustic emissions, the relevant velocity of propagation is the speed of sound in the material.

For part b. X-rays, the frequency and speed of the X-ray through the material are needed.

The propagation speed of electromagnetic radiation through free space is 3E8 m/s. Typical X-ray frequencies are $10^{17} - 10^{20}$ Hz as given in most references, e.g., an encyclopedia.

Using $f = 10^{17}$ Hz gives $\lambda =$ 3E8 m/s / 1E17 /s = 3E-9 m = 3 nm as a first approximation for X-rays traveling through a material or electromagnetic field that does not appreciably change the propagation speed, i.e., materials that are transparent to X-rays..

The speed of sound in steel is about 5000 m/s and using this value since it is given in Problem 7 and ZZZ for the speed of X-rays through steel

a. $\lambda =$ 5000 m/s / 500000 /s = 0.01 m

b. $\lambda =$ 3 nm

c. $\lambda =$ 5000 m/s / 10^6 /s = 0.005 m

Case Study:

Portable Failure Analysis Kit

1). The primary purpose of the requested kit is to collect information and specimens for examination back at the laboratory. It would be inappropriate for the investigator to try to perform laboratory-type examination in the field, especially if these could be better or more accurately performed in the lab. NOTE:
On rare occasions, the mere size of the piece in question (such as a bridge) or the desire for immediate results renders such testing desirable, but such is not usually the case. Therefore, a proposed kit would contain:

a) .Equipment for gathering information, such as the observations and opinions of operating personnel, supervisors, observers, etc. This would include: a notebook, pens and pencils, and a small portable tape recorder (with tapes) .

b). Photographic equipment to record the failure site, the locational relationship of failed components, the stages and sequence of disassembly, and/or the location and orientation of samples removed from the failure or the failure site. A Polaroid camera with color film would assure the access of acceptable photos. A close-up lens and flash attachment would be desirable, as would an ample supply of film (a type that provides a negative would be preferred) and spare batteries for the camera. A ruler or other well known object can be included in photos to reveal the relative size of components.

c) . A variety of hand-operated tools to assist in the removal of components and the collection of laboratory specimens. This might include: A hacksaw and blades, hammer, pliers, screwdrivers, knife, wrenches (socket and straight), clamps, chisels, scissors, tweezers .

d). Examination aids, such as: a flashlight with spare batteries, magnifying glass or jeweler's eyepiece (lOX), low-power binocular microscope, small handheld and dental mirror.

e) . Measuring devices, such as a ruler, measuring tape, micrometer, and vernier.

f) . Marking devices to label specimens and denote in photos the locations of cuts or the orientation of the pieces: magic markers, chalk, grease pencils, and pens.

g). Equipment to perform several basic tests:

- A portable dye penetrant testing kit to reveal the presence of cracks.
- A set of triangular metal files can be tempered in the laboratory to various hardnesses to provide an inexpensive means of getting "ballpark" hardness in the field.

h) . A portable drill with attachments can be used to obtain borings, wire brush surfaces, grind surfaces, produce a crude spark test, etc.

i). Equipment for identifying, preserving, and transporting specimens back to the laboratory: envelopes, labels, plastic bottles, zip-lock bags, cellophane tape and masking tape (can be used to remove and preserve corrosion products for X-ray analysis, as well as more normal uses) .

j). Cleaning agents, chemical reagents (solvents, etchants, macroetches, etc.), abrasives (sand paper, toothpaste, etc.), cloths and rags, toothbrush, other small brushes.

k) . Wax or clear nail-polish to coat and preserve critical fracture surfaces .

1). A small magnet - to check materials and discern various types of stainless steels.

m). Gloves and safety glasses.

n) .Environmental evaluation devices: thermometer, hygrometer (humidity), litmus paper (possibly graded by pH).

0).A small vise.

p). A small propane torch - to heat or loosen components. (NOTE: be sure exposure to heat will not alter or obliterate evidence.)

q) .A cold-mount kit to permanently mount small or fragile specimens .

r) Selected reference manuals on engineering materials and their properties

2). With additional funds, one might want to consider:

a). An additional camera, such as a high-quality 35-mm with a variety of special lenses (telephoto, close-up, wide angle), and upgrade facilities for the previous Polaroid camera, which would be retained to assure the acquisition of acceptable photos.

b) A calibrated portable hardness tester, such as a portable Brinell tester.

c) An improved microscope with special eyepieces to measure case depth, thickness of plating layers, etc.

d). Portable metal identification kit (to identify specific metals and alloys).

CHAPTER 12
Process Capability and Quality Control

Review Questions

1. A PC study examines the output from a process in order to determine the capability of the process in terms of its accuracy (its aiming ability or its ability to hit the desired nominal value) and its precision (the ability of the process to repeat the variability in the process). Accuracy refers to the centering of the process and variability refers to the scattering of the values about the center value. Accuracy is measured by the mean of the values and variability is measured by the standard deviation of the values about the mean -- also called the spread of the distribution.

2. Every process has some inherent variability. The causes of this variability may be known (assignable) but not removable (you know what is causing the variation but it is not feasible or too costly to remove it) or unassignable (i.e., inherent in the process and thus not removable). The latter is its nature.

3. It would look like Figure 12-la with occasional holes scattered to the right of center at various distances from the center -- a random pattern because the wind is gusting, not steady. In real processes, intermittent changes of this sort are extremely difficult to isolate and identify and therefore remove from the process as an assignable cause. This is an example of an assignable cause that would be difficult to remove -- how do you make the wind stop gusting without great cost (i.e. enclose the shooting range) .

4. A good way to get students to review the steps in a P.C. study is to have them try to do one themselves. The example of shooting a gun given in the text can be "simulated" by having the students work with file cards for targets and darts for the bullets. Give each student in your class a different distance to stand from the cards (mounted on a dart board) when the class data is examined as a whole, you will observe the increase in process variability with distance from the target. Depending on the dart throwing ability of the students, there will also be a loss of accuracy.

5. Two "identical" machine tools doing exactly the same process will have different amounts of process variability. The individual machines will have different variability when the work material is changed, the operator is changed, the specific process on the machine is changed, etc. Thus, it is necessary to gather data on the specific machine tool during the process itself .

6. Taguchi experiments can be used to determine the process capability of a process. Taguchi methods used truncated (simplified) experimental designs in which all the causes of variability are explored. They permit the variability to be reduced by selecting the proper combination of input variables to reduce the noise (i.e., the variability) in the output.

7. In typical experimental approach, one variable at a time is examined and all other variables are kept constant. In the Taguchi or experimental design approach, all significant variables are mixed and varied in the same experiment. The latter approach permits one to find the important interactions between dependent variables as well as to evaluate the significance of each variable.

8. The Taguchi approach results in much better understanding and control of the process, particularly the interactions between variables. More importantly, the results point the direction to run complex processes with the minimum variability and explain why some processes go out of control when some parameter is reset.

9. Without doing the actual experiment, one can only guess as to which variables dominate a process. For baking a cake, the oven temperature and the ingredients (like type of flour) would be dominant along with the pressure (altitude) . The cook may be important here also.

For mowing the lawn, the blade sharpness, blade height versus grass height, blade speed, and blade geometry would probably all be important.

For washing dishes, the water pressure, the water temperature, the right kind of soap, and perhaps the dish spacing would be most important. Here the operator would not be as important as the design of the machine. The water softness may also be important. The loading of the machine is setup.

10. Let us assume that you want to drill a 1 cm hole. The drill selected is usually 1 cm in diameter. Undersized holes are not possible until the drill body has worn down, so most of the holes will be oversize. Reground drills often have unequal lip length or rake angles causing the drill forces to be unbalanced, resulting in oversized holes. Assuming you are drilling many holes with many drills, the majority will be oversized, developing a skewed distribution of hole sizes. Do not confuse hole size with hole location. The chisel end of the drill causes problems in obtaining repeated location -- drill "walks" on the surface. Hole location distributions are not necessarily skewed.

11. Examples of items that may receive

a. 100% inspection:
At a general level all automobile engines are tested as the vehicle is driven away from the assembly plant. Critical parts in high value added products used in high potential loss situations are all tested, e.g., large turbine blades in jet aircraft engines.

b. No final inspection:
There are very few manufactured items that do not receive some sort of final inspection. Processes that run very reliably and consistently over long time are candidates for little inspection of the final products. The N = 2 inspection scheme entails inspection of the first and last items and if they pass inspection all items in-between are assumed to be good.

Some items are not inspected immediately after manufacture but the end user is assumed to be the final inspector. If the item does not work for the purchaser it can be returned, e.g., light bulbs.
Examples of no-inspection products are mature products produced in large batches by experienced manufacturers, e.g., nails where often mis-manufactured nails are found in boxes of nails. Manufacturing machines and tools are maintained to produce good parts but individual parts are probably tested only on startup of the operation.

c. Sampling final inspection:
This kind of sampling is usual for almost all but the simplest manufactured parts. Examples are automobile crankshafts and gasoline.

12. If the test is destructive (bullets or flash bulbs), if the test is expensive compared to the cost of the item (newspapers), if the item is made in great volumes by reliable or continuous processes (sheets of paper), if the test takes a long time (lifetime test for electronics), then the output is often sampled. Sampling is thus a more economical means to check the quality, but there is always the trade off that, when you sample, you will make errors in judgement about the whole. See questions

13. When prediction (sample suggestion) is the same as reality there is no error. Type I error, alpha error is when prediction is that change occurred when in reality there was no change. Type II, beta error when prediction is that there was no change when in actuality the process did change.

		In reality, the process	
		Changed	Not changed
Sample suggested that the process	Changed	No error Process bad	Type I error
	Not changed	Type II	No error Process good

14.You always have some probability of error when you sample (look at a selected few) and then make a decision about all. Both types of errors can be detrimental, even devastating. Sampling inspection systems which miss defects that result in automotive recalls are very expensive and hurt the product's reputation with consumers. Suppose you have a herd of cows. The vet finds a sick cow (sample of one) and condemns all the rest (which are not sick). or he looks at one cow, finds it well, but the rest have hoof and mouth disease but are not condemned. Either situation is very bad.

15. It is usually the beta error which leads to legal action since the beta error results in a defective product which was thought ~o be good, according to the sample. Many sampling systems are designed to protect those who do the inspection against making type I or alpha errors (saying something is bad when it is good) because alpha errors are embarrassing --stopping the line only to find nothing is wrong. The same is true in general for beta errors -- the system gets blamed for missing the problem, but since the

engineer took no action, no blame is directly assigned. However, beta errors can be many times more costly in the long run than alpha errors.

16. Assume that some characteristic of many items is being measured and the distribution of the population of measurements is a normal distribution.

The distribution of all the measurements, i.e., measurements of the parent population, has a standard deviation σ'.
For a number, *k*, of samples of size *n* taken from the parent population, some statistics of the individual samples are
- the mean of each sample, $\overline{X}$
- the range of each sample, R
- the average of the *k* sample standard deviations, $\overline{\sigma}$

A distribution of the sample statistics can be formed and some statistics of sample distributions are
- the standard deviation of the distribution of sample averages, $\sigma_{\overline{X}}$
- the standard deviation of the distribution of sample ranges, σ_R
- the standard deviation of the distribution of sample standard deviations, σ_σ

So,
a. σ' is the standard deviation of the population while $\sigma_{\overline{X}}$ is the standard deviation of the distribution of sample average values
b. σ' is the standard deviation of the population while $\overline{\sigma}$ is the average standard deviation for the *k* samples of size *n* taken from the population
c. $\sigma_{\overline{X}}$, σ_R and σ_σ are the standard deviations of three distribution;
- the standard deviation of the distribution of the *k* sample averages,
- the standard deviation of the distribution of the *k* sample ranges,
- and the standard deviation of the distribution of the *k* sample standard deviations, respectively.

16. You have a process which is producing many items and you are measuring some characteristic on each item. All the measurements of all the items create a parent population of measurements of individual items. Assuming the distribution of all the items is normal, it has some standard deviation, called ~. when you take samples from the parent population of size n, you can create distributions of sample statistics. The means of each sample are called ~ and the range of each sample is called R. Thus ~ and ~R are the standard deviations of the distributions of the sample means and sample ranges, respectively. These distributions tend to be normal, regardless of the shape of the parent population (Shewhart's Law of Sample Statistics) .

17. This is the process capability index. A value of 0.8 would mean that the process spread (i.e. the variability as measured by the standard deviation) exceeds the tolerance spread (USL - LSL) . A value of 1.0 means that these two measures are equal. A value of

1.33 means that the tolerance spread exceeds the natural spread of the process so that all parts being made are within the specification, provided the process is centered.

18. The bias factor determines how far the mean of the process lies from the intended mean or the minimal. (How good is the aim of the process?)

19. When the natural variability of the process (6 sigma prime) exceeds the specified total tolerance, you will have a condition which assures that out-of-tolerance products will be made (defectives, scrap, rework, etc.). Has the proper choice of process been made? Can the tolerances be relaxed? Can the process be improved to decrease its variability? (Are there assignable causes of variation which can be eliminated/) Is this a situation where we will have to live with a certain percentage of defective products? Can we automatically sort out the defects? Will a combination of the above kinds of solutions solve the problem?

20. This factor includes a measure of the process's ability to center itself or to be centered or well-aimed.

21. Yes, because sample statistics will be normally distributed about their mean.

22. When a reason for the cause of the variability can be found, one has an assignable cause. A chance cause is inherent to the process and cannot usually be removed, though its effect can be minimized.

23. It is easier to compute (by hand) and easier to understand, but gives less information about the sample.

24. The SD of the distribution of sample means, $\sigma_{\overline{X}}$, is equal to the SD of the parent distribution, σ', divided by the square root of n, the sample size.

$$\sigma_{\overline{X}} = \sigma' / \sqrt{n}$$

25. Customer demands drive much of product development and so customer demands for high quality automobiles is a cause for marked quality improvement.

At the technical or manufacturing level the improvement in automobile quality is in large part due to improved process control, both
- the control of individual or unit processes such as increased accuracy and improved repeatability machine tools,
- at the system control level based on statistical quality control techniques and Taguchi methods resulting in improved parts and products.

Problems:

1. For demonstration of the question, golf balls have been selected. The characteristic to be measured is the diameter. A golf ball is made from hard rubber with a liquid core. It has a dimpled surface to improve flight accuracy and distance. Its diameter is specified as 1.68 inches minimum by the Professional Golf Association. Measurements were made with a 1 to 2 inch micrometer .

Golf balls are made by a process with a natural total tolerance of 6~' approximately equal to 0.01 inches with an average size of 1.68 inch.

The data given for the golf balls (See chart provided) was for good used golf balls found on the golf course near one of the author's home. They were separated by Titleist (TI), Pro Staff (PS), Top Flight (TF), Pinnacle (P1), and Dunlop (DU). Judging from the sample, the Top Flight ball is either the most popular or is played by the poorest golfers, as about half of the balls found were Top Flights. Obviously, this is a mixed sample and all of the balls were not made by the same machine. However, all manufacturers use the same basic process.

You can add to the complexity of the process capability study by using coins and having the student separate the coins by year. Assuming all the coins have been in circulation, if one measures weight or thickness at a given point, one should find a wear factor related to the age of the coin. Thus, the mean should show a trend -- coins get thinner and lighter with use. But what about the standard deviation?

2. This question uses basically the same mathematics as the last. M&Ms come in different colors as candy-coated chocolate. The student must decide what to do with samples from a bag having mixed colors. Ignoring the different colors means that he (or she) assumes that there is no difference in the process, when in fact there must be different processes being used to make the different colors (or different production lines) . It is a bit tricky to measure the thickness or diameter of M&Ms and easier to measure their weight if the student has access to a scale of sufficient precision. The difference between this experiment and the former one is that in the former one, there were only 48 items. Here, there are many items and they are being sampled. Doing the experiment for weight allows the student to see how the sample estimate of X' can be used to obtain the estimate of the true value, which was obtained by weighing all and dividing by the total number. Questions like "Does thickness have a greater variability than diameter?" can be addressed by letting some students measure thickness and some diameter and comparing their results .

Sample No.	Measurements of Diameter	Xbar	R
1 T1	1.683 1.675 1.682 1.680	1.6800	0.007

2 PS	1.681 1.678 1.681 1.682	1.6805	0.003

11 TF	1.678 1.677 1.679 1.677	1.6778	0.002
12 TF	1.675 1.677 1.678 1.676	1.6767	0.004

$\sum \overline{X} =$20.1456

$\sum R =$ 0.044

$\overline{\overline{X}} =$ 1.6788

$\overline{R} = \sum R / 12 =$ 0.044 / 12 = 0.00366

Estimate of $\overline{X} = \overline{\overline{X}} =$ 1.6788

Estimate of $\sigma' = \overline{R} / d_2 =$ 0.00366 / 2.059 = 0.0017775

3. Process Capability

(12-1) $C_p = \dfrac{Tolerance\,spread}{6\sigma'}$

for σ' = 0.0021

C_p = { (1.006 – 0.996) } / { 6 (.0021) } = 0.79

(12-2) $$D = \frac{Estimated\ process\,mean - No\min al}{\frac{1}{2}(Tolerance\,spread)}$$

$D = \dfrac{\overline{X}' - No\min al}{\frac{1}{2}(USL - LSL)}$ = 0.00085 / 0.005 = 0.17

(12-4) $$C_{pk} = \frac{Min\left\{\left|USL - \overline{X}'\right|, \left|LSL - \overline{X}'\right|\right\}}{3\sigma'}$$

$\left|USL - \overline{X}'\right|$ = 1.006 – 1.002 = 0.18

$\left|LSL - \overline{X}'\right|$ = 1.002 – 0.996 = 0.22

C_{pk} = 0.004 / 0.0063 = 0.63

4. Process Capability

(12-1) $$C_p = \frac{Tolerance\,spread}{6\sigma'}$$ = { (0.502 – 0.498) } / { 6 (0.00067) }

= 0.99

(12-2) $$D = \frac{Estimated\ process\,mean - No\min al}{\frac{1}{2}(Tolerance\,spread)}$$

$$D = \frac{\overline{X}' - No\min al}{\frac{1}{2}(USL - LSL)}$$ = (0.500246 – 0..500000) / 0.002 = 0.123

(12-4) $$C_{pk} = \frac{Min\left\{\left|USL - \overline{X}'\right|, \left|LSL - \overline{X}'\right|\right\}}{3\sigma'}$$

$\left|USL - \overline{X}'\right|$ = 0.502 – 0.500246 = 0.001754

$\left|LSL - \overline{X}'\right|$ = 0.500246 – 0.498 = 0.002246

C_{pk} = 0.001754 / { 3 (0.00067) } = 0.87

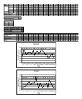
5. The number of measurements per sample is 4 compared to 5 in the 8th edition
The formulas used in the solution are presented in Figure 12-13.
The solution is created in Microsoft Excel 97 and data values can be changed.

It is incorrect to determine the process standard deviation for setting control limits using all the data. The standard deviation from all the data will be affected by the variation between the sample means. The standard deviation for setting control limits must be computed from within-sample variations so excluding between-sample variations.

Further, if the R chart shows that the process is not in control the Xbar chart should not be used – until process control, indicated using the R chart, has been attained.

The net result is that the R chart should be formulated first, but the problem asks for Xbar chart and R chart in that order and this is how the following is presented.

The results using the data in the text give a run of data near the end of the Xbar Chart indicating non-random variation.



6. For the Parent Population, as discussed in Section 12.3

the parent population mean is estimated by $\overline{X}'$ and so is 0.72 calculated above in Problem 5

the parent population standard deviation is $\sigma' = \overline{R}\big/d_2$ and for n = 4,

d_2 = 2.06 (Figure 12-13) and

σ' = 0.078

Process Capability

(12-1) $$C_p = \frac{Tolerance\,spread}{6\sigma'}$$ = { (0.9 – 0.5) } / { 6 (.078) } = 0.855

which is much smaller than the 1.33 value suggested as the minimum value for good process capability.

(12-2) $$D = \frac{Estimated\ process\,mean - No\min al}{\tfrac{1}{2}(Tolerance\,spread)}$$

$$D = \frac{\overline{X}' - No\min al}{\tfrac{1}{2}(USL - LSL)}$$ = { (0.72 – 0.70) } / { ½ (0.9 - .05) } = 0.1

(12-4) $$C_{pk} = \frac{Min\left\{\left|USL - \overline{X}'\right|, \left|LSL - \overline{X}'\right|\right\}}{3\sigma'}$$

$\left|USL - \overline{X}'\right|$ = 0.9 – 0.72 = 0.18

$\left|LSL - \overline{X}'\right|$ = 0.72 - .5 = 0.22

C_{pk} = 0.18 / { 3 (0.078) } = 0.77

7.

	Problem 12.2	Problem 12.6	% difference
Cp	0.99	0.855	(.86-.99)/.99 => - 13%
D	0.123	0.1	(.10-.12)/.12 => - 17%
Cpk	0.87	0.77	(.77-.87)/.87 => - 11%

The lower values for the data in Figure 12-A (Problem 6) indicate a process producing data with a wider distribution – a less "capable process.

8. Will need the nominal hole diameter, and with equal bilateral limits the nominal diameter is (6.70 mm + 6.00 mm) / 2 = 6.35 mm

a. Process Capability

(12-1) $$C_p = \frac{Tolerance\,spread}{6\sigma'}$$

Tolerance spread = 6.70 mm – 6.00 mm = 0.70 mm

$$\sigma' = \overline{R} \big/ d_2$$

$\overline{R}$ = 0.274 mm

and for n = 5 , (Figure 12-13)

d_2 = 2.33

σ' = 0.274 / 2.33 = 0.118 mm

C_p = 0.70 mm / { 6 (0.118 mm } = 0.989

(12-2) $$D = \frac{Estimated\ process\,mean - No\min al}{\frac{1}{2}(Tolerance\,spread)}$$

$$D = \frac{\overline{X}' - No\min al}{\frac{1}{2}(USL - LSL)} =$$

the parent population mean is estimated by $\overline{X}'$

$\overline{X}'$ = 6.299

$USL - LSL$ = 6.70 mm – 6.00 mm = 0.70 mm

Nominal hole diameter = 6.35 mm

D = (6.3 mm – 6.35 mm) / { ½ (0.70 mm) } = - 0.143

(12-4) $$C_{pk} = \frac{Min\left\{\left|USL - \overline{X}'\right|, \left|LSL - \overline{X}'\right|\right\}}{3\sigma'}$$

$\left|USL - \overline{X}'\right|$ = 6.70 mm – 6.3 mm = 0.4 mm

$\left|LSL - \overline{X}'\right|$ = 6.3 mm – 6 mm = 0.3 mm

C_{pk} = 0.3 mm / { 3 (0.118 mm) } = 0.847

b. σ control chart, Figure 12-13 contains relevant information, especially

$$\sigma = \sqrt{\frac{\sum_{i}^{n}\left(X_i - \overline{X}\right)^2}{n-1}}$$

Note: the calculated values, Total, Mean and Range, are incorrect for Lot No. 3

Without further information the control limits are set to 3*(standard deviation of the sample standard deviations). Also, some supplementary content is added to this solution. Specifically, control limits are also set using arguments similar to those in Section 12.3 that result in the A_2, D_3 and D_4 coefficients. Standard texts, e.g., Quality Control and Industrial Statistics, A. J. Duncan, Irwin, present control limits for standard deviation charts as

LCL = B_3 * (average value of sample standard deviations)
UCL = B_4 * (average value of sample standard deviations)

Finally, if the Lower Control Limit is less than zero representing reality calls for setting it to zero.

n	B_3	B_4
3	0	2.568
4	0	2.266
5	0	2.089

Process Capability – using Sigma Chart

$\sigma' = \overline{\sigma}$ = 0.109 mm

$\overline{X}'$ = 6.30 mm

(12-1) $C_p = \dfrac{Tolerance\,spread}{6\sigma'}$

for σ' = 0.0021

C_p = { (6.70 – 6.00) mm} / { 6 (0.109 mm) } = 1.070

(12-4) $C_{pk} = \dfrac{Min\left\{\left|USL - \overline{X}'\right|, \left|LSL - \overline{X}'\right|\right\}}{3\sigma'}$

$\left|USL - \overline{X}'\right|$ = (6.70 – 6.30) mm = 0.40 mm

$\left|LSL - \overline{X}'\right|$ = (6.30 – 6.00) = 0.30 mm

C_{pk} = 0.30 / { (3) (0.109) }= 0.917

c. The charts below were developed using
i. not including the X5 measurements, so *n* = 4
ii. not including X3 and X5 measurements, *n* = 3

i.

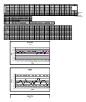
ii.



The Xbar and sigma charts give the following values for $\overline{X}'$ (estimated from the grand average) and σ'. The calculations of the process capability measures are shown below.

n	$\overline{X}'$	σ'	C_p	D	C_{pk}
5	6.30*	0.109	1.070	-0.143	0.917
4	6.30	0.107	1.090	-0.143	0.935
3	6.31	0.106	1.101	-0.114	0.975

* corrected value, different from value given in problem statement

(12-1) $$C_p = \frac{Tolerance\ spread}{6\sigma'}$$

= { (6.7 – 6.0) } / { 6 (0.109) } = 1.070 for n = 5
= { (6.7 – 6.0) } / { 6 (0.107) } = 1.090 for n = 4
= { (6.7 – 6.0) } / { 6 (0.106) } = 1.101 for n = 3

(12-2) $$D = \frac{\overline{X}' - Nominal}{\frac{1}{2}(USL - LSL)}$$

= { 6.30 – 6.35 } / { ½ (6.70 – 6.00) } = -0.143 for n = 5
= { 6.30 – 6.35 } / { ½ (6.70 – 6.00) } = -0.143 for n = 4
= { 6.31 – 6.35 } / { ½ (6.70 – 6.00) } = -0.114 for n = 3

(12-4) $$C_{pk} = \frac{Min\left\{\left|USL - \overline{X}'\right|, \left|LSL - \overline{X}'\right|\right\}}{3\sigma'}$$

$$\left|USL - \overline{X}'\right|$$

= 6.70 – 6.30 = 0.40 for n= 5
= 6.70 – 6.30 = 0.40 for n = 4
= 6.70 – 6.31 = 0.39 for n = 3

$$\left|LSL - \overline{X}'\right|$$

= 6.30 – 6.00 = 0.30 for n = 5
= 6.30 – 6.00 = 0.30 for n= 4
= 6.31 – 6.00 = 0.31 for n = 3

C_{pk} = 0.30 / { 3 (0.109) } = 0.917 for n = 5

C_{pk} = 0.30 / { 3 (0.107) } = 0.935 for n = 5

C_{pk} = 0.31 / { 3 (0.106) } = 0.975 for n = 5

Case Study:

Boring QC Chart Blunders

1. This is an Xbar chart showing the average values of the 19 samples of 4 parts.

2. With control limits of about 3 σ = UCL – Mean = 0.00038 – 0.00017
σ = 0.00006 in

3. The center line is the average of the sample means, not the mean of the population from which the samples were drawn.

4. Cp = (USL – LSL) / 6 σ' = {2 (0.0005) } / { 6 (0.00006) = 2.78
Cpk = MIN { | USL – Xbar' | , | LSL – Xbar' | } / 3 σ' = 0.00033 / 0.00018 = 1.83

5. The specification limits are not measured quantities and so do not belong on the chart.

CHAPTER 13
Fundamentals of Casting

Review Questions

1. Materials processing is the science and technology by which a material is converted into a useful shape with a structure and properties that are optimized for the intended service environment. More loosely, processing is "all that is done to convert stuff into things".

2. The four basic families of shape production processes are:
(1) Casting, (2) Material removal, (3) Deformation processes, and (4) Consolidation processes. Casting processes can produce extremely complex shapes, but may have defects related to shrinkage and porosity. Material removal processes can have outstanding precision, but generate scrap as the material is cut away. Deformation processes can offer high rates of production, but require powerful equipment and dedicated tools or dies. Consolidation processes can produce large or complex shapes, but the joints may possess properties that are different from the base material.

3. Cast parts can range in size from a fraction of an inch and a fraction of an ounce to over 30 feet and many tons. Moreover, casting can incorporate complex shapes, hollow sections or internal cavities, and irregular curved surfaces.

4. In the single-use molding processes, a new mold must be made for each casting. In contrast, multiple-use molds can be used for repeated castings and are generally made of metal or graphite. They are quite costly and their use is generally restricted to large production runs where their cost can be distributed over a large number of castings. For small quantities, the single-use molds would be preferred.

5 . when the molten metal is introduced into the mold, all of the air and gases in the mold prior to pouring and those generated by the action of the hot metal on the mold must be able to escape the mold cavity. This will enable the molten metal to completely fill the mold cavity and produce a fully dense casting that is free from defects.

6. If the mold provides too much restraint to the solidifying and cooling casting, the casting will crack as it tries to contract while its strength is low.

7. A casting pattern is an approximate duplicate of the final casting around which the mold material will be packed to form the mold cavity. A flask is the box that contains the molding aggregate. A core is a sand shape that is inserted into the mold to produce internal features in a casting, such as holes or passages. A mold cavity is the void into which the molten metal is poured and solidified to produce the desired casting. A riser is an extra void created in the mold that will be filled with the

8. The gating system of a mold is made up of a pouring cup, sprue, runners and gates. Its purpose is to deliver the molten metal from the outside of the mold to the mold cavity.

9. A parting line or parting surface is the interface which separates the cope and drag halves of the mold, flask, pattern, or core.

10. Draft is the taper on a pattern and so there will be taper on the casting. Draft permits the pattern to be withdrawn from the mold while minimizing damage to the mold (and the casting to be removed more easily from permanent molds).

11. The two steps of solidification are nucleation and growth. During nucleation, a stable solid particle forms from the molten metal and forms the beginning of a crystal or grain in the finished casting. During the growth stage, the heat of fusion is continually extracted from the liquid material and the nucleated solid increases in size.

12. At the equilibrium melting temperature, the bulk energies of the liquid and solid states are equivalent. However, for a solid particle to form in the liquid, additional energy must be provided to create the new surfaces or interfaces. Thus, for solid formation to occur generally requires that the temperature drop to several degrees below the melting temperature. Here the change in state from liquid to solid releases sufficient energy that the net result (with the additional energy required to create interfaces) is a movement to a lower energy state.

13. Since each nucleation event produces a grain or crystal in a casting, and fine grain materials possess improved strength and mechanical properties, attempts to promote nucleation would be rewarded by the production of superior castings. This practice of promoting nucleation is known as inoculation or grain refining.

14. In most casting operations, heterogeneous nucleation occurs at existing surfaces, such as mold or container walls, or solid impurity particles within the molten liquid.

15. Directional solidification, in which the solidification interface sweeps continuously through the material, can be used to assure the production of a sound casting. The molten material on the liquid side of the interface flows into the mold to continuously compensate for the shrinkage that occurs as the material changes from liquid to solid.

16. The cooling curve for a pure metal contains information that will reveal the pouring temperature, superheat (the difference between the pouring temperature and the freezing temperature of the metal), the cooling rate, the freezing temperature (thermal arrest), and the solidification times (both total and local).

17. Superheat is the difference between the temperature of the molten material when it is poured into the mold and the material freezing temperature. Superheat is related to the time between poring and solidification and so is a factor in the time available for complete mold filling.

18. The term, freezing range, refers to the difference between the liquidus and solidus temperatures, i.e. the temperature range through which the material transforms from all liquid to all solid.

19. The amount of heat that must be removed from a casting to cause it to solidify is directly proportional to the amount of metal or the volume of the casting. conversely, the ability to remove heat from a casting is directly related to the amount of exposed surface area through which the heat can be extracted. The total solidification time, therefore can be expressed as proportional to the volume divided by the area to some exponential power - Chvorinov's Rule.

20.The mold constant, B, in Chvorinov's Rule depends upon the metal being cast, the mold material, mold thickness, and the amount of superheat.

21. Since cooling rate influences the structure of the casting it has large effects on casting properties. Usually the faster the cooling rate the finer and more uniform the casting microstructure and the stronger the part.

22. The chill zone of a casting is a narrow band of randomly oriented crystals that forms on the surface of a casting. Rapid nucleation begins here due to the presence of the mold walls and the relatively rapid surface cooling.

23.The columnar region is clearly the lease desirable. Because of the selective growth process, these crystals are long, thin columns with aligned, parallel, crystal structure. Reflecting this preferred orientation, the properties will be quite anisotropic (varying with different direction) .

24. The equiaxed zone has a structure characterized by a larger number of grains per volume, smaller grains, more spherical grains, randomly oriented grains and so more isotropic properties than the other regions of the casting, the chill zone and the columnar zone. To promote the formation of a larger equiaxed zone more nucleation sites are needed and this situation is promoted by lower pouring temperature, alloy additions and the use of innoculants.

25. Dross or slag is the term given to the metal oxides which can be carried with the molten metal during pouring and filling of the mold. Special precautions during melting, pouring and process design can prevent the dross from becoming part of the finished casting. Fluxes can be used to protect the molten metal during melting or vacuum or protective atmospheres can be employed. Dross can be skimmed from the ladles prior to pouring or the metal can be extracted from the bottom of the molten pool. Finally, gating systems can be designed to trap the dross before it enters the mold cavity.

26. Gas porosity can be eliminated by preventing the gas from initially dissolving in the molten metal, using such techniques as vacuum melting, controlled atmospheres, flux blankets, low superheats, and careful handling and pouring. In addition, dissolved gases can be removed by vacuum degassing, gas flushing, or reaction to produce a removable

product compound.

27. Fluidity is the ability of a molten metal to flow and fill the mold - a measure of its runniness. While there is no single method for its measurement, various ^{33}standard molds'^{3} can be used where the results are sensitive to metal flow. One approach is to use a long thin spiral that progresses outward from a central pouring sprue. The length of the casting is a direct indication of fluidity.

28. Misruns are defects in the casting due to the molten material beginning to freeze before the mold is completely filled. Misruns are due to large differences in temperature in the molten material in the mold and so are due to poor mold design leading to regions of unusually low temperature and to too low a pouring temperature, i.e., insufficient superheat. The resulting defects are regions of greatly different properties and structures over the casting since molten metal is freezing at different conditions and is solidifying around already solidified material.

29. As molten material temperature and mold temperature increase
- the melt fluidity increases allowing the material possibly to flow into small spaces between sand grains and on solidification sand grains are in the casting,
- chemical activity rate increases and melt-mold reactions are accelerated leading to reactions which may alter casting material structure and properties.

30. The rate of metal flow through the gating system is important, as is the rate of cooling as it flows. Slow filling and high heat loss can result in misruns and cold shuts. Rapid rates of filling can result in erosion of the gating system and mold cavity and produce entrapped mold material in the final casting .

31. Turbulence of the molten metal in the gating system and mold cavity could promote excessive solution of gases, enhance oxidation of the metal, and accelerate mold erosion.

32. The choke is the smallest cross section region of the sprue-runner system. The choke controls the rate of flow into the mold and also the location of the slowest flow. So, the closer the choke to the sprue entrance the slower the flow through the entire runner system and the smoother the flow and the greater the mold filling time. If the choke is in the runner near the mold cavity, flow rate through the sprue-runner system is faster and more turbulent.

33. Gating systems can be designed to trap dross and mold material before they enter the mold cavity. Since the lower-density materials will rise to the top of the molten metal, long, flat runners with gates that exit from the lower portion of the runner are effective. Since the first metal to enter the mold is most likely to contain the dross, runner extensions and wells can be used to catch this material and prevent it from entering the mold. Screens or ceramic filters can also be used.

34. Turbulent-sensitive materials, such as aluminum and magnesium, and alloys with low melting points generally employ gating systems that concentrate on eliminating

turbulence and trapping dross. Turbulent-insensitive alloys, such as steel, cast iron, and most copper alloys, and alloys with high melting points, generally use short, open gating systems that provide for quick filling of the mold cavity.

35. The three stages of contraction or shrinkage as a liquid is converted into a finished casting are: shrinkage of the liquid, solidification shrinkage as the liquid turns to solid, and solid metal contraction as the solidified material cools to room temperature .

36. Alloys with large freezing ranges have a wide range of temperatures over which the material is in a mushy state. As the cooler regions complete their solidification, it is almost impossible for additional liquid to feed into the shrinkage voids. The resultant structure tends to have small, but numerous shrinkage voids dispersed throughout.

37.A primary concern regarding the contraction of a hot casting after it has solidified is the change in dimensions. In addition, if the product is constrained in a rigid mold, tensile stresses can be induced that may cause cracking. It is best to eject the castings as soon as solidification is complete.

38. By having directional solidification sweeping from the extremities of the mold to the riser, the riser can continuously feed molten metal and will compensate for the shrinkage of the entire mold cavity.

39. Based on Chvorinov's Rule, a good shape for a riser would be one with a small area per unit volume. The ideal shape would be a sphere, but this is rather impractical to the patternmaker and molder. Therefore, the best practical shape for a casting riser would probably be a cylinder with height approximately equal to the diameter.

40. A top riser is one that sits on top of a casting. A side riser is located adjacent to the mold cavity, displaced along the parting line. Open risers are exposed to the atmosphere. Blind risers are contained entirely within the mold. Live risers receive the last hot metal that enters the mold. Dead risers receive metal that has already flowed through the mold cavity.

41. When using Chvorinov's Rule to calculate the size of a riser, one makes several assumptions. Since both the riser and the mold cavity set in the same mold and receive the same metal, the mold constant, B, is assumed to be the same for both regions. The equations in the text assume N=2 and a safe difference in solidification time to be 25%.

42. Chills are used to speed solidification of the casting. Both internal and external chills absorb heat and so not only decrease solidification time but, in extreme cases, can also effect casting microstructure and properties by causing directional solidification.

An insulating sleeve is a low heat flow material placed around the riser to maintain the material in the riser in a molten state and so decrease the needed riser size.

Exothermic materials are added to the mold around the sides and top of the riser. The heat produced by the exothermic reaction maintains the material in the riser in the molten state and so enables the use of smaller risers.

Riser size is important since material that solidifies in the riser is excess material in the sense that it is not used in producing parts.

43. Casting patterns generally incorporate several types of modifications or allowances. These include shrinkage allowances to compensate for thermal contraction, draft to permit pattern removal, machining allowances, distortion allowance, and compensation for thermal changes in mold dimensions.

44. A shrink rule is a simple measuring device that is larger than a standard rule by the desired shrink allowance. The measurements on the shrink rule are the final dimensions of the part after thermal shrinkage has occurred.

45. Draft (see Question 10) is used on casting patterns to enable the pattern to be withdrawn from the mold without the sand particles being broken away from the mold surface.

46. Pattern allowances increase the size of the pattern, and thus the size and weight of a casting and possibly the amount of material that must subsequently be removed by machining to form a finished product. Therefore, efforts are generally made to reduce the various allowances.

47. At a very high level of description the casting process involves fluid flow filling a mold, heat flow causing solidification and the effects of mold cavity design on these processes. So any interaction between parting plane location and part shape, fluid flow and heat transfer affects the casting process. The location of the parting plane with respect to the mold cavity will influence process design, e.g.,
- number of cores,
- method of core support,
- sprue and gate system configuration,
- the relative volume of the part compared to the sprue-runner-riser volume,

and also the quality of the final part since
- part accuracy and part characteristics such as porosity depend on the solidification process which depends on overall mold design including parting plane location.

48. In general, at changes in shape of solid material bodies stress concentrations or stress raisers occur. This happens in castings and parts made by other processes.

During the production of cast parts casting defects can arise where sections meet. The effective section thickness at the intersection of casting sections is larger than the thickness of the intersecting sections. The increased section thickness region cools and solidifies more slowly than the thinner sections on either side of it. The difference in cooling rates between the relatively thicker intersection region and the thinner surrounding sections can cause problems. Differences in cooling rate and shrinkage cause residual stress and local shrinkage cavities as the adjacent regions adapt to each others temperature and amount of shrinkage. Also, the locally thicker, larger volume region will remain at a higher temperature during solidification this can result in porosity.

Problems:

1. Plate dimension: 2” x 4” x 6”; H/D = 1.5; n =2

$t_{riser} = 1.25\ t_{casting}$

$(V/A)^2_{riser} = 1.25\ (V/A)^2_{casting}$

$(V/A)_{riser} = 1.15\ (V/A)_{casting}$

$\{ (\pi/4) D^2 H \} / \{ 2(\pi D^2/4) + \pi DH \} =$

$\{ (1.15)(2 \times 4 \times 6) \} / \{2(2x4) + 2(2x6) + 2(4x6) \}$

with H = 1.5 D

$\{ n \pi D^3 / 8) / 2 \pi D^2 = 1.15 (0.545)$

$3 D / 16 = 0.627$

D = 3.34 in, H = 5.02 in, Vriser = 43.98 in3

Yield = Vol casting / (Volcasting / Vriser) = 48 / (48 + 43.98) = 52%

2. If the riser sits on top of the casting, heat is not lost from either the casting or the riser at their junction. This interface area should be subtracted from both the area of the casting and the area of the riser in Chvorinov's Rule:

$\{ (\pi D^2 H) / 4 \} / \{ 2(\pi D^2/4) + \pi DH - \pi D^2/4 \} = \{ 1.15 (48) \} / \{ 88 - \pi D^2/4 \}$

$(3D / 14)(88 - \pi D^2/4) = 55.2$

$0.168D^3 – 18.86D^2 + 55.2 = 0$

D = 3.25 in, H = 4.875 in and $V_{riser} = 40.44\ in^3$

Yield = 48 / (48 + 40.44) = 54%

3. For the 3" x 5" x 10" solid

$t_5 = B\ (V/A)^2$

$11.5= B(3 \times 5 \times 10)^2 / \{ 2 (3x5) + 2 (3x10) + 2 (5x10)]^2$

$11.5 = B (150)^2 / (30 + 60 + 100)^2 = B (150 / 190)^2 = B (0.789)^2 = 0.623 B$

B = 11.5 / 0.623 = 18.46

For a casting of 0.5" x 8" x 8" cast under the same conditions:

$t_s = 18.46 \text{ x } (.5\text{x}8\text{x}8)^2 \ / \ [2\ (.5\text{x}8) + 2(.5\text{x}8) + 2(8\text{x}8)]^2$

$= 18.46 \text{ x } (32)2 \ / \ [\ 8 + 8 + 128]^2$

= 0.91 min

Case Study:

The Cast Oil-Field Fitting

1. The binder for the no-bake sand is a polymerizable alkyd-oil/urethane material. Gases can be evolved from the binder when it is heated and the polymer material begins to depolymerize. In fact, there are two possibilities for gas problems with this material. If the binder had been completely polymerized during the manufacture of the core, the high temperature of the cast iron could break down the binder into small fragments having low molecular weight and low boiling point, thus producing the bubbles. In addition, this particular type of binder has a long curing time --12 to 24 hours are required for the polymerization to complete at room temperature. If the core or the mold were not completely cured, there would already be low molecular weight, low boiling point, constituents present that could form gases as soon as the liquid iron entered the mold cavity.

The gases are located near a surface, just beneath the core. It appears that the gas bubbles formed, started to float, and were trapped by the core.

Vents could be added to the core and/or mold to give the gases an easier path to escape through the sand, rather than becoming trapped in the liquid metal. In addition, we want to make sure that the binder is completely cured prior to pouring. A coarser grained sand with a narrow distribution of sand grain sizes will provide higher permeability and permit easier gas removal. Finally, a switch to a different type of binder could reduce the amount of gas produced from that of the oil/urethane.

2. Penetration occurred by liquid metal flowing between the sand grains of the core. It appears that the core was not properly compacted, with relatively large voids between the sand grains. The core may have also had very large sand grains with a very narrow distribution of sizes (although this is contrary to the conclusion of question 1. The core also gets hotter than the mold, since the core is completely surrounded by liquid metal. In addition, the region showing the penetration is adjacent to the gate where it will have received the molten metal first and would have been hotter longer than the remainder of the mold. The long exposure to high heat may have led to the breakdown of the binder and helped the liquid metal penetrate the sand. Finally, the defect was only noted near the bottom of the casting because of the higher metallostatic pressure head (the pressure of the column of molten metal) helping to force the metal between the sand grains.

3. The enlargement could have occurred because the mold was weak and the high

metallostatic pressure crushed the sand, thus enlarging the mold cavity. Better compaction during mold making would produce denser, and stronger, sand. Using a larger amount of binder might also help, but gas problems would tend to become more severe. Another possible cause would be erosion, because the enlargement occurred next to the gate where all of the liquid metal entered the mold cavity. The sand near the gate becomes the hottest, and the binder may have decomposed prematurely. The use of several gates, rather than just one, might help reduce the problem.

4. Penetration over all of the surfaces is likely due to the sand being too coarse and a narrow distribution of sand grains, or perhaps due to a high pouring temperature. Reducing the pouring temperature would be helpful. Another possible cure would be to use finer sands, perhaps with the addition of silica flour to the aggregate -- although lower permeability and metal-mold defects, such as burn-on might become problems.

5. Both the molds and the cores could be reclaimed. The binders are organic, and, with luck, most of the organic material will have broken down during the casting and cooling process. If the organic breakdown is not sufficient, some form of reclamation process can be used. A mechanical reclamation system would perhaps fire the sand grains at a hard metal plate, where the impact would break the brittle polymer binder of f of the sand grain surface. A thermal reclamation system, in which the sand is heated to a high temperature (usually above 1000^0F), will burn off any residual binder. The processed sand is then carefully screened to assure the proper size and distribution of sizes prior to rebonding and reuse.

CHAPTER 14
Expendable-Mold Casting Processes

Review Questions

1. There is a variety of casting processes. Many casting process characteristics are similar but each has distinct characteristics that determine process requirements and cast part properties. Some of the factors that influence choice of casting process are
- quality of cast surface required,
- desired part dimensional precision,
- part production rate,
- the complexity of the process and process tooling that are required to produce a particular part,
- cost of mold or die,
- material characteristics as they determine feasible casting processes.

2. Using molds and patterns as process classification factors results in three general categories of casting processes
i. Single-use molds with multiple-use patterns
ii. Single-use molds with single-use patterns
 - these two types of processes are often called expendible mold casting processes
iii Multiple-use molds

3. Frequently cast metals are iron, steel, aluminum, brass, bronze. magnesium, zinc alloys and nickel-based superalloys. The large range of properties and melting temperatures indicates that almost all metals can be cast, given enough process development resources. However, there are "easy-to-cast" materials and these are typically used. Materials may be inherently "castable" or alloys specially formulated to produce acceptable parts in easily designed and controlled casting processes.

4. The most common casting process is sand casting. Green sand casting is used to produce about 90% of the casting produced in the United States. Its wide use indicates that it is probably the most versatile.

5. A casting pattern is a duplicate of the part to be made, modified in accordance with the requirements of the casting process, metal being cast, and particular molding technique that is being used.

6. The material used for construction of a casting pattern is determined primarily by the number of castings to be produced, but is also influenced by the size and shape of the casting, the desired dimensional precision, and the molding process. Wood patterns are easy to make and are used when quantities are small. Unfortunately, wood is not very dimensionally stable due to warping and swelling with changes in the humidity. Metal patterns are more expensive, but are more stable and more durable. Hard plastics, such as

urethane, have been used, and expanded polystyrene is used for single-use patterns. Expanded polystyrene and wax can be used for single-use patterns.

7. The simplest type of pattern is the one-piece or solid pattern. Since it is the simplest it is usually the least expensive.

8. In casting a pattern is used to form the mold cavity. In making a two part mold the mold material is formed around the pattern and then the pattern is removed leaving the mold cavity. One way to form the pattern, and the form it the mold cavity, is to use a two part, or split, pattern. The two parts of the pattern are fixed to the match plate, the mold formed around the pattern-match plate, the mold halves separated and the pattern-match plate removed.

So, the match plate is a plate to which parts of the pattern are attached. It aids molding in providing a simple structure to help form the pattern and mold cavity. In a general sense the match plate is a fixture for creating the pattern.

9. With a cope-and-drag pattern, the cope and drag halves of the split pattern are mounted onto separate match-plates, thereby permitting larger molds to be handled easier or two separate machines to be simultaneously producing the two portions of the mold.

10. A loose-piece pattern is frequently used when the object to be cast has protruding sections or geometric features such that a more traditional pattern could not be removed from the molding sand.

11. The four requirements of a molding sand are: refractoriness, cohesiveness, permeability, and collapsibility. Refractoriness is provided by the basic nature of the sand. Cohesiveness is provided by coating the sand grains with clays that become cohesive when moistened. Permeability is a function of the size of the sand particles, the amount and type of clay or other bonding agent, the moisture content, and the compacting pressure. Collapsibility is sometimes promoted by adding cereals or other organic materials that burn out when exposed to the hot metal to reduce the volume of the solid bulk and decrease the strength of the restraining sand.

12. The four requirements of a molding sand are not consistent with one another, so good molding sand is always a compromise between the various factors. The size of the sand particles, the amount of bonding agent, the moisture content, and the organic matter are all selected to attain an acceptable compromise. For example, increasing the amount of clay will enhance cohesiveness, but decrease permeability.

13. A muller is a mixing-type device designed to uniformly coat the grains of sand with the additive agents. The discharge frequently contains some form of aerator which prevents the sand from packing too hard during handling.

14. Standard tests have been developed to maintain consistent sand quality by evaluating: grain size, moisture content, clay content, compactibility, and mold hardness,

permeability and strength.

15. A "standard rammed specimen" is a 2" in diameter, 2" long sand specimen that is produced by means of a standard and reproducible form of compaction. A sufficient amount of sand is placed in a 2-inch diameter steel tube so that after a 14-pound weight is dropped three times from a height of 2-inches, the final height of the sand specimen is within 1/32 of an inch of 2 inches .

16. Permeability is a measure of how easily gases can pass through the narrow voids between the sand grains. A casting mold material must possess permeability to permit the escape of air that was in the mold before pouring, plus gases generated from the molding material itself when materials in the molding sand burn, volatilize, or deteriorate when in contact with the hot metal.

17. Water interacts with the surface of clays so that interparticle bonding sites are activated. Too little moisture and bonding sites are limited resulting in low compressive strength. Too much moisture and although all surfaces are covered and bonding sites maximized, the water acts as a lubricant between grains decreasing the strength from the maximum value at the optimum moisture content.

18. The basic size and geometry of the sand grains can be very influential in determining the properties of the molding material. Round sand grains give good permeability and minimize the amount of clay required. Angular sands give better green strength because of the mechanical interlocking of the grains. Large-grain sands provide good permeability and better resistance to high-temperature melting and expansion. Fine-grain sands provide good surface finish on the finished casting. Uniform size sands give good permeability, while a wide size distribution provides a better surface finish.

19. When hot metal is poured into a silica sand mold, the silica sand heats up, undergoes one or more phase transformations, and has a large expansion in volume. Since only the surface sand heats up and expands, while the remainder stays cool, the mold experiences nonuniform expansion, and the hot surface may buckle or fold (sand expansion defects).

20. Since sand expansion defects are caused by nonuniform sand expansion and phase transformations across the mold, steps that minimize temperature gradients, sand expansion and phase transformations will minimize sand expansion defects. Ways to minimize the effects of expansion and phase transformations include

- using sand particles with shapes that relieve expansion stresses by allowing easier particle motion,
- material such as excess clay and cellulose can be added to absorb expansion,
- use of different mold materials that do not undergo phase transitions and/or have lower expansion on heating.

21. Penetration of the hot metal between the sand grains can be produced by high pouring temperatures (excess fluidity), high metal pressure (possibly due to excess cope height or pouring from too high an elevation above the mold), or the use of coarse, uniform sand

particles.

22. Hot tears are cracks that form in castings during solidification. As the molten metal cools and solidifies it shrinks. If the mold exerts sufficient constraint on the solid, but still hot. weak and shrinking metal, stresses may be large enough to from cracks.

Hot tearing can be decreased by designing casting processes so that the stress that arise are minimized, e.g., by assuring collapsibility of the sand mold during part solidification.

23. If sand is placed on top of a pattern and the assembly is then lifted and dropped several times (jolting), the sand is packed firmly around the pattern, with density diminishing as one moves further from the pattern. When squeezing is used, the maximum density is adjacent to the squeeze head. Density then diminishes as the distance from the squeeze head increases. The jolt-squeeze combination combines these two results to produce a more uniform distribution of sand density.

24. After the mold is produced in the flask it is removed from the flask and may be vulnerable to damage. A metal band, called a slip jacket, can be placed around the mold to help protest the mold from damage during handling and pouring.

25. The vertically-parted flaskless molding machine produces blocks of sand that contain a cope impression on one side and a drag impression on the other. When assembled side-by-side, they produce a complete pattern, with one complete mold being provided per block of sand. Other methods require separate cope and drag segments, thereby requiring two blocks per mold.

26. Extremely large molds are often constructed in sunken pits, and are often made as an assembly of smaller sections of baked or dried sand.

27. The two major sources of problems with green sand are low strength and high moisture.

28. Dry-sand molds lack popularity because of the long times required for drying, the added cost for the drying operation, and the availability of practical alternatives.

29. In the carbon dioxide-sodium silicate molding method, the carbon dioxide is nontoxic and odorless, and no heating is required for curing. When hardened, however, the sands have poor collapsibility, making shakeout and core removal rather difficult. Here, the heating from the pour actually makes the mold material stronger.

30. No-bake sands use organic resin binders that cure by chemical reactions that occur at room temperature.

31. In the shell molding process, a thermoplastic binder is used to bond the sand grains and the "cure" is provided by the exposure of the sand and binder mixture to patterns that have been heated to temperatures in the range of 300-450^{0}F. The heat then cures a layer

of mold material adjacent to the pattern.

32. Shell molds have thin walls so the length of path for gases leaving the mold is short and mold permeability is high.

When shell molds are heated by the molten material some of the binder burns off. This leaves a weaker, high collapsibility, mold structure.

33. In the V-process, mold strength is obtained through the use of a specially-designed vacuum flask. When a vacuum is drawn, the sand packs to rather high hardness. In contrast, the Ef f-set process uses frozen water as a binder, and the molds are poured while in their frozen condition.

34. Cores are used to produce internal cavities or reentrant sections in a casting. These are features that would be extremely difficult to produce by alternative methods.

35. The major problems with green sand cores is their weakness. If they are long or narrow, they are prone to breaking and may not even be able to support themselves.

36. The binder in the core-oil process is a vegetable or synthetic oil. Oven drying causes the oil to cross-link or polymerize, bonding the grains of sand.

37. In the hot-box core-making process, a liquid thermosetting binder and a catalyst are used to bind the sand. When the sand contacts a heated core box, the elevated temperature induces curing within 10 to 30 seconds.

38. Room-temperature curing is the primary attraction of the cold-box process. No-bake and air-set sands have the same advantage, but use a mixed catalyst in place of permeated gas to induce the cure.

39. Shell-molded cores offer excellent permeability since they are generally hollow.

40. Since cores may be nearly surrounded by molten metal, they generally require greater permeability than the base molding sand. All gases must escape through the core prints. Excellent collapsibility is required to permit the core material to be easily shaken out from the interior of the casting.

41. Chaplets are small metal devices that provide support for cores and prevent them from shifting in the mold. They should be large enough so that they do not completely melt and permit the core to float, and small enough that the surface melts and fuses with the cast metal.

42. When plaster molds are made, plaster is mixed with water and hardening occurs by a hydration process. If a high-melting temperature metal is poured into a plaster mold, the rapid evolution of the hydration water can cause an explosion. Therefore, plaster molds are only used with the lower-melting temperature nonferrous metals and alloys.

43. Process and part characteristics for plaster casting and ceramic mold casting are given in Table 14-4 and Table 14-5. While there are differences in some part characteristics, (e.g., part thickness limit and tolerance) the most striking difference is the greatly different melting temperature of materials that can be cast. Ceramic casting allows high melting temperature metals to be cast.

44. Graphite molds are often specified for use with highly reactive materials, such as titanium, that would interact unfavorably with many of the more common molding materials.

45. The individual patterns for investment casting are usually made from a molten wax, although plastics and mercury have also been used.

46. Investment casting molds are preheated prior to pouring to assure that the molten metal will flow more readily to all thin sections and to give better dimensional control by permitting the mold and the metal to shrink together during cooling.

47. In investment casting a pattern is formed from a low melting temperature, low vaporization temperature material, often wax. The mold is produced by surrounding the pattern with the mold material. The mold cavity is produced when the pattern is removed by melting/vaporizing the pattern. In early process development with porous mold materials the melted wax from the pattern would migrate into the mold material and be lost.

48. Counter-gravity investment casting uses atmospheric pressure, either negative gage pressure vacuum or positive pressure to cause the molten metal to flow into a sprue down-cavity up mold. In contract to using gravity to cause melt flow into the mold, counter-gravity casting enables molten metal to be drawn up into the mold from below the melt surface. This means that
-the molten metal entering the mold is free of slag and dross,
- the molten metal in the mold has low level of inclusions.

Since after the mold cavity fills the melt in the sprue and runner system can flow back to the melt pool, more of the melted metal becomes product than is gravity casting in which the sprue and runner system solidifies.

At low pressure gradients the metal may flow with lower turbulence than in gravity casting processes.
At higher pressure gradients it is possible to fill thinner mold/part sections than in gravity casting.

Since melt fluidity is less of a concern in counter-gravity casting lower melt temperature can be used resulting in improved grain structure and part properties.

49. The necessity of removing a pattern from a mold often requires some design

modifications, a complex pattern, or special molding procedures. When pattern removal is not required, no draft needs to be incorporated on the pattern, complex single-piece patterns can be used, and it is not necessary to use mold segments, such as a cope and drag.

50. In both full-mold and lost-foam casting processes the pattern-sprue-runner system is made from expanded polystyrene. The differences between the processes is in how the pattern system is supported and the mold created. In the full mold process green or chemically bonded sand is used around the pattern and becomes the mold when the pattern is removed. In lost foam casting a thin ceramic layer is formed on the pattern before the pattern-coating is surrounded by unbonded sand.

In essence, in full mold casting a bonded sand mold is made while in lost foam casting a thin ceramic layer-unbonded sand mold is used.

51. The nature of evaporative pattern casting processes leads to advantages compared to other types of casting operations that include
- complex parts can be produced since pattern removal is not a concern,
- with no pattern or core removal necessary mold and part draft can be eliminated,
- cores and parting planes are not required and so simpler processes and less involved process control result,
- with simpler molds simpler runner systems are often possible leading to increased ratio of product weight to weight of metal pored,
- molten material tends to solidify from the furthest point in the mold to the sprue often eliminating the need for risers,
- particularly with lost-foam ceramic layer molds high precision parts with smooth surfaces can be produced,
- if backup sand used in the mold in not bonded it may be directly reused.

52. In shakeout the part, sprue-runner system, cores, etc. are separated from the flask and mold material. Since the mold is designed and made to withstand damage during the entire mold construction-casting process it is a substantial, relatively strong structure. Therefore,
- shakeout entails additional operations to obtain the part,
- the shakeout operations have the potential for damaging the part and so have to be carefully designed and operated.

In general, shakeout implies additional, involved processes.

53. Castings can be cleaned by abrasive means in which particles are caused to impact on the part and so mechanically remove adhering sand, oxide, scale and parting line burrs/flash. The abrasive media can be nonmetallics such as sand, alumina and glass beads or metal shot. The abrasive accelerating system can be high velocity air (sand blasting) of centrifugal force, e.g., produced by feeding shot to the center region of a spinning, vaned wheel.

Problems:

No problems

Case Study:

Moveable and Fixed Jaw Pieces for a Heavy-duty Bench Vise

1. The mechanical properties and size of the piece clearly favor the use of some form of ferrous material, and the size and shape tend to dictate casting. The high elongation can be met by some of the more specialized cast irons, such as ductile cast iron, but also tends to favor the cast steels. Because of the size of the product, some form of expendable-mold sand casting would be likely. While green sand is a possibility the molds will require considerable strength and processes involving stronger molds, such as shell mold will be preferred. Cores will be used to produce the interior channels.

2. Because of the wide variation in section size, the as-cast products would be expected to have high and complex residual stresses and variability of structure and properties. To relax stresses, achieve uniformity, and attain the desired properties, most of the recommended alloys would require some form of heat treatment. Because the properties are not extremely demanding, a furnace anneal may be all that is required. Normalizing may be used if the variability with section size and location can be tolerated. The replaceable jaws would need the higher hardnesses produced by a quench and temper heat treatment process.

3. Corrosion resistance to a shop environment is desirable, and would most likely need to be imparted by paint or other form of surface treatment. If paint is selected, both adhesion and durability (including resistance to various oils and solvents) would be selection conditions. A sand blast treatment may be useful in cleaning the surfaces and producing the roughness necessary for enhanced adhesion.

CHAPTER 15
Multiple-Use Mold Casting Processes

Review Questions

1. The major disadvantage of the expendable-mold casting processes is the requirement that a separate mold be created for each casting. Variations in mold consistency, mold strength, moisture content, pattern removal, and other factors contribute to dimensional and property variation within a production lot.

2. Since the multiple-use molds are generally made from metal, the processes are often restricted to the casting of the lower-melting-point nonferrous metals and alloys. Part size is often limited, and the dies or molds can be rather costly.

3. The reusable molds for permanent mold casting are frequently made from gray cast iron, steel, bronze, or graphite. Aluminum, magnesium, and the copper-based alloys are the metals most frequently cast.

4. Advantages of the permanent-mold casting process include: a reusable mold, good surface finish and dimensional accuracy, the possibility of controlling solidification to give desired properties, and a fast cooling rate to produce a strong structure. Cores can be used to increase the complexity of the castings.

5. Permanent molds, and ancillary equipment, have to be designed to have long lives and so tooling costs for permanent mold casting operations are high. Setup and operating costs are also high. This high process cost cannot be recovered in low part production runs.

6. Permanent mold life depends on part material related characteristics such as melting temperature and melt-mold material compatibility and process related conditions such as pouring temperature and mold temperature.

The primary mold feature that influences mold life is difference in section size through the mold. Different section sizes produce temperature gradients and so differences in mold expansion contraction and also determine the flow patterns as the melt fills the mold.

7. Permanent-mold castings are generally removed from the mold immediately after solidification because the rigid cavity offers great resistance to shrinkage. Tearing might occur if the part is restrained while cooling.

8. Permanent molds are not permeable and usually have smooth mating surface. Venting is usually implemented using slight opening between the mold halves or the addition of small vent holes and passages from the mold cavity to the outside.

9. Slush casting can be used to produce hollow shapes with good surface detail. Wall thickness is variable, so products are largely decorative items, such as candlesticks, lamp bases, and statuary.

10. Low-pressure permanent-mold casting introduces the molten metal into the die by forcing it upward through a vertical tube. The driving force is a low pressure of 5 to 15 psi applied the molten bath.

11. Since no risers are used in the low-pressure permanent-mold process (the pressurized feed tube acts as a riser) and the molten metal in the feed tube can be immediately reused, the yields of the process are generally greater than 85%. The metal is exceptionally clean since it is bottom-fed and never passes through air. Nonturbulent filling further reduces gas porosity and dross, and directional solidification and pressure feeding act to minimize shrinkage problems.

12. Vacuum permanent-mold casting offers all of the advantages of the low-pressure process (clean metal, low turbulence, low dross, compensation for shrinkage, high yields, and good mechanical properties) . In addition, the vacuum produces an even greater cleanliness and low dissolved gas content. Thin-walled castings can be produced with excellent surface quality.

13. In low-pressure permanent-mold casting, the feeding pressures are on the order of 5 to 15 psi. In die casting, the molten metal is forced into the molds by pressures of thousands of pounds per square inch and is held under this pressure during solidification .

14. Most gravity permanent-mold dies are made from gray cast iron. This material has great resistance to thermal fatigue and machines easily. In contrast, die casting dies are generally made from hardened tool steels, since cast iron cannot withstand the casting pressures.

15. Because high pressures might cause turbulence and air entrapment, lower injection pressures may be preferred, followed by higher pressure after the mold has filled completely and the metal has started to solidify.

16. Hot-chamber die-casting machines cannot be used for the higher-melting-point metals, such as brass and bronze, and molten aluminum has a tendency to pick up iron from the casting equipment. Therefore, the hot-chamber machines are generally used with zinc-, tin-, and lead-based alloys.

17. In hot-chamber die-casting machines the molten metal may be in the machine chamber for an extended period. Metals that have high melting temperatures compared to the machine material or react with the machine material are not suitable for hot-chamber die-casting machines. Cold-chamber machine are used to die cast these kinds of materials and examples of such materials are aluminum which picks up iron and magnesium. copper and high-aluminum zinc.

18. Die casting dies fill with metal so fast that there is little time for the air in the mold cavity to escape. To minimize entrapped air problems, such as blow holes, porosity and misruns, the dies must be properly vented, usually by the incorporation of wide, thin vents at the parting line.

19. Since the molten metal is injected into the mold cavity under pressure and this pressure is maintained throughout solidification, risers are not incorporated into the mold design in die casting. Sand cores cannot be used because the pressure of the molten metal would cause them to disintegrate as the metal is injected or produce extensive penetration during the cast. Retractable metal cores can be incorporated into the dies.

20. By introducing the molten zinc directly into the die cavity through a heated manifold and heated nozzles, one can eliminate the sprues, gates and runners normally incorporated into a die-casting die, significantly increasing the yield of the process .

21. Die casting is characterized by extremely smooth surface finishes, excellent dimensional accuracy, and high production rates. A single set of dies can produce many thousand castings without significant changes in dimension.

22. The manufacturing cost of a part includes all the processes needed to produce the part. Typically a series of processes is needed and so if die casting can reduce the number of operations needed and/or simplify the processes, the higher cost of die casting may be offset by lower costs for other, required operations. An example is decreased costs of subsequent finishing (machining to produce specified dimensions and surface finishing to produce desired appearance) for higher cost but more accurate, better surface die cast parts compared to lower cost parts from other types of casting processes that need more or more complicated finishing.

23. In squeeze casting, a precise amount of molten metal is poured into the bottom half of a preheated die set and allowed to partially solidify. An upper die then descends, applying pressure throughout the completion of solidification.

24. A thixotropic material is a semi-solid (liquid plus solid) material that can be handled mechanically like a solid, but shaped at very low pressures because it flows like a liquid when agitated or squeezed. As an alternative to squeeze casting, it eliminates the need to handle molten metal, and reduces or eliminates many of the molten metal problems, such as gas pickup and shrinkage.

25. In semisolid die-casting
- injection temperature is low and so solidification time is short, less substantial machines are needed and machine component life is long,
- the mechanical action breaks up the structure of the semisolid and so a more desirable metallic, isotropic, structure can be produced.

26. In true centrifugal casting, the metal is forced against the outer walls of the mold with

considerable force and solidifies first at the outer surface. Products have a strong, dense exterior surface. Lighter-weight impurities tend to be present on the inner surface, which is frequently removed by a light machining cut.

27. In centrifuging, centrifugal force is used to force metal from a central pouring reservoir into thin, intricate mold cavities removed from the axis of rotation. Thus, the mold cavities fill under the pressure of centrifugal force. In semicentrifugal casting, a single, axisymmetric casting is poured by introducing metal into the centermost region of a rotating mold. The center pouring region is an integral part of the casting .

28. In the electromagnetic casting process there is no interaction with a container, and the electromagnetic stirring promotes a homogeneous, fine-grained structure.

29. Selection of a furnace or melt procedure depends on such factors as: the temperature needed to melt and superheat the metal, the alloy being melted, the desired melt rate and quantity, the desired quality of the metal, the availability and cost of fuels, the variety of metals to be melted, the desire for either batch or continuous melting, the required level of emission control, and the capital and operating costs.

30. Cupolas are used to produce gray, nodular and white cast irons.

31. In cupola-melting operations, temperature and chemistry control is somewhat difficult. The nature of the charged materials and the reactions that occur within the cupola can all affect the product chemistry. Moreover, when the final chemistry is determined by the analysis of the tapped product, there is already a substantial quantity of material within the furnace. Therefore, final chemistry adjustments are often performed in the ladle via ladle metallurgy.

32. In order to increase the melting rate of the metal in a cupola the rate of heating of the incoming air and of the metal have to be increased. Incoming air can be preheated by passing it through a heat exchanger that uses the stack gas as a heat source. Oxygen can be added to blast to increase temperature and increase reaction rate and melting rate. High energy density heat sources can be used, e.g., plasma torches.

33. The stirring action, temperature control, and chemistry control of the indirect fuel-fired furnaces are all rather poor. The major attractive feature is the low capital equipment cost.

34. Arc furnaces offer rapid melting rates, the ability to hold molten metal for any desired period of time to permit alloying (a flux blanket protects the metal), and ease of incorporating pollution control .

35. Channel-type induction furnaces, where the molten metal circulates through a secondary coil loop and gains heat, offer great ability to provide precise temperature control. These make excellent holding furnaces, where the molten metal must be held for long periods of time at a specified temperature.

36. The poring operation has to be designed to insure that the proper pouring temperature is maintained and that only high quality metal gets into the mold. The poring ladle is a critical part of the pouring system.

37. Some of the typical cleaning and finishing operations performed on castings include: removal of cores, gates, risers, fins, and rough spots on the surface, cleaning of the surface, and repairing of any defects.

38. Sand cores are removed by mechanical shaking which may sometimes be preceded by chemically dissolving the binder.

If the runners, risers and gates joining different sections of the part-runner system are small in cross section the part can be broken off of the runner system. If section area is large cutting is necessary using saws, abrasive wheels or oxyacetylene or plasma torches.

39. Some types of casting defects can be repaired readily by arc welding In addition, surface porosity can be filled with a resinous material, such as polyester, by a process known as impregnation.

40. In metal-casting operations, robots can be used to tend stationary, cyclic equipment, such as die-casting machines. They can be used in finishing rooms to remove sprues, gates and runners, perform grinding and blasting operations, and assist in the heat treatment of castings. They can dry molds, coat cores, vent molds, and clean and lubricate dies. In certain processes, they can be used to dip patterns into mold material slurries and position them to dry. Further implementation might include their use to position the pattern, fill the flask with sand, pour the molten metal, and manipulate a cutting torch to remove the sprue.

41. Some of the features affecting the cost of a cast product include: the direct cost ~t material and the energy to melt it, and the indirect cost of patterns, molds, dies, melting and pouring equipment, scrap metal, cleaning, inspection and labor. While the direct costs do not change with the number of castings being produced, the indirect costs must be shared over the production lot. An expensive die may not be justifiable for a small number of castings.

Problems:

No problems

Case Study:

Baseplate for a Household Steam Iron

1. The baseplate must heat to elevated temperatures quickly and cool to room temperature quickly after use. It must sustain repeated thermal cycles without deterioration, be light enough to facilitate ease of use but heavy enough to press out wrinkles without requiring a pushing force, and provide scratch resistance to buttons, snaps, rivets and zippers. The material must be corrosion resistant to steam (and all of the associated contaminants of various waters), as well as a variety of laundry products. It must be fracture resistant to dropping from waist height. The heating element must be thermally-coupled, but electrically-insulated (NOTE: Normally, thermal conductivity and electrical conductivity are proportional properties for metals!). While the key properties are thermal conductivity, corrosion resistance, and light weight, strength, wear resistance, toughness, and resistance to creep and thermal fatigue must all be present at moserate levels. An attractive appearance may be desired for marketability, and machinability may be required to produce the necessary holes, threaded recesses, and dimensional precision .

2. While aluminum would be the primary material to be considered, some possible alternatives might be: Stainless steel (heavy and poorer thermal conductivity), copper alloys (heavier than steel), and cast iron (heavy). Aluminum alloys offer the desired low density, low cost, high thermal conductivity, good corrosion resistance, machinability, and appearance.

Jumping ahead to marry material and process, the most attractive process appears to be die casting, and the family of aluminum die casting alloys is relatively small. Alloy 380 presently accounts for the overwhelming majority of such castings (probably more than 80%). While other alloys may offer better thermal conductivity, the enhancement may not be sufficient to justify deviation from a material that has become the industry norm.

3 . Because of the integral heating element, production would most likely be by some form of casting with a "cast-in insert". Alternative methods include: sand, shell mold, full mold, permanent mold, plaster mold, investment and die casting, as well as various methods of forging or powder metallurgy, for which the insert would have to be a secondary addition.

Within the realm of reasonable production capability, none of the processes could produce the completed part to net-shape directly. Die casting appears to come closest, being capable of producing the narrow webs and 1/8 inch diameter recesses, but is not capable of producing the 1/16 inch holes for the steam vents by means of coring. Surface finish and dimensional precision are excellent for this application.

4. The 1/16 inch holes would most likely be added by some form of secondary machining operation, such as drilling. In addition, the larger holes are threaded, but the simplest means of core removal is simple retraction. Therefore, it is likely that these would be made as smooth-bore cavities in the casting, sufficiently undersized to permit the machining of the threads as a secondary operation.

5. The simple buff and polish may well be the best possible finish. The long-term durability of the teflon coating is questionable, and the anodized layer would produce a

darker dull gray finish on the silicon-containing casting alloy. In addition, this layer has been known to flake off due to the differential thermal expansion characteristics and the brittle nature of the oxide material.

CHAPTER 16
Powder Metallurgy

Review Questions

1. Powder metallurgy processes involve blending of powders, pressing of the powders to a desired shape and sintering.
Since powders are used, the composition of the part can be varied over a wide range and so a wide range of part properties can be produced.
By using a powder component that can be removed after the part is formed permeable parts can be made.
Since powders are compacted in relatively high precision tooling, accurate parts can be produced.
Compaction may require high pressure and in such a case compaction forces will be large and parts will be small.
Sintering enables part characteristics to be controlled by controlling the sintering process.

In general, small, high precision parts that need to have carefully controlled microstructure are candidates for production using powder metallurgy techniques.

2. Some of the earliest mass-produced powder metallurgy products included coins and medallions, platinum ingots, and tungsten wires. These were followed by carbide cutting tool tips, nonferrous bushings, self-lubricating bearings, and metallic filters.

3. Automotive applications currently account for nearly 75% of P/M production. Other major markets include: household appliances, recreational equipment, hand tools, hardware items, business machines, industrial motors, and hydraulics.

4. Iron and low alloy steels are used in about 85% of powder metallurgy production. The large amount of this metal family previously (and currently) used and the workability and experience with working it led to the early and continued development of powder metallurgy processes using it.

5. The powder metallurgy process normally consists of four steps: powder manufacture, mixing or blending, compacting, and sintering .

6. Some important properties and characteristics of metal powders are: chemistry and purity, particle size, size distribution, particle shape, and the surface texture of the particles .

7. The most common means of producing metal powders is by melt atomization where molten metal is fragmented into small droplets and the droplets solidify into particles of metal. Any material that can be melted can be atomized and the resulting particles retain the chemistry of the parent material.

8. Other techniques of powder manufacture include chemical reduction of particulate compounds, electrolytic deposition from solutions or fused salts, pulverization or grinding of brittle materials (comminution), thermal decomposition of hydrides or carbonyls, precipitation from solution, and condensation of metal vapors .

9. Powder production processes based on processes in which elemental forms of material are produced and exist will be practically useful (not overly complicated, time consuming, energy intensive, easily controllable) only for producing elemental powder. For example, as chemical reduction, thermal decomposition and condensation processes occur different elements are obtained at different stages (time, temperature or composition) and so elemental powders are the logical product to be produced using such processes.

10. The production of amorphous and rapidly solidified powders requires large energy density (energy per unit volume of material produced) and so with reasonable energy levels only small particles can be produced. That is, for fixed energy input the requirement of high energy density means that only small volume products can be produced. To make useful products these small particle, powder, raw materials have to be combined and powder metallurgy techniques accomplish this consolidation task effectively and efficiently.

11. To make a powder metal product powder in placed in a die, pressed and then sintered. To describe the ability of the powder to flow into the die and into various, small, sections of the die cavity and to be uniformly distributed in the die, quantitative measures of powder flow are useful. Flow rate tests provide such a powder behavior measure in flow rate.

12. Apparent density is the density of the loose powder to which there has been no application of external pressure. Final density is measured after compaction and sintering and is typically about twice the value of the apparent density.

13. Green strength refers to the strength of the powder metallurgy material after pressing, but before sintering. Good green strength is required to maintain smooth surfaces, sharp corners, and intricate details during ejection from the compacting die or tooling and subsequent transfer to the sintering operation .

14. Mixing or blending is performed to combine various grades or sizes of powders or powders of different compositions, or add lubricants or binders to the powder.

15. The addition of a lubricant improves the flow characteristics and compressibility of the powder at the expense of reduced green strength.

16. While lubricants such as wax or stearates can be removed by vaporization, the graphite remains to become an integral part of the final product. In the production of steel products, the amount of graphite lubricant is controlled so it will produce the desired

carbon content in the final material when it is dissolved in the iron powder.

17. Composites of compatible (easily bonded in sintering) materials should be easy to produce by powder metallurgy techniques.

Since there is a large amount of mechanical working of the powders used in powder metallurgy processes, and since surface areas are high energy regions on material bodies, and since powder surface area is large, the opportunity for producing composites of usually incompatible materials exists. That is the combination of mechanical working and high surface energy may make powder sintering possible and an effective way to create composite materials. Examples are composites composed of an immiscible material dispersed in a matrix and combinations of metals and nonmetals.

18. The goal of the compacting operation is to compress and densify the loose powder into a desired shape. Uniform high density is desired and the product should possess adequate green strength .

19. Compacting pressures generally range between 3 and 120 tons per square inch, with values between 10 and 30 being most common. The total pressing capacity of compacting presses is the feature that generally restricts the cross-sectional area of P/M parts to several square inches.

20. During compaction, the powder particles move primarily in the direction of the applied force. The powder does not flow like a liquid, but simply moves in the direction of pressing until an equal and opposing force is generated through either friction between the particles and die surfaces or by resistance from the bottom punch.

21. When pressing with rigid punches, the maximum density occurs adjacent to the punch and diminishes as one moves away. With increased thickness, it is almost impossible to produce uniform, high density throughout the compact. By using two opposing punches, a more-uniform density can be obtained in thicker pieces.

22.The final density of a P/M product can be reported as either an absolute density in units of weight per volume, or as a percentage of the theoretical density, where the difference between this number and 100% is the amount of void space still present in the product.

23. Conventional powder metallurgy products fall into the classes of
1. Porous or permeable products that are design and produced to small pores or voids that can be filled with another material or to function as porous media as do filters.
2. Complex shaped parts with dimensional and geometric tolerance and surface finish requirements that require only light finishing when produced by powder metallurgy. Such parts can be produced in powder metallurgy dies and so avoid complex machining operations.

3. Product made from high melting point or difficult to machine materials. The mechanical action in compaction and high surface energy of powders make consolidation by sintering practical and avoids difficult machining tasks.
4. Products made from composite materials. Composites can be made from compatible, easily sintered materials and even from some incompatible materials (Question 17).

The use of the concepts of better properties and economic advantage (items 5 and 6 in the text) are useful for describing the advantages of the powder metallurgy processes, but not for describing types of products.

24. Isostatic compaction is the process in which the powder is exposed to uniform compacting pressure on all surfaces, and is usually achieved by encapsulating the powder in a flexible mold and immersing it in a pressurized gas or liquid. The process is generally employed on complex shapes that would be difficult to compact by the faster, more traditional techniques.

25. Warm, elevated temperature, compaction produces more uniform compaction and improved as-compacted and after processing properties, primarily strength. As temperature is increased powder strength decreases. During warm compaction increased deformation of the powder and increased mechanical action makes for more uniform density and increased bonding due to disruption of surface layers on the powder particles. The increased, more intimate contact between powder particles also increases the material consolidation effects of sintering.

26. To increase the powder flow capability, very small particles are used in the powder used in metal injection molding compared to the particle size of powders in conventional powder metallurgy processes.

27. Depending on the binder used, it is removed by
- solvent extraction,
- heating to above the binder volatilization temperature,
- catalytic chemical binder decomposition.

28. During sintering, P/M injection molded parts shrink between
15 and 25% as they achieve their final density and properties.

29. Since small particle size powders are expensive as is binder removal, the ideal geometry for a metal injection molded part is
- a part in which mechanical performance (strength and deformation behavior) is obtained by efficient design rather that by use of a large amount of material, e.g., the ability to get the same performance with less material in an I-beam than with a rectangular cross section beam. Powder cost implies small, complex parts.
- a thin part. Binder removal will be faster and more effective if the binder-surface distance is small. Binder removal implies small, thin parts.

30. P/M injection molding enables the P/M production of small, complex components

that were previously investment cast or machined directly from metal stock. Parts can be made with thin walls and delicate cross sections that would be impossible to compact in a conventional press.

31. The three stages of sintering are: (1) the burn-off or purge -- designed to remove air, volatilize and remove lubricants and binders, and slowly raise the temperature of the compacts; (2) the high-temperature sintering stage, with the temperature being constant; and (3) the controlled cool-down.

32. Most metals are sintered at temperatures between 70 and 80% of their melting point. Certain refractory metals may require temperatures as high as 90% of the melting point.

33. When sintering, one must slowly raise the temperature of the compacts in a controlled manner because rapid heating would produce high internal pressure from heating air entrapped in closed pores and volatilizing lubricants. This would result in swelling or fracture of the compacts.

34. Controlled, protective atmospheres are necessary during sintering because the fine powder particles have large exposed surface areas and, at elevated temperatures, rapid oxidation will occur and impair the properties of the product.

35. During sintering, metallurgical bonds form between the particles. In addition, alloys may form, product dimensions will contract, and density will increase.

36. The purpose of sinter brazing is to join two or more powder metal parts. The brazing process is carried out during the sintering of the individual parts.

37. Products of HIP techniques generally possess full density with uniform, isotropic properties that are often superior to those of products produced by alternative techniques. Near-net shape production is possible, and reactive materials can be processed since they are isolated from the environment.

38. The primary limitations of the HIP process are the cost of "canning" and "decanning" the material, and the long time required for the processing cycle. The sinter-HIP process permits the production of full-density products without the expense and delay of canning and decanning.

39. Sinter-HIP and pressure assisted sintering are intended to produce the same desirable part characteristics as hot isostatic pressing. The main advantage of sinter-HIP and pressure assisted sintering is that the canning and decanning operations in HIP are eliminated.

40. Alternative techniques for the production of high-density P/M products include the various high-temperature forming methods, the Ceracon process, and spray forming (also called the Osprey process).

41. In spray forming
- a stream of molten droplets is produced,
- the droplet stream is sprayed into a collecting container,
- the temperature of the initial material and droplet velocity and flow rate are controlled so that the droplets are in a semisolid or slushy state when they interact with each other in the container,
- the collection of droplets freezes into the part of a structural shape depending on the shape of the collecting container.

High density, fine grain size parts can be made since the interacting droplets are small and can deform extensively in the process since they are in the semisolid state.

42. Repressing, coining or sizing operations are generally used to restore dimensional precision. Only a small amount of metal flow takes place.

43. Repressing cannot be performed with the same tooling that was used for compaction because the compaction tooling is designed to produce an over-sized compact to compensate for the dimensional shrinkage that occurs during the sintering operation.

44. During repressing, only a small amount of metal flow takes place, and the part retains its starting shape. PIM forging, however, imparts a considerable amount of plastic deformation as the material flows from a simple starting shape to a more-complex shape forging.

45. While impregnation and infiltration are both processes that fill the permeable void space with another material, infiltration refers to the filling of the voids with another metal, while impregnation employs a liquid, plastic, or resin.

46. Powder metallurgy product density is directly related to the number and size of the pores in the product. The voids or pores can effect the performance of secondary or finishing operations. The effects are due to the voids in the part and the surface area of the pores.

In heat treatment the part environment during heating and quenching can enter the voids in the part, at least the pores near the surface. Any undesirable reactions between the environment and the part will occur on the part surface and internal to the part in the pores. Protective or nonreacting heating atmospheres may be required. Quenching medium entering the part leads to more extreme temperature gradients in powder metallurgy parts than in solid parts of the same size and shape. Material-quench medium chemical reactions occur not only on the surface but also over the wetted surfaces of the pores. Certain liquid quenching mediums may not be useable.

Both mechanical and fluid-part interactions occur in machining. The density of powder metallurgy parts can indicate potential concerns when machining these parts. When the cutting tool passes through the powder metal workpiece and encounter voids the mechanical loading in the tool edge-work material interaction region changes. Cutting forces become intermittent. The deformation imposed on the work material changes since the tool passes from solid material – to a void – to solid material. The changing cutting forces and deformation patterns lead to a less controlled machining process and potentially a rough, damaged machined surface and increased tool wear. Sharp tools and light cuts can help minimize undesirable mechanical effects in machining. Cutting fluids can enter the pores in the powder metal part and produce undesirable temperature gradients and deleterious fluid-work material chemical reactions.

Surface treatments can involve mechanical, thermal and chemical effects depending on the treatment, e.g., shot peening to produce compressive residual stress, heat-and-quench treatments, carburizing. Powder metal part density, volume of pores, can indicate potential problems with deformation and fracture in mechanical processes and surface-environment problems in thermal and chemical processes as discussed above.

47. The fracture-related properties, such as toughness, ductility, and fatigue life show the strongest dependence on product density.

48. When converting the manufacture of a component from die casting to powder metallurgy, it is important to realize that P/M is a special manufacturing process and provision should be made for a number of unique factors. Products that are converted from other manufacturing processes without modification in design rarely perform as well as parts designed specifically for manufacture by powder metallurgy.

49. The ideal powder metallurgy product has a uniform cross-section, and a single thickness that is small compared to the cross-sectional width or diameter.

50. Powder metal parts provide opportunities for improved part performance since in may be possible to add performance improving additives into the pores in the part. Even with no added material the pores in powder metal parts can be used. By controlling pore size the flow of gases, liquids and particles through the part can be controlled. Examples of products that use part porosity or permeability to advantage are oil impregnated powder metal bearings, powder metal filters and flow regulators.

51. In the electrical industry, copper and graphite are frequently combined to provide both conductivity and lubrication. Electrical contacts frequently combine copper or silver with tungsten, nickel or molybdenum, where the material with high melting temperature provides resistance to fusion during the conditions of arcing and subsequent closure.

52. Machining has two general goals, to produce desired shapes and dimensions and to produce specified surface finish. Finish machining usually is concerned with producing tight tolerance dimensions and low rough ness surfaces. To accomplish these goals high accuracy, rigid, dynamically stable machine tools are required and usually mild cutting conditions are used with resulting low rate of material removal and long machining time. Expensive machine tools and tooling and low material removal rates lead to high cost finish machining operations.

53. In casting materials that are immiscible, that do not form solutions or are outside solubility limits will not form useful continuous solid materials on solidification. While these types of materials cannot be cast, often they can be combined by the mechanical and thermal processes in powder metallurgy processes. An extreme case example is the production of metal-ceramic composites such as aluminum-alumina.

In many forming processes complex shapes are produced and so large deformations are required to form the parts. If the required deformation exceeds the maximum deformation possible before fracture the part cannot be formed or can only be formed in complex, costly processes such as forming-annealing-forming. With the same material in powder form, compacting and sintering can be used to produce the desired shape without the limits imposed by maximum possible deformation. After sintering final sizing by a deformation process to relatively high deformation levels can often be achieved. The residual porosity after sintering effectively increases material ductility as pores are closed in mechanical sizing operations. The conclusion is that powder metallurgy processes may be useful for forming brittle metals such as uranium and zirconium.

Also, composite parts can be made using powder metallurgy processes, Question 17.

54. Because of the high pressures and severe abrasion involved in the compacting process, the dies must be made of expensive materials and be relatively massive. The set-up and alignment of punches and dies is frequently a time-consuming process. Production volumes of less than 10,000 identical parts are rarely practical .

55. The higher cost of the starting material for powder metallurgy is often offset by the absence of scrap formation and the elimination (or reduction) of costly machining operations. Moreover, P/M is usually employed for the production of small parts where the material cost per part is not very great.

56. When compared to cast or wrought products of the same material, conventional P/M products generally possess inferior mechanical properties. This may be an unfair comparison, for if the P/M material and processing is designed to produce a desired product, the desired mechanical properties can often be obtained at lower cost than by alternative techniques. The material, however, is frequently different from that used in wrought or cast equivalents. If full density can be achieved, the properties of PiM products are often superior to their wrought or cast counterparts.

Problems:

1. In addition to chemical purity, the key properties or characteristics for material being used in powder metallurgy are those that affect how the powder will, flow, fill space, compact (i.e. respond to pressure), and sinter, as well as those that will directly affect the final properties. These include:
surface chemistry, particle size and size distribution, particle shape (and shape distribution), surface texture, and microstructure (or mechanical properties) . Since the

material is processed as a solid, all of the geometric and property features of the solid become important.

The characterization of starting material for a powder metallurgy process is far more extensive than specifying the starting material for casting (where the material will be melted and both the geometry and the properties will be significantly altered by the process), and forming (where the properties are important, but the starting geometry will be highly altered) .

2. The hot pressing process would not be attractive for the manufacture of conventional P/M parts because loose powder must be protected from oxidation when it is at the elevated temperature. Conventional P/M permits compaction in air because the powder is at room temperature, and reaction rates are acceptably slow. Protective atmospheres are provided during elevated temperature sintering. In hot pressing, some form of "canning" or isolation must be provided and this brings about additional expense and decreased rate of production.

Case Study:

Impeller for an Automobile Water Pump

1. The relatively low mechanical property, ductility, hardness and wear resistance requirements make this part a candidate for a variety of materials. Because of the presence of coolant and a additional materials in the shaft and housing of the pump, material selection should take into account galvanic corrosion. Possible materials include aluminum, cast iron, copper alloys, stainless steel and others.

2. As designed, the part is a two level part with flat surfaces. With the relatively low surface area and small thicknesses the part can be manufactured by conventional press-and-sinter powder metallurgy using a double acting press. Alternative means of manufacture are some form of casting, such as die casting, permanent mold, shell or investment casting. It would be difficult to use forming processes to form the part because of the lack of draft on the impeller blades. With design changes forging could be used.

3. Possible manufacturing processes are listed in part 2. Each is more compatible with the use of some materials rather than others.

4. Since the part will constantly exposed to water over a range of temperature, the compatibility of polymers with this environment is a major concern. Many polymers absorb water and swell. The change in part dimension in use is unacceptable. This limits the material choice to high performance, engineered polymers which are probably not practical for such a mass produced, low cost part.

CHAPTER 17
Fundamentals of Metal Forming

Review Questions

1. Plasticity is the ability of a solid to flow, plastically deform, without deterioration of its properties. The mathematical description of plastic deformation stresses and strains, and the relations between them is known as the theory of plasticity.

2. Deformation processes shape metal in the solid state through the rearrangement rather than the removal of material. Unfortunately, large forces are required, and the machinery and tooling can be quite expensive. Large quantities may be necessary to justify the capital expenditure.

3. Large production quantities are often necessary to justify the use of metal deformation processes because the large forces require costly machinery and tooling.

4. Independent variables are those aspects of a process over which the engineer has direct control. They are generally selected or specified when setting up the process.

5. The specification of tool and die geometry is an area of major significance in process design. Since the tooling will produce and control the metal flow, the very success or failure of a process often depends upon good tool geometry.

6. It is not uncommon for friction to account for more than
50% of the power supplied to a deformation process. Product quality is often related to friction, and changes in lubrication can alter the material flow and resulting material properties. Production rates, tool design, tool wear, and process optimization all depend upon friction and lubrication. In addition, lubricants often act as coolants, thermal barriers, corrosion inhibitors, and parting compounds .

7. Lubricants, and metal working lubricants in particular, can act as coolants, thermal barriers and corrosion inhibitors. Often lubricants are formulated to include or enhance these functions in addition to their use in reducing friction.

8. If the speed of a metal forming operation is altered, several changes can occur. Many materials are speed-sensitive and will behave differently at different speeds. Ductility may vary, and many materials appear stronger when deformed at faster speeds. In addition, faster speeds promote lubrication efficiency and reduce the amount of time for heat transfer and cooling.

9. Dependent variables are aspects of a process determined by the process itself as a consequence of the values selected for the independent variables.

10. It is important to be able to predict the forces or powers required to perform a specific forming process, for only by having this knowledge can the engineer specify or select the equipment for the process, select appropriate tool or die materials, compare various die designs or deformation methods, and ultimately optimize the process.

11. The engineering properties of a product can be altered by both the mechanical and thermal history of the material. Therefore, it is important to know and control the temperature of the material throughout the process.

12. Metal-forming processes are complex systems composed of the material being deformed, the tooling performing the deformation, lubrication at surfaces and interfaces, and various other process parameters. The number of different forming processes is quite large, and various materials often behave differently in the same process. The independent variables interact with one another, so the effects of any change are often quite complex.

13. The predictive link between independent and dependent variables is generally based on one of three approaches:
experience, experiment, or process modeling.

14. To be truly valid, direct experiments should be full-size at production speeds. Reduced magnitude testing generally alters lubricant performance and thermal effects. Results should be extrapolated to production conditions with caution. In addition, experimentation is costly and time-consuming.

15. Process modeling, particularly numerical modeling and simulation, has experienced greatly expanded use because
- of the availability of computers with continually increasing computational power,
- the accuracy of simulations.

In addition, there are many useful results that can be obtained through use of process models and some of these are listed in the answer to Question 17. below.
- of the use of quantitative results to provide understanding of details of deformation processes,
- obtaining quantitative results that correspond to reality demonstrates process understanding,
-of reductions in production delays and lead times due to having accurate predictions of process performance and part characteristics at the process design stage of manufacturing,
- they can be used as laboratory tools to run numerical experiments to
--- simulate processes using varying processing conditions and tooling to answer “what if?” questions,
--- investigate feasibility of modifications to processes and products and evaluate new processes and products.

16. The accuracy of the various process models can be no better than that of the input

variables, especially those like strength of material and interfacial friction.

17. In general, process models are used to predict process behavior and resulting product properties. Process behaviors such as forces and power required to produce a given deformation pattern and product characteristics such as deformation in surface regions and the resulting residual stress state can be calculated – is accurate process models are available.

In addition, and expanding on the thoughts underlying Question 15:
Process modeling, particularly numerical modeling and simulation, has experienced greatly expanded use because
- of the availability of computers with continually increasing computational power,
- the accuracy of simulations.
- of the use of quantitative results to provide understanding of details of deformation processes,
- obtaining quantitative results that correspond to reality demonstrates process understanding,
-of reductions in production delays and lead times due to having accurate predictions of process performance and part characteristics at the process design stage of manufacturing,
- they can be used as laboratory tools to run numerical experiments to
--- simulate processes using varying processing conditions and tooling to answer “what if?” questions,
--- investigate feasibility of modifications to processes and products and evaluate new processes and products.

18. A constitutive equation for an engineering material is an attempt to mathematically characterize the material's behavior under various conditions of temperature, strain, strain rate, and pressure .

19. Many of the process models describe friction by a single variable of constant magnitude -- i.e. friction is the same at all locations and throughout the entire time of the process.

20. It is important that the metal-forming engineer know the strength or resistance to deformation of the material at the relevant conditions of temperature, speed of deformation, and amount of prior straining. In addition, he would benefit from information on the formability and fracture characteristics, the effect of temperature and variations in temperature, strain hardening characteristics, recrystallization kinetics, and reactivity with various environments and lubricants.

21. Typically interface forces and temperatures are high in metalworking processes. This situation leads to high friction forces. So, friction is important in metalworking processes since high friction forces result in high overall forces (friction and deformation forces) and high energy dissipation. Large forces cause machine and tooling deformation and so the need for large, rigid, expensive forming machines. High energy dissipation rates

cause high temperatures and so increased tool wear and possibly deleterious effects on the workpiece/final part.

22. The friction encountered during metalforming operations is significantly different from that observed in most mechanical operations. In forming, a hard, nondeforming tool interacts with a soft, plastic, workpiece at relatively high pressure. Only a single pass is involved, and the workpiece is often at elevated temperature. Mechanical operations usually involve materials of similar strength, under elastic loading, with a wear-in cycle, and at relatively low temperatures.

23. Two important phenomena in determining resistance to motion of one surface over another, friction force, are
- the plowing of asperities on the harder surface through the softer surface,
- the breaking of bonds between the two surfaces. The bonds form when surfaces are brought into contact since local stresses can be very high and asperity-asperity bonding occurs.

24. Since the workpiece passes over the tooling only once, wear on the workpiece is generally not objectionable, and may actually be desirable as it produces a shiny, fresh-metal surface. Wear on the tooling, however, alters the dimensions and surface finish of the product and increases the power losses due to friction. Replacement of costly tooling may be required along with lost production during the changeover.

25. Lubricants should be selected for their ability to reduce friction and suppress tool wear. Other considerations include:
ability to act as a thermal barrier, coolant, or corrosion retardant; ease of application and removal; lack of toxicity, odor and flammability; reactivity; thermal stability; stability over a wide range of processing conditions; cost; availability, surface wetting; and the ability to flow or thin and still function .

26. If one can achieve full-fluid separation between a tool and workpiece, the required deformation forces may reduce by 30 to 40% and tool wear becomes almost nonexistent.

27. In general, an increase in temperature brings about a decrease in material strength, an increase in ductility, and a decrease in the rate of strain hardening - all effects that would tend to promote ease of deformation.

28. The temperatures required for hot working generally exceed 0.6 times the melting point of the material on an absolute temperature scale. Cold working generally requires temperatures below 0.3 times the melting point, and warm working is the transition region, between 0.3 and 0.6 times the melting point.

29. Hot working is deformation under conditions of temperature and strain rate such that recrystallization occurs simultaneously with the deformation.

30. Hot forming operations do not produce strain hardening and the companion loss of

ductility, permitting the material to be deformed by extensive amounts without the likelihood of fracture or the use of excessive force (elevated temperature lowers the strength and deformation does not increase it) . In addition, diffusion is promoted, pores can be reduced or welded shut, and the metallurgical structure can be altered to improve properties.

31. Disadvantages associated with hot working involve the reactions which may be promoted by elevated temperature, such as rapid oxidation. Tolerances are poorer and the metallurgical structure will be nonuniform if the amount of deformation or thermal history varies throughout the product.

32. If a metal is deformed sufficiently at temperatures above the recrystallization temperature, the distorted structure (of deformation) is rapidly replaced by new, strain-free grains. The final structure of the metal is that produced by the last recrystallization and the any subsequent thermal history. The production of a fine, randomly-oriented, spherical-shaped grain structure can improve not only the material strength, but also the ductility and toughness.

33. While the metal grains recrystallize during hot forming, inclusions and nonmetallic impurities do not and serve to impart an oriented or fiber structure (directional properties) to the product .

34. Heated dies are often used in hot forming operations to reduce the amount of heat loss from the workpiece surface to the tooling and maintain the workpiece temperature as uniform as possible. Nonuniform temperatures may produce surface cracking or nonuniform flow behavior and undesirable properties.

35. When dies or tooling is heated, the lifetime tends to decrease. Therefore, the upper limit to tooling temperature is generally set by some minimum desired lifetime.

36. Compared to hot working, cold working requires no heating, produces a better surface finish, and offers superior dimensional control, better reproducibility, improved strength, directional properties, and reduced contamination problems.

37. Some disadvantages of cold working include: higher forces, required use of heavier and more powerful equipment, less ductility, required surface cleanliness, and the possible need for recrystallization anneals . Detrimental directional properties and undesirable residual stresses may also be produced .

38. Cold working can replace the forming and some strengthening process sequence of operations with only a forming operation - if the required part strength level can be achieved by the strain hardening that occurs during cold working.

39. Key tensile test properties that can be used to assess the suitability of a metal for cold forming include: the magnitude of the yield-point stress, the rate of strain hardening, and the amount of ductility that is available.

40. Springback is an important phenomenon in cold working because the deformation must be carried beyond the desired point by an amount equal to the subsequent springback. Moreover, the amount of springback tends to differ from material to material.

41. Luders bands or stretcher strains are the ridges and valleys that can form on the surface of sheet metal that has undergone a limited amount of stretching. If the total stretch is less than the yield-point runout, some segments of the metal will undergo deformation and thin by an amount consistent with the entire yield-point runout while other regions resist deformation and remain at the original thickness. Both responses can occur since both require the same applied stress.

42. Cold working produces large changes in metal structure and changes the material properties that depend on microstructure. Compared to the same material in the not-cold-worked state, cold worked material will fracture at a lower strain, i.e., ductility decreases, Figure 17-8. The disruption of metallic structure will also make electron transport through the material more difficult and so electrical conductivity will decrease. The increasing number of smaller grains with cold working means that more grain boundaries are formed. Grain boundaries are high energy areas and so will be more sensitive to corrosion and material corrosion resistance decreases and stress corrosion cracking susceptibility increases.

Depending on the processing state and use of the material, increasing strength due to cold working may be a beneficial or deleterious effect. In continuing processing the increased strength means high processing forces and so increasing strength is a decline in material property. An aspect of this is considered in Question 43. If increased strength is beneficial to the product, cold working induced increase in strength is an improvement in properties.

43. In cold working work material strength increases and ductility decreases. Both of these effects can be changed in annealing processes. Intermediate anneals in a series of cold working operations can be used to undo the strain hardening/cold working effects of previous operations and so increase ductility and decrease processing forces in a subsequent operation. The final intermediate anneal (an anneal followed by one or more cold working operations rather than a final anneal after all cold working), combined with the final cold working process, can be used to control the strength and ductility of the final product. The final anneal will increase material ductility and decrease strength while a subsequent cold working process will decrease ductility and increase strength. Design of this final combination of processes being cognizant of the tradeoff allows production of a final part with desired strength and ductility.

44. Compared to hot forming, warm forming offers reduced energy consumption, less scaling and decarburization, better dimensional control, improved surface finish, less scrap, and longer tool life. Compared to cold forming, it offers reduced forces on tooling and equipment, improved material ductility, and a possible reduction in the number of

intermediate anneals.

45. The slow development of warm working processes is due to the lack of knowledge about material behavior in the warm working range and the limited enabling technology developed for use in this working temperature range. Cold and hot working processes have a long history and so the material knowledge bases for low and high temperatures are extensive and materials, machine tools, tooling and lubricants for use in them are well developed. The recent advent of warm working means that material property data for the relevant temperature range is scanty and very effective tooling, lubricants, etc., still need to be developed.

46. The work material characteristic that is the driving force for isothermal forming is a large dependence of material strength on temperature. For materials that are typically hot worked and whose strength increases rapidly with decreasing temperature a decrease in working temperature during processing will produce a large increase in strength and in the associated loads in the process. Such materials are candidates for isothermal forming.

47. Isothermal forming is more expensive than conventional forming since increased forming temperature has to be produced and the temperature and effects of increased temperature on the work and tooling materials have to be controlled. For example,
- work and dies have to be heated which is an increased cost over cold working,
- the increased tooling temperature will cause decreases in tool life,
- the energy dissipated in material deformation is almost all dissipated as heat. So, during forming the work temperature increases and large temperature changes defeat the purpose of isothermal forming. The simplest way to control this deformation work induced temperature rise is to decrease the deformation rate. This leads to lower production rates and increased costs.
- long time exposure of the work and tool materials to elevated temperatures may cause severe enough effects such as scale formation, decrease in strength and corrosion to warrant protecting the forming operation from the environment. Any controlled shielding such as by use of an inert gas will raise the initial cost the manufacturing machine and the operating cost since process complexity in increased.

Problems:

1. The problem deals with the amount of cold work and its effect on material strength and ductility as shown in Figure 17-8. A quantitative measure of "amount of cold work" is needed and one is provided in Chapter 2 in

percent reduction in area R.A. = $\{ (A_o - A_f) / A_o \}$ 100%

This is also a logical measure of deformation imposed in drawing, and is the one used.

The problem setting is

- there is a specified amount of deformation necessary,

  R.A. = $\{ (A_o - A_f) / A_o \}$ 100% = $\{ (0.110 - 0.008) / 0.110 \}$ 100%,

  R. A. = 93%,

- the required final yield strength of at least 50,000 psi means that the material must be subjected to a net amount of cold working of at least 27% - Figure 17-8,
- the required final product ductility of at least 10% elongation implies that the final drawing process in a sequence of draws should impose no more than about 31% cold work – Figure 17-8,

A solution is

- the final drawing process should impose cold work of about 30% on the work material that is in a state approximating its initial undeformed condition,
- assuming that an annealing process can bring the work material back to its initial condition, there should be an anneal before the last draw and the last draw is one imposing a 30% R.A.,
- the entire drawing sequence has to impose an amount of cold work = R.A. of 93%,
- so before the final anneal the previous drawing process(es) have to have produced a 63% amount of cold work,
- the question is then, can this previous 63% R.A. be accomplished in one drawing pass?
  - if so then a possible solution is
    draw to 63% R.A. then anneal then draw to 30% R.A.

I - if not, there is a limit on the amount of reduction that can be imposed in a single draw and a solution is

draw to a reduction less than maximum possible reduction, anneal, draw, anneal, draw etc with the individual draw reductions set to make the total reduction 93% and last draw reduction 30%

The maximum reduction possible in a wire drawing process is not discussed in the text. Quantitative models for maximum possible reduction exist. The general concept is that the drawing force acting on the wire should not result in a drawing stress that is larger than the yield strength of the wire leaving the die. Both the drawing stress and the wire yield strength depend on the amount of reduction, along with other factors such as die-work friction. Setting expressions for drawing stress and yield strength equal to each other gives the maximum reduction condition.

2. a) . Additional costs would include the cost of a heating furnace and the energy costs to achieve the warm working temperature. Tool life would be affected by the combination of increased temperature (decreasing lifetime) and the reduced loads associated with thermal softening (increasing lifetime) . Experience would determine which of the above effects would dominate. The reduction in strain hardening could reduce or eliminate the need for intermediate anneals, but consideration should be given toward attaining the desired final properties. Expanded capabilities in terms of size, complexity, and range of possible materials may expand possible markets.

b) . The conversion from hot forming to warm forming would be accompanied by an obvious savings in energy (heating the workpiece to a lower temperature and heating less material due to higher precision) . Additional energy might be saved if it is possible to achieve the desired final properties without requiring a final heat treatment (there is some strain hardening with warm working) . Improved dimensional precision and surface finish (reduced scaling and decarburization) can mean savings through a reduction in finish machining and the amount of material converted into scrap. Tool life is increased because of the reduced temperatures and the reduction of thermal shock and thermal fatigue. The forces required for forming will increase by 25 to 60%, 50 machinery must be more powerful, or the size of products produced on a given machine must be reduced.

3. Machining operations simply cut through the existing structure, removing the unwanted portion of material. The dimensions of the starting material must be sufficient to contain the crests of the threads. Thread rolling, on the other hand, forms the threads by displacing material from the root of the threads up into the crests. The starting diameter is between that of the root and crest. The benefits of material conservation and oriented flow continue as discussed in the text, but by cold forming the threads, the effects of strain hardening must also be considered. The deformed material will become stronger, but less ductile. The strengthening can be a significant asset, as long as the accompanying loss of ductility does not make the material too brittle. The residual stress pattern imparted by the deformation can be another concern as it can affect fatigue performance and contribute to failure by stress-corrosion cracking. In addition, it should be noted that the increased strength can be lost if the surface is exposed to elevated temperatures during operations such as hot-dip galvanizing.

Case Study:

Repairs to a Damaged Propeller

1). The specific recommendation would depend upon a number of factors: (1) What is the present condition or structure of the metal? Is it as-cast, age hardened, or annealed? ;(2) What is the ductility of this material in this condition? Can it be mechanically reformed without fracture? ;(3) Would elevated temperature aid in the reshaping? ;(4) Would any subsequent treatment be required after reshaping to restore the desired properties?

If the material is in the as-cast or annealed condition (one can determine this by hardness testing), and if the material has sufficient ductility, a reshaping may be possible directly. However, one should keep in mind that the propeller has undergone extensive cold working in the initial bending and may not possess sufficient remaining ductility. If insufficient ductility is present, a softening anneal may be required before the reshaping should be attempted. Depending upon the available ductility and the extent of damage, a series of anneal and deform operations may be necessary.

Finally, consideration should be given to the desired service properties. If the material were directly restored to shape, the bent portions of the propeller would have undergone two rather severe cold forming operations, and would likely be very low in remaining ductility and, therefore, prone to fracture upon any subsequent impact. Since the initial propeller was able to sustain such a severe deformation without fracture, it appears that the initial condition was one with substantial ductility. Therefore, it may be desirable to restore uniform ductility through an anneal after the reshaping.

If the propeller had been age hardened for strength, this heat treatment should be reperformed after the straightening to again produce the strong, homogeneous structure.

Finally, after all heating and cooling, the propeller should be rebalanced to provide smooth running at high RPMs. An out-of-balance propeller can produce excessive loads on bearings and power train components in the engine.

2). In most cases, such a repair can be made, if done properly. The cracked region should be machined out to assure removal of all cracked metal and the exposure of good, clean metal surface. A matching chemistry metal (or near matching to prevent the formation of a galvanic corrosion cell) should then be deposited into the machined groove. Oxyacetylene welding or repair brazing would be the most likely techniques for such a repair.

After deposition, the surface should be rough ground and then fine ground or abraded to produce a smooth surface. Consideration should then be given to the structure of the base metal and the possible effects in the heat-affected zone. If necessary, the entire propeller should be heat treated to produce a uniform structure. Alternately, a stress-relief treatment should be considered to remove potentially damaging residual stresses imparted by the braze. Finally, the propeller should be rebalanced .

If properly performed by an experienced repairman, the repaired propeller will function adequately and will probably cost about half of a new part. Failure to perform a proper repair, however, will result in further cracking problems and the ultimate need to replace the component.

CHAPTER 18
Hot-Working Processes

Review Questions

1. Metal forming probably began with "tools" as simple as rocks being used to shape bits of naturally-occurring metal. Hand tools and muscle power then gave way to machine processes during the industrial revolution. The machinery further evolved, becoming bigger, faster, and more powerful, and the sources of power also changed. Most recently, computer control and automation have been incorporated.

2. Various means have been used to classify metal forming process. These include: (1) primary processes that produce intermediate shapes, and secondary processes that produce finished or semifinished products; (2) bulk deformation processes and sheet-forming operations; and hot-working processes and cold-forming processes .

3 . The division of metal forming processes into hot working and cold working is quite artificial. With increased emphasis on energy conservation, the growth of warm working, and new advances in technology, a temperature classification is often arbitrary. Processes normally considered as hot forming processes are often performed cold and cold-forming processes can often be aided by some degree of heating.

4. At elevated temperatures, metals weaken and become more ductile. With continual recrystallization, massive deformation can take place without exhausting material plasticity. In steels, hot forming involves the deformation of the weaker austenite structure as opposed to the much stronger, room temperature ferrite .

5. Ingots are usually the primary product supplied to rolling mills. Rolling is used to convert the primary product to wrought products that are called by different terms depending on cross section size and shape.

Simple cross section shape products of rolling such as rectangular, square or circular sections are separated by size with
- blooms having thickness greater than 15 cm,
- billets smaller than blooms with rectangular or circular cross section shape,
- slabs have rectangular section shape with width greater than twice the thickness,
- plates, sheets and strips have rectangular cross sections with differing width to thickness ratios.

Blooms and billets can be further rolled to slightly more complex cross section shapes to produce semifinished shapes such as bars and rods that are usually processes further.

Still more complex shapes can be produced by further rolling of billets, bars and rods to produce structural shapes finished products such as channel sections, I-beams and railroad rails.

6. Because the rolls are so massive and costly, and multiple sets of rolls may be required to produce a given product, hot-rolled products are normally available only in standard sizes and shapes for which there is enough demand to permit economical production.

7. In a rolling operation, friction between the rolls and the workpiece is the propulsion force that drives the material forward. If the friction force is insufficient to deform the material, the material remains stationary and the rolls simply skid over the surface. No deformation is achieved.

8. The temperature related concerns in rolling are the rolling temperature or nominal temperature of the work and the variation of temperature over the workpiece. The finishing temperature or the temperature during the final phase of hot rolling must be controlled since temperature affects grain size and the final properties of the rolled product. If finishing t temperature is not adequately controlled undesirable, nonuniform grain structure and properties such as strength will result.

If the rolled product is the final product it will have nonuniform properties and perhaps undesirable shape due to warping and twisting as the product emerging from the rolls responds to its nonuniform structure, properties and stress state. If the rolled product is to be further processes, any nonuniformities in microstructure and properties will affect material behavior in subsequent processing.

9. Early reductions (with thicker pieces) usually utilize two-high or three-high mills with large diameter rolls. The three-high configuration allows the material to be passed back-and-forth through a single mill without having to stop and reverse the direction of roll rotation. Smaller diameter rolls are more efficient when rolling thinner material, but are less rigid and flex into a distorted configuration. To utilize these more efficient rolls and yet provide rigidity, four-high mills are used with support being provided by the more-massive backup rolls.

10. Foil is almost always rolled in a cluster mill because
- small diameter rolls are used to roll thin product since this results in smaller roll-work contact area. The small reductions in rolling foil combined with large diameter rolls gives large, undesirable, rolling forces.
- small diameter rolls have low stiffness and so can deflect to unacceptable extent. To add stiffness to the entire rolling mill backup rolls are used and cluster rolling mills us for thin product such as foil.

11. In a continuous or multi-stand rolling mill, it is important that each stand pass the same volume of material in a given time so as to prevent buildup between the stands or tearing of the material being rolled. As the cross-section is reduced, length increases, so the rolls of each successive stand must turn faster than the preceding one by an amount

equivalent to the cross-sectional area reduction taken by the previous stand.

12. Ring rolling is used to produce rings or hoops having a uniform cross-section throughout the circumference.

13. Hot rolling is expected to produce little or no directionality in product properties and no residual stress. However, if large nonuniformity in structure and/or deformation is produced there will be directional properties, residual stress and the resulting characteristics that these effects produce, e.g., warping of relatively thin, complex shaped product due to residual stresses.

Nonuniform structure can result during hot rolling if nonmetallic inclusion exist in the work material. These inclusions do not recrystallize as the surrounding metallic material does and so nonuniform material and directionality of properties results.

Nonuniform deformation and nonuniform temperature and cooling rate will cause directional properties and residual stress. The extent of recrystallization depends on the amount of initial metal deformation and the time-temperature history of the cooling product. Rolling can produce nonuniform deformation over the rolled section, particularly in sections with varying, thin parts. The deformation pattern near surfaces of the part is different than in regions away from the surfaces (constraint on material deformation is due to surrounding material). So sections such as I-beam are deformed to different extent in different regions of the section.

Variations in cooling rate can produce residual stress. When cooling rate variations are combined with differences in deformation, directional properties and residual stresses can form during cooling from the rolling temperature.

14. The rolling of uniform thickness product requires that the gap between the rolls be uniform. Three-point bending occurs when the rolls are loaded in the middle and supported by bearings on either edge. Attempts to compensate by "crowning" the rolls are designed for a specific load, which may vary with changes or fluctuations in material, temperature, lubrication, and other factors. When the thickness is not uniform, the amount of lengthening will not be constant over the entire width, resulting in such defects as wavy edges, wavy center, fractured edges, or fractured center.

15. Crowned rolls, rolls with varying diameter along the roll length, are used to compensate for roll flexure during rolling. Roll flexure depends on the forces acting on the rolls, the roll cross section shape and the mechanical end or support conditions at the roll end. Since the roll support conditions are constant, the roll design problem is to specify the roll shape to compensate for roll deformation due to the rolling forces. Rolling forces depend on the amount of workpiece deformation, the work deformation pattern, friction and work material properties. That is the rolling forces depend on the particular rolling process and material and so crowned rolls have to be designed for the – particular process and work material.

16. Thermomechanical processing consists of simultaneously performing both deformation and controlled thermal processing so as to directly produce the desired levels of strength and toughness in the as-worked product. The heat for the property modification is the same heat used in the forming operation, and the need for subsequent heat treatment is often eliminated. Product properties can be improved and cheaper materials might be employed .

17. Steam or air hammers use pressure to both raise and propel the hammer. They give higher striking velocities, more control of the striking force, easier automation, and the capability of shaping pieces up to several tons. Computer control can be used to provide specified blows of energy for each step of a process.

18. Open-die forging does not confine the flow of metal in all directions, so the final shape is dependent upon the manipulation and skill of the equipment operator. Impression-die forging operations confine metal flow in all directions to provide good repeatable control of size and shape.

19. Open-die forging is not a practical means for the production of large quantities of identical parts because the shape is produced by manipulation and positioning of the workpiece in the hands of a skilled operator (flow of metal is not controlled) rather than by rigid confinement in a set of shaped dies. Each workpiece, therefore, is a separate entity and is not identical to the others.

20. Because flashless forging involves total confinement of the material within the die cavity, precise workpiece sizing is required along with precise positioning of the workpiece within the cavity and control of the lubrication.

21. In forging the initially very simple shape workpiece is forged to the final shape in series of operations using a series of more complex shape dies. In the intermediate operations the dies are used for blocking the material to close to it final shape and the impressions on the blocking dies are blocking impressions.

22. Because counterblow machines permit the excess energy to be dissipated in the form of recoil, there is a reduction in the amount of noise and vibration, two of the major concerns of regulating agencies concerned with the forging industry.

23. Dimensions contained entirely within a single die cavity can be maintained with considerable accuracy. Dimensions across the parting plane are dependent upon die wear and the thickness of the final flash. While frequently within several hundredths of an inch, these dimensions are noticeably less precise than dimensions set totally within the die cavity.

24. Press forging is often preferred to hammer forging when the workpiece is large or thick and the energy of the hammer is insufficient to produce uniform deformation.

25. Heated dies are usually employed in press forging because the long time of die

contact with the hot workpiece would otherwise permit considerable surface cooling and could produce cracking of the surface.

26. Hammers impart a blow of energy, travel at high speed, and have short time of actual contact. Presses have longer periods of contact and apply a squeezing action or force. Mechanical presses have consistent and reproducible stroke, and are more rapid than hydraulic presses, which are more flexible and can have greater capacity. Since they move in response to fluid pressure, they are controlled by forces or pressures and position is not as reproducible.

27. Upset forging is the term applied when the diameter of a piece of material is increased by compressing its length.

28.Upset forging operations are often used to forge heads on bolts and other fasteners and to shape valves, couplings, and a number of other small components, like those illustrated in Figure 18-15.

29. Automatic hot forging offers numerous advantages. Input material is low cost and production rates are high. Minimum labor is required and scrap production is reduced. The as-forged structure is often suitable for machining. Tolerances are good, surfaces are clean, and draft angles are low. Tool life is nearly double that of conventional forging. On the negative side, however, is the high initial cost of the equipment and the restriction of large production quantities.

30. Roll forging is a process by which round or flat bar stock is reduced in thickness and increased in length. A heated bar is placed between two semicylindrical rolls containing shaped grooves, and as the rolls rotate, the bar is squeezed and rolled out toward the operator.

31. Swaging refers to two kinds of material deformation (in contrast to material removal) manufacturing processes. Swaging can be the hammering of a rod or tube to a final shape by a series of blows from a die that acts as the hammer. The hammer/die can be shaped and the work rotated to produce parts with relatively complex cross sectional shapes. This is usually a cold working process.

Swaging also refers to a process in which a simple cross section workpiece is forced trough a die to change its “diameter” or cross section size. Typically this process is performed at elevated work temperature. This process is conceptually similar to wire or rod drawing but usually applied to large sections with little imposed deformation.

32. The objective of net-shape or near-net-shape forming is to directly form products that are close enough to specified dimensions that few or no secondary operations are required. Cost savings and increased productivity can be attributed to the reduction in secondary machining operations, reduced quantities of generated scrap, and a decrease in the energy required to produce the product.

33. The extrusion process offers a number of attractive features. Almost any cross-sectional shape can be extruded, including many that could not be achieved by rolling. Size limitations are few. No draft is required, and the amount of reduction in a single step is limited only by the capacity of the equipment. Frequently only one die is required for a product. Because only a single die change is required to change products, small production quantities are economically feasible. Dimensional tolerances are quite good.

34. The primary limitation of the extrusion process is that the cross section must be the same for the entire length of the product being extruded.

35. In indirect extrusion there is no relative motion between the sides of the workpiece and the extrusion container. With no motion there is no friction and the primary attraction of indirect extrusion is that no frictional energy dissipation occurs in the process.

36. In extrusion, the final surface area is considerably greater than the surface area of the starting billet. Therefore, as the material is flowing through the extrusion die, the initial layer of lubricant must spread and thin by a substantial amount, while still functioning as an acceptable lubricant.

37. In a spider-mandrel extrusion die, the flow of material divides into several channels and then reforms. If the surfaces are fresh, uncontaminated metal, they can be pressed together to form high-quality, virtually undetectable, welds. If a lubricant were used, the surfaces of the various segments would acquire a coating of lubricant that would prevent the formation of the welds necessary to produce the continuous wall around the hollow shape.

38. Hot drawing can be used to produce tall, thin cups, by several methods. If the wall thickness can be thinner than the base, drawing with ironing can be employed. If uniform wall thickness is desired, one or more redraws, or multiple-die drawing can be used.

39. Ironing is the name given to the process where a cup is placed over a punch and driven through a die where the gap between the punch and die is less than the cup material thickness. The cup wall is thinned and elongated, while the bottom thickness remains unchanged.

40. Steel skelp can be converted into pipe by either butt welding, or lap welding operations. The welding operations occur simultaneously with the hot deformation.

41. In hot-piercing operations, the billet is forced over a pointed mandrel that is held in place in the roll gap. Since the product must flow over the mandrel and the mandrel must be held rigidly in position, the length of product tubing cannot exceed the length of the mandrel (which is rather limited).

Problems:

1. The assignment here is direct and needs no further explanation .

2.

a. S = surface area without ends

$S_{product} = \pi\, d_p\, L_p$

$S_{billet} = \pi\, d_b\, L_b$

$S_{product} / S_{billet} = d_p L_p / d_b L_b = \{ (0.03 \text{ m})(7.5 \text{ m}) \} / \{ (0.15 \text{ m})(0.3 \text{ m}) \} = 5$

b. $S_{product} = 4$ (edge length) (product length) $= 4\, a\, L_p$

$S_{billet} = \pi\, d_b\, L_b$

$S_{product} / S_{billet} = 4\, a\, L_p / \pi\, d_b\, L_b$

work material volume is constant so with
cross section area A
$A_b L_b = A_p L_p$
$L_p / L_b = \{ (\pi/4) (0.15 \text{ m})^2 \} / \{ (\pi/4) (0.03 \text{ m})^2 \} = 25$
same final cross section area so
$a^2 = (\pi/4) (0.03 \text{ m})^2$
$a = 0.0266$ m

$S_{product} / S_{billet} = \{ 4 (0.0266 \text{ m}) (25) \} / \{ \pi (.15 \text{ m}) \} = 5.64$

c. The problem says the reduction ratio, R, is 25 => $R = A_b / A_p$
with A being the cross section areas

the surface area ratio is

$Sp / Sb = (\pi\, dp\, Lp) / (\pi\, dp\, Lp)$

since work material volume is constant
$A_b L_b = A_p L_p$
$L_p / L_b = A_b / A_p = R$
the cross section areas are
$A_b = (\pi/4)\, d_b^2$
$A_p = (\pi/4)\, d_p^2$
and
$d_p / d_b = \text{SQRT}(A_p / A_b) = \text{SQRT}(R)$

$Sp / Sb = R / \text{SQRT}(R) = \text{SQRT}(R)$

3. a).Force = (.441) x 50,000 x 3.309 = 73,100 pounds

b) .At maximum force of 60,000 pounds, the pressure will be

= 60,000 / Area of the penny
= 60,000 pounds *I* 0.441 square inches
= 135,900 psi

4. Strip thickness is in the denominator of the equation and so the roll separating force will increase with decrease in strip thickness. For very small thickness as in foil, the roll separating force can become substantial.

One way to minimize the effect of thin materials is to note that the term is proportional to R/t_{av}. Therefore, if the diameter of the rolls can be decreased in proportion to the decrease in thickness, the effect can be canceled.

The various types of rolling mills and their uses, as described in the text, follow this trend. Billets, blooms and thick slabs are rolled in two-high mills with large diameter rolls (often in the range of 22 to 28 inches in diameter). Conventional sheet and strip is rolled on four-high mills with work roll diameters typically in the range of 4 to 10 inches. Foils are rolled on cluster mills with the contact roll being as small as ¼ inch in diameter, and multiple thicknesses may be rolled simultaneously to increase the total thickness being rolled.

5. The area under the direct extrusion curve is proportional to the work required to form the product with billet-chamber friction. The area under the indirect curve is the work required to form the product without frictional resistance. Therefore the "efficiency" of the direct extrusion process could be regarded as the fraction of the total work that is producing deformation. This can be computed as the percentage of the direct curve that is within the indirect region, i.e. the area under the indirect curve, divided by the area under the direct curve, times 100%.

Case Study:

Outboard Motor Brackets

1. The requirements for this part include static strength, corrosion resistance to salt and fresh water, light weight and resistance to vibration. A variety of engineering materials would be possibilities, including aluminum, titanium, magnesium and even the copper-base alloys. Copper is heavier than steel and would only be recommended if other alternatives failed. The corrosion resistance of magnesium is questionable and the cost and fabrication difficulties do not favor titanium. Some form of aluminum alloy would appear to be the attractive choice – either a casting alloy or a wrought alloy, depending on the recommended fabrication process.

2. The geometry (size and shape) is such that impression-die forging or some form of casting process would be the obvious alternatives. The various pros and cons can be evaluated with consideration being given to the estimated production quantity. If forging is selected, the recommended material should be some form of wrought aluminum. If cast, the recommended alloy should be selected for compatibility with the process. NOTE: There are aluminum alloys specifically designed for use with processes such as die casting.

3. If aluminum alloys are used, an age hardening treatment would most likely be required to achieve the desired mechanical strength. This would involve the stages of solution treatment, quenching and aging.

4. The corrosion resistance of aluminum would be adequate for fresh water usage, but might be attacked by salt water. Treatment might be utilized to provide aesthetics as well, and in this case, a color anodizing treatment, such as that commonly seen on aluminum softball bats, might be preferred.

CHAPTER 19
Cold-Working Processes

Review Questions;

1. Attractive features of cold working over hot working include: no heating is required, surface finish is better, dimensional control is superior, reproducibility is better, strength properties are improved so cheaper material may be utilized, directional properties can be imparted, and contamination problems are minimized.

2. Cold-working equipment is usually more powerful that that used for hot-working because the starting material is stronger (no thermal softening), and the material becomes even stronger as it is being formed due to the effects of strain hardening.

3. Sheet or strip is often given a skin-rolled reduction pass to produce a smooth surface and a uniform thickness, and also to improve the yield-point phenomenon that causes the formation of Luders bands.

4. The cold rolling of shaped products generally requires a series of shaping operations, each requiring a separate pass through specially-grooved rolls. Since these rolls are usually expensive, two such rolls are required for each pass, and multiple passes are usually required to produce a product, large production quantities are usually requires to justify the expense of the shape-rolling process.

5. If the starting material is a tube, and a shaped mandrel is inserted before swaging, the metal can be collapsed around the mandrel to simultaneously shape and size the interior and exterior of the product.

6. Viewing material waste as the chips generated in machining a part, if the same shape can be produced by forging, cold forging saves material since chips are not formed.

If machining operations are needed to finish hot formed products, cold forging can reduce material waste if products can be cold forged to within dimensional and shape tolerances. Again, finish machining is not needed.

Depending on the tolerances specified, cold forging can be used to produce parts close enough to required final dimensions so machining in not required and material is not lost to chips.

7. With cold forging, production rates are high, dimensional tolerances and surface finish are excellent, and machining can be reduced. Strain hardening can provide additional strength, and favorable grain flow can be imparted.

8. By combining extrusion and cold heading, the product can be made from a starting stock of intermediate size. Here, the upset head can now be made easily from the starting material size, and the extrusion of the shank reduces the need for extensive machining.

9. In the hydrostatic extrusion process, billet-chamber friction is eliminated, billet-die lubrication is enhanced by the pressure, and in the pressure-to-pressure mode, the pressurized environment suppresses crack initiation and growth and enables the extrusion of relatively brittle materials. Unfortunately, temperatures are limited, sealing problems are common, and complete ejection of the product by the pressurized fluid must be avoided.

10. In pressure-to-pressure hydrostatic extrusion the work material moves from one pressurized chamber to another pressurized chamber. The effect of forming the work material under pressure is to minimize void formation, crack initiation and crack growth. Since the work is always under pressure crack initiation is minimized and the material’s ductility is increased.

With increased ductility materials can be deformed to a greater extent in extrusion and normally brittle materials that cannot be extruded may be have enough ductility imparted to them that they can be extruded.

11. Surface friction is the propulsion force in continuous

12. Roll extrusion is typically used to produce thin-walled cylinders with diameters ranging from 3 to 20 inches.

13. When only one side of a joint is accessible, riveting can be accomplished through the use of either explosive rivets, or pull-type or pop-rivets where the shank on the inaccessible side is expanded mechanically.

14. One hardened hub can be used to form a number of identical cavities, so only one part needs to be machined to precision. In addition, it is often easier to machine a male shape on the hub as opposed to a female cavity in the die.

15. During peening, the highly localized blows deform and tend to stretch the metal surface. This surface deformation is resisted by the metal underneath, producing a compressive residual stress in the surface. Since the compressive stresses subtract from applied tensile loads, they serve to impart added fracture resistance to the product.

16. Burnishing involves rubbing a hard object over the surface of a material under considerable applied pressure. Minute surface protrusions are deformed, producing a smooth, deformed surface .

17. "Bending[31] is plastic deformation about a linear axis with little or no change in surface area. When multiple bends are made in a single operation, that operation is often called "forming". If the axes of deformation are not linear, or are not independent, the

process is called drawing".

18. When a material is bent, the material on the outside of the bend is elongated, while that on the inside is compressed. Since the material yields first in tension, more deformation occurs by the tensile mode than the compressive one, and the net result is a thinning of the bend.

19. Springback is the tendency of the metal to unbend somewhat after bending. This is a natural consequence of the outside tension and inside compression of the material and the material seeking to relax these stresses. To form a desired angle, a material must be overbent to compensate for springback

20. Press brakes can be used to produce simple bends, complex bends, seaming, embossing, punching, and other operations.

21.In overview, minimum bend radius is set by the condition that the strain at the material tensile surface becomes equal to the fracture strain of the material in a tensile test.

The minimum bend radius is determined by:
- The ductility of the work material, usually specified by the percent reduction of area at fracture in a tensile test. The higher the ductility the smaller the minimum possible bend radius.
The thickness of the work material. For a given bend radius the thicker the material the smaller the strain at the material surfaces.

The usual bending process-material behavior parameter used to describe bending radius is R/t with R the bend radius and t the material thickness.

22. Whenever possible, the bend axis should be perpendicular to the direction of previous rolling. If two perpendicular bend axes are involved, the metal should be oriented with the rolling direction at 450 to both axes.

23. By designing products to have all of the bends with the same bend radius, manufacturers can significantly reduce setup and tooling costs. The same tooling can then be used to produce all bends.

24. Bottoming dies compress the full area within the tooling, while air-bend dies form the desired geometry through simple. three-point bending. Air-bend tooling is quite flexible since the degree of bend can be varied by a simple change in press position. Bottoming dies, however, produce a more consistent product .

25. Roll bending produced curved shapes when plates, beams, pipe and structural shapes move through a set of closely spaced rolls, Figure 19-29. Although the radius of curvature of the workpiece can be varied as it is being formed by continuously changing roll spacing, usually roll position is fixed. So the type of parts produced are those with

constant curvature. An example is the individual short sections of jet engines that are joined to form the entire engine housing.

26. To prevent flattening at the outside or wrinkling at the inside of a tube when it is bent the tube material can be supported so as not to deform or the imposed deformation state can be altered. Packing an easily removed material such as sand in the tube before bending can support the tube and decrease flattening and wrinkling. Using flexible tooling, e.g., flexible mandrels changes the loading and deformation imposed on the tube in bending and so can reduce flattening and wrinkling.

27. Cold roll forming progressively bends flat strip into complex (but uniform) cross-sectional shapes. Various moldings, channeling, gutters and downspouts, automobile bumpers, and other uniform cross section shapes have been produced. Short lengths of specialized products would be better produced by tools like a press brake, because of the high cost of the roll forming tooling
--multiple sets of profiled rolls.

28. Rod or sheet can be straightened by two techniques: (1) roll straightening (or roller leveling) which involves a series of reverse bends designed to stress the material beyond its elastic limit, and (2) stretcher leveling in which the material is stretched beyond its elastic limit.

29 Shearing is the mechanical cutting of materials without the formation of chips or the use of burning or melting.

30. Sheared or blanked edges are generally not smooth because the cutting tools actually deform the material only to the point where the applied stresses exceed the rupture strength of the remaining material. The remainder of the edge is produced by a metal fracture and has a rough appearance.

31. If the punch and die (or shearing blades) have proper clearance and alignment and are maintained in good condition, the sheared edges can often be sufficiently smooth to avoid the need for further finishing. Edge condition can be further improved by clamping the stock firmly against the die from above and restraining the movement of the piece through the die by an opposing plunger or rubber cushion that applies pressure from below the workpiece.

32. Since fineblanking presses incorporate separate motions and forces for the punch, hold-down or clamping ring, and opposing (or bottom) punch, they are multiple-action machines and are noticeably more complex than presses used in conventional blanking .

33. Progressive shearing involves a smaller volume of material being sheared and so a smaller shearing force than if the entire sheared length is produced at the same time.

The force required for shearing depends on the work material strength and the volume of material being deformed. In shearing the deformation zone thickness perpendicular to the shear is constant so the deformation volume is proportional to the length of the deformation zone in the direction along the shear edge. Progressive shearing takes place in a smaller deformation zone than one long shear.

34. Slitting is the length-wise continuous shearing process used to slice rolls of material into narrower strips. The work material passes between rolls that have grooves that form shearing edges.

35. Piercing and blanking are both shearing operations in which a curved shearing punch pushes material into a die. They both involve the same cutting action, but when the piece being punched out is the scrap the process is piercing, and when the piece being punched out is the product, the process is one of blanking.

36. In the progressive piercing and blanking operation shown in Figure 19-50 the ram holds both the piercing punch and blanking punch so both tools move up and down at the same time. If the piercing and blanking punches were the same length at least two problems would arise. One problem is that the deformation processes occurring in the piercing region and in the blanking region would interact. Control of the deformation processes and so of the accuracy and quality of the part produced would be lost. Another problem is that the mechanisms used to hold down the work during piercing and punching, and the overall machine, would have to be heavier and stiffer to withstand the higher processing forces.

37. Variations of piercing and blanking that have come to acquire separate names include: lancing, perforating, notching, nibbling, shaving, cutoff, and dinking.

38. By grinding a slight angle on the face of a piercing or blanking punch, the maximum cutting force can be reduced. Instead of the entire circumference being sheared simultaneously, the angle allows the cut to be made in a progressive fashion, much like the opening of a pull-tab on a beer or soda can.

39. To produce a uniform cut, it is important that a blanking punch and die be in proper alignment. A uniform clearance should be maintained around the entire periphery.

40. By mounting punches and dies on independent die sets, they can be positioned and aligned prior to insertion into the press, thereby significantly reducing the amount of production time lost during tool change.

41. Standard subpress dies can frequently be assembled and combined to produce large parts that would otherwise require large and costly die sets. In addition, when the die set is no longer needed, the components can be removed and used to construct tooling for another product.

42. When dies are constructed as multipiece assemblies die components can be individually changes into the die or modified. Whether for changing overall die configuration or for repairing or regrinding shearing components of the die, dealing with one component of the die rather that a large one piece die is easier, safer and less expensive.

43. A progressive die set consists of two or more punches and dies mounted in tandem. Strip stock is fed through the dies, advancing incrementally from station to station with each cycle of the press performing an operation at each of the stations. Figure 19-50 illustrates a progressive die operation.

44. In progressive dies one or more punches are mounted in one punch holder and all punches more at the same time. The work material movement is usually linear between the different stations in the die, e.g., sequentially punching of strip work material. In transfer dies usually individual parts are moved from die to die in a single press with the possibility of changing part orientation between the dies that perform one operation each.

45. In compound dies more than one tool is mounted in the die at essentially the same location in the machine tool. The machine motions and tools actuation are such that the punching processes occur sequentially at one location in the machine, Figure 19-51. In progressive dies, Figure 19-50, individual tools are mounted at different locations and the work material moves to each and through a sequence of punch positions.

In progressive dies the punching processes are sequential with all tools moving at the same time and the work moved between punch strokes. In compound dies sequential operations are performed on a stationary working piece with sequectual actuation of different tools.

46. Turret-type punch presses have the capability of holding a large number of punches and to quickly set punch-work position by moving the workpiece. This enables a large number of different size and different shape holes to be placed in complex patterns.

47. The term cold drawing can refer to two different operation. For sheet metal, cold drawing involves plastic flow of material over a curved axis, as in the forming of cup-shaped parts. If the stock is wire, rod, or tubing, the term applies to a process where the cross section of the material is reduced by pulling it through a die.

48. In tube drawing, rigid tooling is used to accurately size both the inner and outer diameters of the product. In tube sinking, only the outside diameter is directly controlled (there is no mandrel or plug to restrict and size the inner diameter) .

49. Tube drawing with a floating plug can be used to produce extremely long lengths of tubular product with a controlled inner diameter .

50. Straight-pull draw benches are normally employed to produce finite lengths of products that cannot be conveniently bent or coiled. Wire, and smaller products that can

be coiled, is generally drawn in a continuous operation on draw blocks where the length of product is limited only by the amount of starting material .

51. Because the reduced section of material is subjected to tensile loading in the wire drawing process, the possible reduction is limited by the onset of fracture. In order to affect any significant change in size, multiple draws are usually required .

52. Since the metal being deformed by spinning deforms under localized pressure and does not flow across the form block under pressure, the form block can be made of relatively inexpensive material, such as hardwood or even plastic.

53. During shear forming, each element of the blank maintains its distance from the axis of rotation. The metal flow is entirely in shear and no radial stretch has to take place to compensate for the circumferential shrinkage. Wall thickness, however, will vary with the angle of that region to the axis of rotation .

54. Stretch forming is used to form large sheet metal components that have relatively small production quantities.

55. In drawing of sheet metal the typical part is, in a very general sense, a closed bottom-open top shaped structure, e.g., cylindrical cans and rectangular automobile oil pans. When the part depth is less than the smallest opening dimension the drawing process is called shallow drawing. Deep drawing processes produce parts with depth greater than the smallest opening dimension.

56. The pressure-ring or hold-down in a deep-drawing operation serves to control the flow of metal and suppress wrinkling, tearing, or undesirable variation in thickness.

57. There are three major reasons that thin material may be difficult to draw into a cup, compared to thicker material.

i. Thin work material is susceptible to tearing. In cup drawing tensile stresses arise in the cup wall as it is being drawn. Tensile stress increases as wall thickness decreases if there is not a corresponding decrease in tensile force. In draw the force acting in the wall of the forming cup is due to stretching, bending and friction. The effects decreasing work thickness on increasing wall stress are greater than the effects of wall thickness on decreasing wall force.
ii. Thin work material is more likely to buckle in the flange region. If the wrinkling extends into the cup wall region it is not likely to be removed when the top edge of the cup is trimmed.
iii. In tensile deformation materials may exhibit tensile instability. This instability is analogous to the nonuniform deformation in necking in the tensile test. Nonuniform deformation is itself a defect in a drawn cup and can act as a site of locally increasing deformation leading to tearing.

58. Draw beads are protrusions and matching grooves on the faces of the die and blankholder or blank holddown plate.

The purpose of drawbeads is to locally impede the flow of the workpiece into the die and so control deformation in drawing processes.

For example, in drawing a rectangular part the material along the straight sections of the die flows more easily into the die that the material around the die corners. To produce more uniform deformation over the forming part the material flow along the straight sections can be restricted by building drawbeads into these sections of the die.

59. Because of prior rolling and other metallurgical and process variables, the flow of metal in deep drawing is generally not uniform in all directions. Excess material is often required to assure desired final dimensions, and a trimming operation is generally employed to establish the final dimensions.

60. The Guerin process employs rubber as the female die, providing the pressure necessary to wrap the sheet metal around a male punch. The hydroform process replaces the female die member with a flexible diaphragm backed by hydraulic pressure. Both processes eliminate the female die member to substantially reduce tooling cost.

61. Bulging using fluid or rubber tooling can be performed by
- holding the workpiece on a machine base so that the hollow workpiece is closed at one end,
- placing fluid or rubber tooling in the part,
- closing the top of the workpiece either with the punch to be used or separate mechanism,
- using a punch to increase fluid pressure or deform the rubber tooling,
- apply enough punch displacement so that the workpiece bulges to a confining split die to form the part,
- release the punch and remove the part from the die.

62. Sheet hydroforming is a process in which a fluid under pressure replaced the solid punch or die in conventional forming. In one process configuration the fluid may act as a punch on one surface of the sheet workpiece to force the work material into a die. In another configuration the fluid may act on the free side of the work material to force it to bend over and conform to a punch.

63. The deformation of the work material in sheet hydroforming is more uniform than in conventional, hard tooling, forming processes. In hydroforming uniform pressure is exerted over the entire workpiece and so deformation is uniform. The uniform strain means that locally nonuniformly strained regions do not exist, and so cannot interact and increase local deformation bringing the material locally closer to its forming or ductility limit. The material is more formable in hydroforming.

64. Regions of the tube that increase in diameter in tube hydroforming experience wall thinning. To compensate for the wall thinning the end of the tube can be compressed. The inward movement of the end plugs is supposed to cause tube compression and help compensate for wall thinning.

65. The high energy-release rates needed by the HERF processes can be obtained by: underwater explosions, underwater spark discharge, pneumatic-mechanical means, internal combustion of gaseous mixtures, and the use of rapidly-formed magnetic fields.

66. Two factors account for the low springback observed during high-energy-rate forming. High compressive stresses are set up when the metal is forced against the die, and some elastic deformation of the die occurs under the high applied pressure, allowing the workpiece to become somewhat overdeformed.

67. Common examples of ironed products include brass cartridge cases and the thin-walled beverage containers. Common embossed products include highway signs (like STOP signs) and industrial stair treads.

68. The intent of superplastic forming is to make it possible to produce very large strains in the workpiece. With regard to workpiece material, ultrafine, uniform grain size increases material ductility and so makes the material suitable for superplastic forming.

Materials are more ductile at higher temperatures and less ductile at higher strain rates. So with regard to processing conditions, superplastic forming is carried out at high temperatures and very low strain rates.

69. The major limitation to superplastic forming is the low forming rate that is necessary to maintain the superplastic behavior. Typical cycle times may be on the order of 5 to 40 minutes per part. on the positive side, superplastic forming has made possible the economical production of complex-shaped parts in limited production quantities. Deep or complex shapes can be made as one-piece, single-operation pressings, rather than multistep conventional pressings or multipiece assemblies. The required forces are low. tooling is relatively inexpensive, precision is excellent, and fine details can be reproduced.

70. By measuring and evaluating the distorted grid pattern, regions where the area has expanded can be detected as locations of sheet thinning and possible failure. Areas that have contracted have undergone thickening and may be sites of possible buckling or wrinkles.

71. A forming limit diagram is a plot of the major strain and related minor strain on the surface of metal sheet, indicating the conditions for which fracture occurs. Deformation in regions below this line (the forming limit) can be performed without fracture. Deformation which induces strains at or above the line will incur fracture.

72. In the right hand section of the forming limit diagram the minor strain measured in a forming deformation experiment is positive. In the left hand region of the forming limit diagram the measured minor strain is negative.

73. Thin complex-shape products can be produced without the use of metalforming techniques through processes such as electroforming, in which metal is electroplated onto an accurately-shaped mandrel and stripped free, and plasma spray forming, where molten metal is sprayed onto a shaped mandrel where it then solidifies.

74. In general, mechanical drives provide faster action and more positive displacement control. Once designed, the stroke of a mechanical press is fixed and cannot be changed. In addition, the available force varies with position and is greatest near the bottom of the stroke. Hydraulic drives offer greater forces and more flexibility of forces, speeds, and strokes. They are generally slower than mechanical drives and do not offer as great a control of position or displacement.

75. Presses with different types of frames are gap-frame presses, open-back presses, inclinable presses and straight-sided presses.

76. Inclinable presses are often tilted to enable ejection of the finished parts to be accomplished with the aid of gravity or compressed air jets.

77. A transfer press is designed to accept a number of die sets, positioned side-by-side to create a multiple station (progressive die-type) operation. With each stroke of the press, each individual station performs its operation on the material positioned between the dies. The strip material then advances forward to the next station, where the press undergoes another cycle. Since all operations are performed simultaneously with each stroke of the press, one product is made per stroke.

Problems:

1. The wire drawing process can be characterized as continuous (provided the various segments of incoming product can be butt welded), but limited in reduction. Since the deformation force is applied as tension to the reduced product, the maximum reduction in area (for perfect frictionless conditions) is 62%, and a typical reduction is between 20 and 50%. The process works for almost all ductile materials and can be performed at high speeds. Because of the large surface area and small volume, the material is rarely heated; most operations are performed at room temperature. Hydrodynamic lubrication is possible because of the high relative speed between the workpiece and die.

Conventional extrusion can perform massive reductions in a single operation (up to a 400 to 1 reduction ratio), but is limited to finite length segments of starting material (i.e. it is a piece-rate process). The process can be performed both hot and cold on both nonferrous and ferrous metals. Because of the large amount of deformation and the conversion of deformation energy into heat, the speed of the process is often rather limited. High strength materials are usually formed hot with special lubricants to prevent pressure welding to the chamber and/or die.

Continuous extrusion is an attempt to achieve the best of both worlds -- namely a continuous, high-reduction process. Present techniques are largely limited to the weaker, nonferrous metals, and are usually conducted with room temperature starting stock. Speeds can be relatively fast, provided adequate cooling can be provided to offset the adiabatic heating induced by the large amounts of deformation being performed in a single operation .

2. Tubular products – advantages and limitations have to do with both the production process and the functioning of the product in use.

Process	Advantages	Limitations	Applications
Extrusion	- high accuracy - small tolerance - uniform properties along length and around circumference - low surface roughness - high strength if cold extruded - no seam	- complicated tooling - limited length due to mandrel - extra operation to join - welded joints, seams have different properties than rest	- high performance tubing such as in heat exchangers
	deformation texture may be advantageous or detrimental - e.g., advantageous for along tube loading, weaker in hoop direction under internal pressure loading		
Seam Welding, Forming and Butt-welding	-simple forming operation - high speed process	- workpiece heating needed - different properties in welded zone - only easily welded materials - internal support needed for large diameters	- common pipe and tube
Piercing	- seamless - large diameter	- limited length - subsequent sizing may be required	- fabrication of small, low pressure, pressure vessels
Drawing	- high strength if cold drawing - accurate	- limited length if mandrel used	- high performance, short tubes as in high pressure hydraulic lines

3. Applications are shown in Figure 19-79.
A cursory search for "hydroforming" gave

www.thefabricator.com/xp/Fabricator/Articles/Experts/Article111/Article111_p1.xml

containing pictures of exhaust manifolds, mention of a rear axel and a description of the advantages accrued in an automobile frames. A list of advantages and disadvantages of hydroforming is provided.

www.cooper-cooper.com.hydroform.htm

contains photographs of several different kinds of products

www.lajonchere.com/hydroform.htm

has a simple animation of the hydroforming process that summarizes the process steps and schematically shows the production of a product, a bellows-like part.

4. The amount of springback depends on the deformation imposed on the material during processing and on the elastic modulus of the work material. This general concept is summarized in Figure 17-6. The typical solution to springback is to overform the workpiece so that it will spring back to the desired final shape.

Given that springback depends only on the modulus of elasticity for a given radius, single axis bend, springback cannot be minimized, but only compensated for, in this case.

To minimize springback in the general case of possibly changing material and part design leads to two general approaches.

i. Changing to a material with larger elastic modulus will result in less springback for the same single axis bend. Changing to a different alloy of the same class of material will have little benefit since alloying has only small effects on elastic properties.

ii. More complex bends can reduce springback since the bends will interact with each other in determining overall springback. This is a radical solution and requires accurate deformation models of complex processes.

5. Residual stresses in cold working result from different amounts of deformation in different regions of the workpiece. Residual stresses will be high, and so important and probably intensely studied, for processes that produce large deformation gradients in the workpiece/product.

One such process is rolling. It is easy to imagine that as the amount of reduction is increased workpiece deformation zones near the surfaces grow and eventually overlap. Conceptually, for light reductions more deformation is expected near the surfaces of the workpiece than further into the work. This will result in compressive residual stress near the surface balanced by tensile residual stresses in the central region of the work. As reduction increases the deformation becomes more complex with frictional constraints at the surface and overlapping deformation. While the net result is not clear, it is clear that the residual stress state will be different.

A short internet search for “residual stress” & “rolling” yields many useful results. The residual stress distributions in both rolling and transverse directions and the distributions after stress relief for a typical rolling operation are shown at www.lanl.gov/projects/residual/alum.html

The results show not only compressive and tensile residual stress regions but also qualitatively different distributions before and after stress relief.

Case Study:

Diesel Engine Fuel Metering Lever

NOTE: This problem is particularly attractive because of the large variety of material-process combinations that can meet the requires geometric, physical, and mechanical properties.

1. As is usually the case, the part could be fully machined from a large piece of metal, such as a rectangular flat. This, however, is usually an inefficient use of material and time and labor considerations may be restrictive, especially for a production run of 10.000 pieces.

The small size of the part, smooth surface finish, and presence of a through hole, make the part attractive for one of several casting processes, including investment, die and, permanent mold. In addition, the part might even be attractive for centrifuging.

Noting that many of the surfaces are flat and parallel (such that if the part were viewed along the hole axis, the cross section would be uniform), one might want to consider extrusion of a shaped section, rolling of a shaped bar, or cold drawing, plus machining to remove the unwanted portions of the metal. This would significantly reduce the amount of machining from the first alternative in this section.

Finally, the prescribed size and small wall thicknesses render the part a candidate for powder metallurgy, or P/M injection molding, as a means of production.

2. These properties are not very restrictive and can be met by a number of metals and alloys, both ferrous and nonferrous. These include most steels, ferrous P/M alloys, copper-base alloys, some heat-treatable aluminum alloys, zinc-aluminum die casting alloys, and a variety of others.

3. The processes listed in part one include both wrought forming and casting, as well as powder metallurgy. This section is designed to get the student to focus on process-material limitations. Almost all metal can be machined, but if 100% machining were to be employed, a free-machining metal or alloy should be seriously considered. Of the cast processes, investment would be the slowest and most costly. This would probably only be considered if ferrous materials were required. Since alternative metal systems can provide the desired properties, die casting of either a copper-base or zinc-aluminum alloy would be an attractive alternative. Ferrous materials cannot be die cast and the higher-melting-point copper-base alloys have a limited die life, so the zinc-aluminum, alloys might be preferred here. Extrusion would require a ductile, wrought alloy, such as an age

hardenable aluminum. Cold drawn bars of low carbon steel would also meet the requirement and copper-base alloys might be considered here. If powder metallurgy were pursued, a ferrous powder would likely be required, but the low hardness and ductility requirements provide ample room for such a solution. The complexity of shape might lead to a preference for P/M injection molding over the conventional press-and-sinter powder metallurgy approach.

4. The conclusion as to which solution is the best is indeed a question of “multiple shades of gray”. Each of the above possibilities has merits and the “best” solution may well be based on the experience, available equipment and expertise, and current economics of the various processes and materials.

In each case, the form of the starting material would be different. Full machining would begin with mill-length bars of standard configuration. Casting would begin with melt quality ingots. If using extrusion or complex cross-section bars, the primary operation would likely be contracted out to a specialist firm and the product could be purchased with a specified degree of cold work amenable to both finish machining and final properties. Powder metallurgy would begin with a specified blend of powder and lubricant.

The necessity for heat treatment again depends on both the material and the method of manufacture. Some of the above systems would require age hardening to attain the desired final properties. Ferrous P/M would require a quench and temper. Other alternatives could meet the goals with cold work.

CHAPTER 20

Review Questions

1. Plastics, ceramics and composites are substantially different from metals in both structure and properties. As a result, the processes of fabrication also tend to be different. Many of the fabrication processes can take the raw material to a finished product in a single operation. Large, complex shapes can be formed as a single unit, often eliminating the need for multipart assembly. Joining and fastening operations are quite different from those used on metals. Color, surface finish and precision can often be obtained directly, eliminating the need for surface finishing.

2. Thermoplastic polymers can be heated to a temperature at or near the melting temperature so that the material becomes either a formable solid or a liquid. The polymer can than be cast, injected into a mold, or forced through a die to produce the desired shape. With thermosetting polymers, once the polymerization has occurred, no further deformation can occur. Thus, the polymerization reaction and the shape-forming process must be accomplished simultaneously.

3. Plastic sheets and plates can be cast between plates of glass. Continuous product can be made by introducing the liquid polymer between moving belts of stainless steel, or into the gap of a rolling mill setup. Tubular products can be made by spinning the liquid against the walls of a rotating mold.

4. Cast plastics generally contain no filler, so they present a distinct lustrous appearance.

5. Blow molding is a process that is used to shape thermoplastic polymers into bottles or other hollow-shape containers. Common thermoplastics for this process include: polyethylene, polyvinyl chloride, polypropylene, and PEEK.

6. In blow molding (and in injection molding) the parts have to harden in the mold before they can be removed from the mold. While parts are hardening the machine cannot be used for forming more parts, it is unproductive time. The part hardening phase of blow molding cycles can be reduced, and production rates increased, by building cooling systems into the molding machine.

7. Compression molding is most economical when it is applied to small production runs requiring close tolerances, high impact strength, and low mold shrinkage. Most products have relatively simple shapes because the flow is rather limited. Parts should not contain regions with thick section because of the long curing times.

8. Mold temperatures for compression molding typically run between 300 and 400^{o}F, but can go as high as 1200^{o}F. They are generally made of tool steel and are polished or chrome plated to improve material flow and product quality.

9. Thin sections, excellent detail, and good tolerances and finish are all characteristic of the transfer molding process. In addition, inserts can be incorporated into the product as the liquid resin is introduced at relatively low pressure.

10. Injection molding is used to produce more thermoplastic products than any other process.

11. Injection molding of thermoplastic polymer is very similar to die casting of metal. Sprues and runners channel molted material to the various closed-die cavities where the material solidifies after mold filling. Injection pressures provide rapid filling and prevent premature solidification. The die segments then separate for easy part ejection.

12. By using a hot runner distribution system, the thermoplastic material is kept in a liquid state until it reaches the gate. The material in the runner does not solidify and can be used in the subsequent shot, thereby reducing the amount of scrap and the amount of material that must be heated for each shot (or product). In addition, quality is improved due to the uniformity of temperature and the absence of recycled material in the melt.

13. The typical molding cycle in the injection molding of thermoplastics takes from 1 to 30 seconds and is very similar to the die casting of molten metal. Because thermosetting plastics must be held at elevated temperatures and pressures for sufficient time to permit curing, the cycle time for the injection molding of these materials in significantly longer than for thermoplastics.

14. In reaction injection molding metered amounts of the materials to be mixed are formed into two high pressure streams. The streams interact in the mixing head of the machine, out side the mold.

15. Since the reaction injection molding is a low temperature, low pressure process the process and the machine have attractive characteristics. In the process itself the solidification time is determined by the curing time of the blend and may be short. This is in contract to processes that use heated polymers such as injection molding. In injection molding solidification time is determined by the time required to remove heat from the heated melt. Depending on the extent of cooling of the mold injection molding cycle times may be long.

The machine and tooling for reaction injection molding can be simpler than for high temperature, high pressure process. Since no heating is required, no heating system in needed in the molding machine. Low pressure means that molds need not be as strong and stiff as molds in high pressure processes. Low temperature and low pressure result in less mold wear than in high temperature, high pressure processes and so mold material requirements are less stringent and less expensive molds may be possible.

16. Plastic products with long, uniform cross sections are readily produced by the extrusion process. Common production shapes include solid forms, tubes, pipes, and even

coated wires and cables. If the emerging tube is blown up by air pressure, allowed to cool, and then rolled, the product can be a double layer of sheet film

17. Twin-screw extruders have advantages associated with the materials that can be extruded and the mixing and heating of the materials. The screws in twin-screw machines enable the extrusion of complex plastics. Since the flow pattern of the plastic is more complex than with single-screw machines better mixing occurs. The greater extent of mixing means that there is more shear heating of the plastic/melt. Shear heating, unless extreme enough to cause high temperatures and plastic degradation, can be an important heat source for melting the feedstock in addition to the heaters built into the extruder.

18. Thermoforming is a process designed to shape thermoplastic sheet material into a uniform-thickness shaped products, similar to those produced by embossing of metal sheet.

19. Rotational molding is used to produce hollow, seamless products of a wide variety of shapes and sizes. These include storage tanks, refuse containers, footballs, helmets, and even boat hulls.

20. Open-cell foams have interconnected bubbles that permit the permeability of gas or liquid. Closed-cell foams have the property of being gas- or liquid-tight.

21. Rigid-type foams plastics are used for structural application, for packaging and shipping containers, as patterns for the full-mold casting process, and for providing rigidity to thin-skinned metal products.

22. In spinning thermoplastic material filaments are formed and several filaments can be spun into twists and wraps similar to cables. Products can be the spun material as it comes out of the machine, e.g., plastic string. Another kind of product is woven twists that resemble cloth.

23. Since plastics are poor thermal conductors, little of the heat that results from chip formation will be conducted away through the material or be carried away in the chips. Consequently, the cutting tools run very hot and may fail more rapidly than when cutting metal. In addition, the high temperature at the point of cutting can cause thermoplastics to soften and swell, possibly binding or clogging the cutting tool.

24. Since bending and recovery of tabs is necessary for effective snap fits material properties related to strength, stiffness and elastic limit are important. Plastics have relatively low values of modulus of elasticity and so small forces are needed to deform the mating sections during assembly of snap fits. While not unusually high the yield strain of plastics is large enough so that mating sections of snap fits will not be permanently deformed during assembly of adequately designed snap fits.

25. Plastics offer designers a number of unique material properties, including light weight, corrosion resistance, good thermal and electrical insulation, and the possibility of

integral color. Some of the design limitations of plastics include" the inability to perform at elevated temperature of operation, poor dimensional stability, and the deterioration of properties with age.

26. Adequate fillets between the adjacent sections of a mold ensure smooth flow of plastic into all section of the mold and also eliminate stress concentrations at sharp interior corners. These fillets also make the mold less expensive to produce and lessen the danger of mold breakage. Rounding exterior edges will act to reduce the possibility of chipping.

27. Uniform wall thickness is desirable in plastic products for several reasons. Since the curing time is determined by the thickest section, it can be optimized for the product if the sections are uniform. In addition, nonuniform wall thickness can lead to serious warpage and dimensional control problems.

28. Dimensions parallel to the parting line are contained entirely within a given section of the mold and can possess good dimensional precision. Larger tolerances are required for dimensions which cross the parting line for they can vary with the fit of the die segments, wear of the dies, and the thickness of any flash that forms.

29. Threaded metal inserts are frequently molded into plastic products because of the difficulty of molding threads in plastic parts and the fact cut threads tend to chip. The inserts provide strength and allow frequent assembly and disassembly.

30. Metal inserts are placed in plastic parts either by forcing the insert into a molded cavity or by molding around the insert. The inserts are held in place by mechanical interactions, not chemical bonding, between the insert and surrounding material. Insert function can be lost if the inserts pull out or rotate. To aid in resisting forces acting along and insert and torques acting to twist the insert inserts are bent, split along their length notched, swaged or formed to produce protrusions and noncircular heads, grooved and knurled, Figure 20-12.

31. Since the mold is the reverse of the product, depressed letters or designs would require these features to be raised above the mold. This would require the entire remainder of the mold to be cut away at a considerable expense. If the details were raised, only these details would have to be machined.

32.A parting line problem is the appearance of the part if flashing occurs during molding and the flash at the parting line has to be removed. Locating the parting line at a sharp corner means that any operation needed to remove possible flash will be performed at an edge, not on a flat surface. Any surface appearance effects of flash removal will be less apparent.

33. Countersinking holes that are to be threaded has two intents.
i. The countersink can aid in locating and starting the tapping or screw insertion operations.

ii. If any damage results from tapping or screw insertion it will be in the countersink and so not visible.

34. Dipping can be used to produce relatively thin elastomeric products with uniform wall thickness, such as boots, gloves, and fairings.

35.Rubber sheets are usually made in calendering processes. Rubber is fed into the gap between two closely spaced rolls. Roll rotation draws the rubber feedstock into the gap forming a sheet of uniform, specified thickness. The rubber sheet leaving the calendering roll gap may be laid onto substrate such as woven fabric.

Dipping of rubber is usually the build up thin layers over a form or mold to produce a shaped product. Dipping using plate is not done to form rubber sheets.

36. Ceramic materials generally fall into two distinct classes, glasses and crystalline ceramics. The glasses are fabricated into useful products by forming a viscous liquid and then cooling it to produce a solid. The crystalline ceramics are fabricated by pressing moist aggregates of powder to a desired shape, followed by drying and bonding by chemical reaction, vitrification or sintering.

37. By rapidly cooling the surfaces of hot glass, a residual stress pattern of surface compression can be induced. The resulting glass is stringer and more fracture resistant. Annealing operations can be used to relieve unfavorable residual stresses when they exist, and heating can also be used to promote devitrification – the precipitation of a crystalline phase from within the glass.

38. Glass ceramics are amorphous, glassy, ceramics that contain regions of ordered, crystalline, structure. A glass ceramic is produced and then subjected to heat treatment to initial and control the formation and growth of crystalline regions.

39. Plasticity can be imparted to the crystalline ceramics in a number of ways. Clay products can be blended with water and various additives to permit shaping. Plastic forming involves the blending of various ceramics with additives to make the mixture formable under pressure and heat. The additive material is subsequently removed by controlled heating before the fusion of the remaining ceramic.

40. In injection molding of plastics
- a one component material, the plastic,
- is heated to a relatively high temperature,
- injected under high pressure into a mold,
- let solidify
- and ejected as a final part.

In injection molding of ceramics
- a two material feedstock is used, ceramic powder and a binder,
- the material is injected at relatively low temperature and pressure,

- after removal from the mold thermal, solvent, catalytic or wicking operation is needed to remove the binder,
- the part is fired to produce final strength and density.

41. Firing or sintering operations provide useful strength to ceramic materials by driving the diffusion processes that are necessary to form bonds between the individual particles. In some cases surface melting or component reactions produce a liquid component that flows to produce a glassy bond.

42. While machining before firing enables the cutting of weaker material, there is usually a greater concern for the dimensional changes that will occur during firing. Therefore, machining performed before firing id usually rough machining designed to reduce the amount of finish machining to be performed after firing establishes both the final properties and dimensions. In both cases, caution should be exercised relating to the handling of brittle materials that will fail by fracture.

43. Since the brittle ceramics cannot be joined by fusion welding or deformation bonding. and threaded assemblies should be avoided because of the brittleness of the material , ceramics are usually joined by some form of adhesive-type bonding. Even here, however, the residual stresses can lead to premature failure of the brittle material. As a result, it is best if ceramic products can be produces as a single piece (monolithic) structures.

44. The overriding characteristic that influences the design of ceramic parts is the brittleness of ceramics. Ceramic part design guidelines emphasize avoiding situations in which cracks are initiated and stresses cause cracks to grow. For example, ceramic parts should be designed so
- tensile and bending stresses (which give rise to tensile stress) are minimized,
- stress raisers due to part shape changes should be minimized so large abrupt changes in section should be avoided,
- sharp corners and edges should be avoided since they are stress raisers,
- corners should be rounded to avoid stress raisers and chipping and crack formation at outside corners,
- secondary or finishing operations are minimized since these operations are difficult and expensive for hard, strong materials such as ceramics,
    - --- features that are difficult to produce in the initial ceramic part production process should be avoided as this will result in additional processing,
    - --- dimensional tolerances should be as large as possible so it may be possible to meet them in the as-fired ceramic part with no secondary processing,
    - --- surface finish specifications should be as loose as possible so it may be possible to meet them in the as-fired ceramic part with no secondary processing.

45.Since particulate composites are composed of discrete, stable solid particles dispersed in a matrix material there is no need for special processes to produce a different kind of structure such as a solution or compound. Processes used to combine other materials and bond different materials into a composite, e.g., mixing, compaction and sintering of powder metal composites, are useful for forming particulate composites.

46. A quality bond can be formed between the distinct layers of a composite through such processes as: roll bonding, explosive bonding, and the various lamination techniques (adhesive bonding, brazing, etc.).

47. Fiber-reinforced composites use the strength of the fibers to impart additional strength to the fiber-matrix whole. The use of fibers means that added strength will be in the fiber length direction. The commonly used fiber forms are
- long, continuous fibers are their use results in increased strength in the fiber length direction,
- fibers woven into fabric layers used in thin sheet composites and they add strength in the two in-plane fiber directions,
- woven fabrics of fibers formed in three dimensions so that when embedded in the matrix strength in three dimensions is increased,
- short, chopped fibers that can be oriented in a particular direction or randomly.

48. Prepregs are segments of woven fabric produced from the fibers, which is then infiltrated with the matrix material. Subsequent fabrication involves stacking the prepreg layers and subjecting them to heat and pressure to complete the cure of the resin. Answer for question.

49. Sheet molding compounds are sheets composed of chopped fibers and resin, the sheets being about 0.1 inch in thickness. These can be press-formed in heated dies to provide an alternative to sheet metal where light weight, corrosion resistance and integral color are desired. Bulk-molding compounds are fiber-reinforced thermoset molding materials containing short fibers in random orientation. They are formed into products using processes like compression molding, transfer molding or injection molding.

50. In pultrusion, bundles of continuos reinforcing fibers are drawn through a resin bath and then through a preformer to produce a desired cross-sectional shape. The material is then pulled through a series of heated dies which further shapes the product and cures the resin. Like wire drawing and extrusion, the product is a long length of uniform cross-section.

51. Filament winding is used to produce hollow, container-like shapes with high strength-to-weight ratio. Small quantities of large parts can often be economically made by the filament winding process. The special tooling for a new product (a new form block) is relatively inexpensive. By making these products as a single piece, additional savings can be obtained through reduction in: labor, total manufacturing time, assembly, and tooling costs.

52. Laminated sheets containing woven fibers can be formed to produce the curves required for products, such as boats, automobile panels, and safety helmets. This fabrication is generally performed by processes, such as vacuum-bag molding or pressure-bag molding. Alternative methods include compression molding, resin-transfer molding, and hand layup.

53. Spray molding utilized chopped fibers mixed with a catalyzed resin. The starting material for sheet stamping is a thermoplastic sheet reinforced with woven fibers. Both chopped and continuous fibers can be used in injection molding using several techniques.

54. Spray molding uses chopped fibers that are mixed with a catalyzed resin.

55. There a number of ways to produce fiber-reinforced, metal-matrix composites. Variations of filament winding, extrusion, and pultrusion have been developed. Sheet materials can be made by electroplating, plasma spraying or vapor deposition onto a fabric or mesh that is then shaped and bonded. Diffusion bonding of foil and fabric sandwiches, roll bonding, and coextrusion are other options. Liquid metal can be cast around fibers through capillary action, pressure casting and vacuum infiltration. Discontinuous fiber products can be made by powder metallurgy techniques or spray forming.

56. In ceramic matrix composites, the matrix is a brittle material and failure occurs by fracture. A primary purpose of the "reinforcement" is often to impart toughness rather than strength. One means of imparting toughness is to prevent (or interrupt) the propagation of cracks across the matrix. By designing weak interfaces, propagating cracks are diverted along the interface, rather than crossing it and continuing their propagation.

57. Fiber reinforced composites are cut using conventional machining processes such as sawing, drilling, routing, tapping, turning and milling. There are problems unique to the cutting of fiber reinforced composites.

Cutting fiber reinforced composites involves cutting through the fibers, the matrix and the fiber-matrix interface regions. Moving a cutting edge through this complex material causes separation of the individual composite material components and the possible separation of the components, e.g., cutting of fibers and separation of the fiber from the matrix. Separation of the material components can result in cracking, splintering, fraying and delamination. To minimize such problems deformation and material separation should be confined to very small regions and so tool sharpness is important. High cutting speeds also help.

The fiber or matrix or the interface material in fiber reinforced composites may be abrasive and call for the use of hard, strong cutting tool materials such as polycrystalline diamond.

Fundamentally different material cutting techniques can be used to cut fiber reinforced composites to circumvent some of the problems associated with conventional machining processes. Water-jet, abrasive water-jet and laser machining can be used.

58. When fiber-reinforced materials must be joined, the major concern is a lack of continuity of the fibers in the joint area. The thermoplastic resins can be welded. Thermoset materials require the use of mechanical joints and adhesives.

Problems:

1. There are a number of possibilities here including the aligning of fibers in the shafts of golf clubs (pultruded or extruded), the laminates of woven sheets in skis, the various sheet type products in racing car bodies, and the continuous fiber reinforcements included in both the frame and handle regions of tennis racquets. Advances are continually being made in both the materials and processes, and sporting goods is one of the most active and competitive markets for the employment of composite materials.

Case Study:

Fabrication of Lavatory Wash Basins

CHAPTER 21

Review Questions

1. The deformation zone in which the chip is produced is not completely bounded. In contrast to drawing for example where the workpiece is deformed in the die, in metal cutting the workpiece has free surfaces. In lathe turning there are free surfaces at the workpiece diameter and on the top of the forming chip. And, the boundaries that do exist (the tool-chip interface and the not well-defined deformation zone boundary in the work material) are difficult to characterize.

Further complications of the process are that the strains are very large and the strain rate is very high. Material properties at such conditions are not typically known. There are also a large number of process variables.

Theoretical solutions or process models have to be validated experimentally. It is difficult to obtain reliable, consistent experimental results that quantitatively describe the local deformation in the chip formation zone. The chip formation zone extends into the workpiece below what will become the finished surface.

2. The input parameters or independent variables for the process include the cutting speed, feed, depth of cut, the cutting tool geometry, cutting tool material and the cutting fluid.

The input parameters determine the process outputs or dependent variables and process performance. e.g.,. material removal rate, machining time, tool wear, finished surface roughness, surface integrity (finished surface and subsurface deformation state), cutting zone temperature, cutting forces, chip formation and machine tool dynamics.

Other process variables may be constrained so as to be not completely defines or fixed. There may or may not be complete control over such process characteristics such as the work material, machine tool, workholding device.

3. Single point:
turning, facing, boring, shaping, planing, fly cutter milling, some modes of deep hole drilling and other variations of lathe operations such as cutoff, recessing plunge or form turning.

The rest of the machining processes are multiple point and include drilling, milling, broaching, sawing, filing and many forms of abrasive machining.

4. In turning the feed rate is the speed of the cutting tool along the workpiece longitudinal direction. If the lathe carriage is driven independently of the spindle (inch/minute or mm/min) there is no necessary relation between feed speed and cutting speed. There are the practical considerations of cutting forces, machine vibration, etc. In many lathes one motor drives both the spindle and the carriage. The carriage is usually driven through a gearbox and so feed rate is in inches or millimeters per revolution of the spindle. In this case the linear feed speed and the feed rate in units of distance/revolution are related as

feed rate (in/min or mm/min) = N_s (rev/min) f_r (in/rev or mm/rev)
$f = N_s f_r$

In contrast to the linked spindle speed-feed rate lathe turning operation, in other machining operations there may be no relationship between cutting speed and feed rate.

For example in end milling the spindle and table are driven independently. If the feed rate is the table speed past the spindle, v, it is set by the table feed motor-drive system. The spindle is driven by the spindle motor and the cutting speed, V, is the speed of the cutting edge through the workpiece. For spindle rotational speed N rpm the cutting speed at the cutter periphery is

$V = (N) (\text{cutter circumference}) = N \pi (\text{cutter diameter})$
$V = N (\text{rev/min}) \pi d (\text{in or mm})$

The description of the amount of material being removed is usually given by the advance of an individual cutting edge into the workpiece in one revolution of the cutter. This is the bite per tooth or the chip load. Bite/tooth is dependent on both spindle speed and table speed. For a cutter with A flutes or cutting edges, the bite/tooth, B, is

$B = \text{advance of one cutting edge per revolution of the cutter}$
$B = \{ (v \text{ in/min or mm/min}) (\text{time for one cutter revolution}) \} / (\text{edges / revolution})$
$B = (v \text{ in/min or mm/min}) (1 / N \text{ rev/min}) (1 / A \text{ teeth/rev})$

In some machining processes the feed rate is set by the tool, in broaching the feed is built into the tool, rise per tooth as shown in Figure 26-6. Feed will be the same regardless of cutting speed.

There may be only indirect influences between feed and cutting speed in machining operations. In power sawing using a horizontal saw such as shown in Figure 26-17 and Figure 26-12 it may be that the saw in acted on only by gravity, that is, the vertical force is not controlled or the mechanism controlling this force is inactive. The net downward force will be due to gravity and the cutting forces acting. If the cutting forces change with cutting speed the net downward force will change and so the feed rate changes. In sawing soft materials or materials with definite anisotropic structure with a high tooth rake angle saw the cutting action may pull the saw down into the work.

5. The machine motion related to feed in milling is the table speed or table feed and combined with the spindle speed gives the feed per tooth or bite per tooth as explained in 4 immediately above.

So, the two feeds in milling are the table feed (in/min, mm/min) and the feed per tooth (in/tooth, mm/tooth). The table feed is the direct input to the machine. Spindle speed is a machine input that is used to set the cutting speed.

6. A shear-front lamella structure is developed by very narrow shear fronts which segment the chip material into very narrow lamellae. The mechanism is developed out of the compression deformation which precedes the shear. If the material is already cold worked, very little additional compression deformation is needed to activate the shear

process. If the material is annealed (or as-cast), the compression deformation is extensive, causing the workpiece to bulge and upset prior to shearing. The shear fronts have micron-spaced periodicity and are the result of many dislocations moving at the same time. The onset of shear begins at the shear plane (defined by ϕ) and moves at the angle φ to form the chip. This process is microscopic and not visible to the naked eye, except in very special circumstances. The primary dislocation mechanism appears to be one of dislocation pileups against the cell structure produced by compression deformation or prior work hardening of the workpiece material.

7. The metalcutting process has been labeled as an adiabatic shear instability, meaning that heat input and heat dissipated are balanced, or that there is excess heat which results in softening (lowering the strength of the material) so that the shear instability can take place. However, the metalcutting observed in Figure 21-12 is taking place at such low speeds, that such a mechanism appears to be unlikely. At faster cutting speeds, adiabatic shear may be responsible for the large saw-tooth structures seen in chips as the elastic energy is rapidly dissipated over the shear front.

8. In orthogonal cutting the cutting speed direction and cutting edge are perpendicular to each other. This is not the case in oblique cutting.

Oblique cutting is what is typically done in machining processes, with the exception of experimental setups designed to eliminate one cutting force, thus converting oblique (3 forces) cutting to orthogonal (2 force) cutting. The exceptions to this in industrial practice are broaching and slab milling with a straight tooth cutter. Orthogonal machining can be converted to oblique machining simply by canting the cutting edge with respect to the direction of motion of the tool.

9. The approximate equation for turning is (21-4):

$$MRR = 12\ V\ f_r\ d$$

base on the assumption that the depth of cut d is small compared to the workpiece diameter, D_1.

The exact equation for turning is:

$$MRR = \text{volume removed} / \text{time}$$

$$MRR = \{ (\pi D_1^2 - \pi D_1^2) L \} / \{ 4 L / f_r N \}$$

$$N = 12\ V / \pi D_1$$

$$MRR = 12\ V\ fr (D_1^2 - D_2^2) / 4\ D1$$

10. The mechanics of the chip formation process can become quite complicated when a radius is used rather than an edge. Almost all of the analysis work in metalcutting assumes a zero radius cutting edge.

11. The magnitude of the strain and strain rates are very large for metal cutting compared to tensile testing. Metal cutting strain is on the order of 1 to 2 compared to tensile testing's 0.20 to 0.40 and metal cutting strain rates are 10^5 to 10^9 in/in/sec compared to tensile testing's 10^{-2}.

12. Titanium is very strain rate sensitive. The faster it is deformed, the stronger it behaves. This causes problems because of the high strain rates in metal cutting.

13. Cast iron has a structure that is filled with flake graphite. These flakes produce regions that act like sharp-cornered flaws or voids which concentrate the compression stresses. The shear fronts cannot cross these regions. Under the large strains, the metal fractures through the flake and the chips come out segmented or in fractures chunks.

14. In metal cutting shear stress is a material constant. This means that it is not sensitive to changes in cutting parameters or cutting process variations. Once this value is known for a metal, it can be used in basic engineering calculations for machining statics (forces and deflections) and dynamics (vibrations and chatter).

15. The primary or largest force is always the cutting force, F_c which is in the direction of the cutting speed vector, V. The cutting speed is much larger than the feed speed and the radial speed.

16. The energy F_cV is divided into shear (actually compression and shear) to form the chips (about 75%) and secondary shear and sliding friction at the tool/chip interface.

17. The energy that produces plastic deformation does so through the production of dislocations, which multiply and move. The energy in the dislocations is returned to the metal as heat when the dislocation absorb each other (annihilate). In short, energy is converted to heat. Only a very small portion of the input energy is stored in changes in metallic structure.

18. F_c can be estimated from:
   a) the unit power, eqn (21-12)
) the specific energy, eqn (21-15)
   b) the shear stress, eqn (21-30) with an estimate for F_t
      usually Ft is estimated at F_c / 2

19. The rate of wear (on both the flank and the rake face) of the tool is most directly influenced by cutting speed. The higher the cutting speed, the shorter the life of the tool. This is because increasing V directly drives up the temperature, and increasing the temperature of a tool rapidly increases wear rates.

Question 17 is concerned with the heat generated in machining. The power dissipated in machining is FV (the sum of the products of all cutting forces and corresponding velocities) and so increasing V increases power, increasing heat generation and increasing tool temperature.

Tool wear is discussed in Sections 22.5, 22.6.

20. As temperature goes up, the hardness (resistance to penetration) decreases. See Figure 22-3.

21. The case of constant cutting force with increasing cutting speed, Figure 21-11, can be due to either
- cutting speed has no effect on the machining process and on work material behavior/properties,
- or that the effects of cutting speed increase on the process and/or material offset each other to produce no net effect.

Specifying the effect of cutting speed, V, on cutting force, F_c, can be approached from two starting points.
i. The power for machining as described in Section 21.3 can be used.
Using the definition of power $P = F_c V$,
and the machining process model $P = HPs\ MRR$ relating power and unit power and material removal rate gives

$F_c = P / V = HPs\ MRR / V$

$MRR = V fr\ d$ with fr being feed advance d the depth of cut

then

$F_c = HPs\ fr\ d$

Feed advance and depth of cut do not depend on cutting speed. This implies that that for constant F_c, HP_s does not depend on cutting speed. That is, unit power is constant with increasing cutting speed.

However, more careful consideration of the unit power may lead to a different conclusion. If unit power is determined by work material properties and chip formation process mechanics then a balance of competing effects may result in constant unit power. For example, if
- work material shear strength increases with cutting speed (the strength of many materials increases with strain rate)
- and the amount of deformation to form the chip decreases with increasing cutting speed due to formation of a smaller shear zone,
- and work material strength decreases with increasing cutting speed due to increased temperature in the shear zone,

perhaps these effects will combine to produce a constant value of unit energy. In reality a more realistic statement is that they combine to produce a small enough change in unit energy so that cutting force appears to be constant.

ii. The force model of machining can be used to add more detail to explaining constant cutting force in terms of process and material interactions.

The process model, force system is shown in Figure 21-20.
From Figure 21-20

$F_c = R \cos(\beta - \alpha)$

again from Figure 21-20 $F_s = R \cos (\beta - \alpha + \phi)$

or $R = F_s / \cos (\beta - \alpha + \phi)$

now known material behavior is introduced by putting shear force in terms of shear strength

$F_s = \tau\ As$

$$A_s = t\, w / \sin \phi$$

$$F_s = \tau\, t\, w / \sin \phi$$

$$R = (\tau\, t\, w) / \{ \sin \phi \cos (\beta - \alpha + \phi) \}$$

and finally

$$F_c = \{ \tau\, t\, w \cos(\beta - \alpha) \} / \{ \sin \phi \cos (\beta - \alpha + \phi) \}$$

If cutting force is to remain constant then all terms on the right hand side of the equation should not change with cutting speed or the effects of changing process and material parameter values have to compensate, i.e., cancel each other.

The width of cut, *w*, the depth of cut or uncut chip thickness, *t*, and the tool rake angle, α do not change with cutting speed. The changes with cutting speed of the remaining parameters, τ, β, ϕ, are not so clear-cut.

It seems reasonable as a first approximation to assume that the work-tool coefficient of friction is constant and so the friction angle β = constant. The shear angle ϕ is given in the Merchant chip formation model by

$$\phi = 45^o + \alpha / 2 - \beta / 2$$

and the shear angler does not depend on cutting speed for constant friction coefficient.

The revised description of shear angle in Section 21.7 is

$$\phi = 45^o + \alpha / 2 - \psi$$

with ψ dependent on material hardness.

So, what is left is the explanation that cutting force is constant with increasing cutting speed since the work material shear strength, τ, is constant with increasing cutting speed. The argument that increase in τ with increasing strain rate is balanced by decrease in τ with increasing temperature as cutting speed increases leads to the conclusion that cutting force remains constant with increasing cutting speed.

(An Aside: The development of the initial Merchant model of chip formation was based on the independence of friction and shear strength from shear angle. Subsequent models developed by Merchant and others explicitly included consideration of the work material strength.)

22. In overview, the cutting force increases with increasing feed or depth of cut since the amount of material being removed increases.

The same cutting force equation as immediately above can be used and the argument is

$$F_c = \{ \tau\, t\, w \cos(\beta - \alpha) \} / \{ \sin \phi \cos (\beta - \alpha + \phi) \}$$

and if *t* and/or *w* increases, F_c increases.

Problems:

1. Excel spreadsheet solution

shear angle $\phi = \tan^{-1} \{ r_c \cos \alpha / (1 - r_c \sin \alpha) \}$

shear stress $\tau_s = F_s / A_s$

$F_s = F_c \cos \phi - F_t \sin \phi$

$A_s = t\, w / \sin \phi$

coefficient of friction $\mu = F / N$

$F = F_c \sin \alpha + F_t \cos \alpha$

$N = F_c \sin \alpha - F_t \cos \alpha$

In the orthogonal metal cutting model the only nonzero velocity is the cutting velocity and so the only power is (cutting force)(cutting velocity)

HP_s = Power / Material Removal Rate

HP_s = = { (F_c lb) (V ft/min) (12 in/ft) } / { (t in) (w in) (V ft/min) (12 in/ft)

HP_s = { F_c / $t\,w$ inlb/min / in^3/min }{ hp / 396,000 inlb/min }

HP_s = F_c / $t\,w$ hp/ in^3/min

Figure 21-21 shows shear stress for annealed 1018 steel = 75,000 psi

- this is close to the results of the calculations for 1020 steel
  - while it is not definite, sometimes it is said that the effects of increasing work strength with strain rate are offset by decreasing strength due to increasing

temperature and the room temperature shear strength of the work can be used for approximate calculations of machining variables.

The calculated unit power values of about 0.7 – 0.8 hp/in3/min seem lower than the values in Table 21-3. This is probably due to the simplifications in the orthogonal model of chip formation.

In actual machining there is a feed direction velocity that when multiplied by the feed direction force gives a power dissipation. Calculation of this power with typical values will show that it is negligible with respect to the cutting force power.

2. rc = t / tc

weight density = ρ = weight / volume = Wt / (l_c w_c t_c)
with l_c = chip length, w_c = chip width, t_c = chip thickness
t_c = Wt / (l_c w_c ρ)

rc = t Wt / (l_c w_c ρ)

Know Wt, l_c, ρ

t is the uncut chip thickness in the orthogonal model and is the feed in conventional turning and should be known since a machining process was run to obtain the chip.

w_c is the chip width and in the orthogonal cutting model is the width of workpiece and is constant since two-dimensional deformation is a basis for the model. In conventional turning the deformation is often close to plane strain and then the chip width is the depth of cut.

3. $U_s = F_s V_s$ / Material Removal Rate
$= F_s V_s / (V t w)$

$F_s = F_c \cos \phi - F_t \sin \phi$
$V_s = V \{ \cos \alpha / \cos(\phi - \alpha\}$
V = cutting speed
t = uncut chip thickness = feed advance per revolution
w = width of cut

$U_f = F V_c$ / Material Removal Rate
$= F V_c / (V t w)$

$F = F_s = F_c \sin \alpha + F_t \cos \alpha$
$V_c = V r_c$

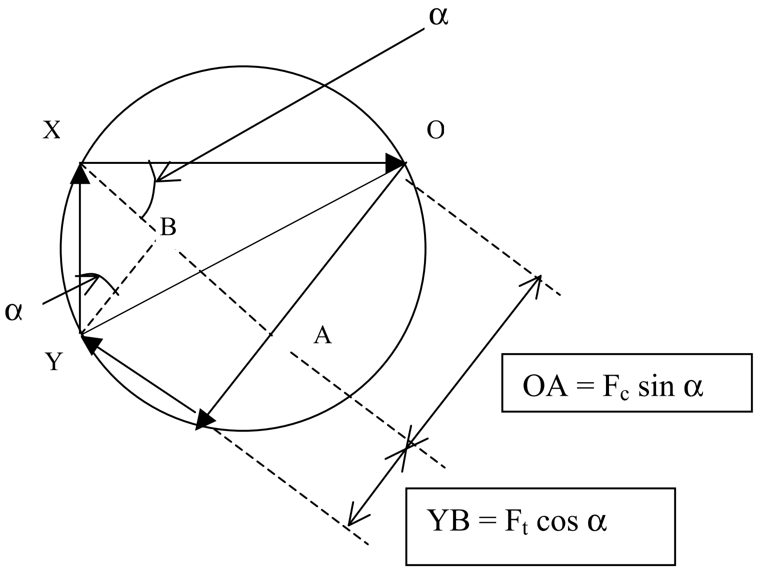
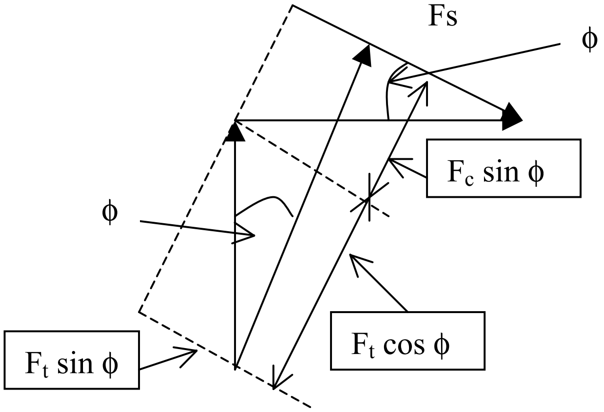
4.



5.



6. shear strain = $\gamma = \cos\alpha / (1 + \sin\alpha)$

	w	0.2	in				
	alpha	0	deg				
	V	530	sfpm				
Run	F_c (lb)	F_t (lb)	Feed (ipr)	r_c		**shear strain**	**1 / rc**
1	330	295	0.00489	0.331		**2.00**	**3.02**
2	308	280	0.00489	0.381		**2.00**	**2.62**
3	410	330	0.00735	0.426		**2.00**	**2.35**
4	420	340	0.00735	0.426		**2.00**	**2.35**
5	510	350	0.00981	0.458		**2.00**	**2.18**
6	540	395	0.00981	0.453		**2.00**	**2.21**

The inverse of the chip thickness ratio 1 / rc = tc / t decreases with increasing feed rate. This indicates that the chip is relatively less deformed, i.e., the chip thickness goes from about three times the uncut chip thickness to about twice the uncut chip thickness. Given the change in deformation, the constant value of shear strain is surprising.

7 With cutting conditions known (except for cutter rake angle) and a chip formation mechanics model available, what remains to be obtained is material property values. The candidate sources of material behavior are material strength and the unit machining power for the particular work material.

The rake angle is presumably known as it is measurable. For a strong tough material a low rake angle, and so strong, tool is probably used, say $\alpha = 0^o$. (Lacking specific information, one way to proceed is to consider several realistic possibilities, i.e., a range of rake angle values. However, using the force data provided that is for one case with different rake angles implies that cutting force is independent of rake angle. This is not the case.)

i. eqn (21-30) gives

$F_c = \{ \tau_s\, t\, w + F_t \sin 2\phi \} / \{ \sin\phi \cos\phi \}$

given $F_t = F_c / 2$

$F_c = (\tau_s\, t\, w) / (\sin\phi \cos\phi - \tfrac{1}{2} \sin 2\phi)$

$\phi = \tan^{-1} \{ r_c \cos\alpha / (1 - r_c \sin\alpha) \}$

$r_c = t / t_c = 0.020$ in / 0.080 in = 0.25

$\phi = 14^o$

Figure 21-21 shows τ_s for Inconel 600 to be 105,000 lb/in^2

$t = 0.020$ in

$w = 0.25$ in

$F_c = 2555$ lb

An alternative problem solution is to use tabulated values of unit machining power such as Table 21-3.

For Iconel 700, HP = 1.4 hp/(in^3/min)

Power = F V

in turning $P = F_c V + F_t V_{feed} + F_r V_r$

in turning a straight shaft the radial velocity $V_r = 0$

the feed direction force Ft is given as Ft / 2 but this component of power will not be included since tool velocity in the feed direction is small compared to the cutting speed.

e.g., even at 1000 rpm spindle speed

V_{feed} = (1000 rev/min)(0.020 in/rev) = 20 in/min = 1.7 fpm

Power = F_c V

P = F_c V = HPs (Material Removal Rate)

Fc = P / V

MRR = V f d = (250 ft/min)(0.020 in)(0.250 in)(12 in/ft)

MRR = 15 in3/min

P = { 1.4 hp/(in^3/min) } { 15 in^3/min } = 21 hp

V = 250 ft/min = 3,000 in/min

Fc = { 21 hp / 3,000 in/min }{ 396,000 (inlb/min) / hp } = 2,772 lb

8. For rough machining typical ranges of cutting conditions are:

Cutting speed, 200 sfpm to 800 sfpm

Feed rate, 0.010 ipr to 0.085 ipr

Depth of cut, 0.125 in to 0.675 in

MRR = 12 V f d

MRR_{min} = 12 (200 ft/min) (0.010 in) (0.125 in) = 3 in^3/min

MRR_{max} = 12 (800) (0.085) (0.675) = 550 in^3/min

For finishing

MRR_{min} = 12 (700 ft/min) (0.005 in) (0.0125) = 0.525 in^3/min

MRR_{max} = 12 (1600) (0.015) (0.0675) = 19.44 in^3/min

9. HP = Fc V ftlb/min/ 33,000 ftlb/min/hp

V can be obtained from the MRR

MRR = 12 V fr d = 550 in3/min

V = 550 in^3/min { (12) (.005 in) (0.675 in)

V = 13,580 ft/min

HP = (10,000 lb) (13,500 ft/min) / 33,000 ftlb/min/hp

$HP = 4090$ hp

The 4000 hp value calls for investigation of this unreasonable number. Although the cutting speed seems high it might be possible. The difficulty is probably with the 10,000 lb “measured” force.

10. HP_s = Power / MRR

Power = 24 hp
MRR = 550 in^3/min

HPs = 0.0436 hp/in^3/min

Table 21-3, Steel (200 BHN)
HPs = 1.50 hp/in^3/min & 0.73 hp/in3/min

The calculated value is well out of the expected range.

CHAPTER 22

Review Questions

1. The most important material property for cutting tools is hardness. The tool must be harder than the material being machined to prevent rapid wearing and early failures.

2. Hot hardness is the ability to sustain hardness at elevated temperatures. See Figure 21-22.

3. Impact strength is a material property which reflects the ability of a material to resist sudden impact loads without failure. It is a combination of strength and ductility and is measured by the energy absorbing capability of the material. The two tests used for impact testing are the Charpy and the Izod Impact test. The general term for impact strength is toughness.

4. Many cutting tools experience impacts during routine cutting processes. Interrupted cuts are common in milling. Cutting tools may also impact on hard spots or hard surfaces of a material .

5. RIP is hot isostatic pressing, a powder metallurgy process used to make cutting tools, particularly carbides. See Chap. 16.

6. Primary considerations in tool selection include: What material is going to be machined, what process is going to be used, what are the cutting speeds, feeds, and depths of cut needed, what is the tool material, and what are lubricants going to be used. See Figure 22 - 2 for complete answer.

7. A hard, thin, wear-resistant coating is placed on a tough, strong, tool material. Such composites have good impact strength and good wear resistance.

8. Cermets are a relatively new cutting tool material compared to composed of ceramic materials in a metal binder. See Figure22-10 for a comparison of cermets to other tool materials.

9. CBN is manufactured by the same process used to make diamonds. The powder is used as a coating for carbide blanks in the same way poly-crystalline diamonds are made. CBN powder is sintered and compacted onto a carbide substrate, diced with a laser into segments and the segments brazed into pockets in a standard tungsten carbide insert. The CBN layer is about 0.020 inches thick.

10. F. W. Taylor developed the experiments which lead to the Taylor tool life equation, developed the principles of scientific management and stop watch time study, developed the tool grinder methodology for grinding specific angles on cutting tools, and is considered to be one of the founders of Industrial Engineering. He was also the first

United States tennis doubles champion, dispelling the myth he had bad eyesight.

11. Cast cobalt alloy tools would be made by investment casting, due to the high temperatures of the alloys.

12. The compacted powders are compressed into a solid of uniformly fine grains. If cobalt is used as a binder, the solid cobalt dissolves some tungsten carbide, then melts and fills the voids between the carbide grains. This step is called sintering.

13. When the cobalt powders melt and fill the voids between the carbide grains, they "cement" the carbide grains together. This is an old term still used in the cutting tool industry to describe sintered, powder metallurgy tools.

14. The ground inserts are more precise - have less variability from tool insert to tool insert -- so that there is very little difference between tools. This is important when changing tools in automatic equipment or rotating the insert in an indexing tool holder. Therefore, the tool does not have to be reset when the insert tip is changed. Pressed inserts may vary in size as much as .005 inches and may carry this size change into the process.

15. The chip groove is placed on the rake face directly behind cutting edge. Depending upon the depth of cut, the chip groove can make the land in front of the groove act as a controlled contact surface and modify the cutting process. It can cause the shear angle to increase and therefore reduce the power and cutting forces. It can also cause the chips to bend sharply and fracture into short segments which makes chip disposal easier. See Figure 22-9.

16. As shown in Figure 22-13, a groove forms at the outer edge of the cut during the machining of materials with a hard surface or a surface with hard particles in it. The groove is called the depth of cut line or the DCL since it forms at a distance from the cutting edge equal to the depth of cut.

17. a) High speed steel will deflect the most - smallest E
b) Ceramic will resist penetration the most - hardest
c) High speed steel is the most ductile
d) Carbides are the strongest in compression.

18. Tools get hot and expand during machining. Different materials have different coefficients of expansion. The layers are graded with respect to thermal coefficients of expansion to reduce the probability of thermal cracking of the coats. Some layers are also used to promote bonding between the materials.

19. For high-speed steel, black oxide and nitriding are quite common but TiN of RSS is becoming very popular. Coating carbides with TiN and TiC and other materials is popular now using CvD. Aluminum oxide coating is becoming more popular. Ceramics are usually not coated or surface treated.

20. The reaction forms hydrogen chloride which can affect the impact strength and other material properties.

21. Lowering the coefficient of friction at the tool/chip interface reduces the secondary deformation. This has the effect of reducing the friction force, F. The reduction of F results in rotation of the force circle (or an increase in the shear angle). For a given cutting geometry, this means a reduction in F_s (because $F_s = {}_sA_s = \sim t\ w/ \sin\phi$) and F_c (because F_c is a function of F_s). Thus, the tools run at lower forces and lower temperatures and last longer.

22. CBN tools are used when other factors, such as interrupted cutting, do not mitigate against using as high a cutting speed as possible. An example is lathe turning of low strength materials. The machining processes amenable to the use of CBN cutters are similar to machining situations in which diamond cutters are used – with the exception of ferrous workpieces. Diamonds react chemically with ferrous materials while CBN does not.

23. Diamond reacts chemically with ferrous materials while CBN does not.

24. The coefficient of variation is the ratio of the standard deviation of a statistic distribution to the mean of the distribution. A large value indicates that the process which produced the data for the distribution has a large amount of process variability .

25. Tool life varies from tool to tool even when the tools are being used under identical conditions. Lifetime is a random variable, whether we are talking about tools, people, tires, or light bulbs. The random variable nature of tool life means that predicting tool death will be very difficult.

26. Metal cutting tool life data tends to be log-normal and have a coefficient of variation of .3 to .4. Compare this to values for yield strength data or UTS data which have values of
.03to .05.

27.Machinability is defined many different ways. The two most common ways are: machining specific horsepower (RP~) which reflects the power needed to remove a cubic inch of metal per minute - the more difficult metals will have higher numbers for specific horsepower; and machinability numbers based on tool life comparisons. A material is selected as the standard. A material which can be machined faster with the same tool life as the standard material has a higher rating than the standard. So the first measure is based on equal volume of material removed and ignores tool life, and the other on equal tool lives, ignoring power consumed. Other measures of machinability have been proposed using ease of chip removal and surface quality as criteria .

In the 1970's, one of the authors (Black) tried (without much success) to get people to think about flow stress, τ_s, as a machinability standard (like UTS) and developed a prototype machine to determine flow stress values for various materials. Many of the values given in Figure 21-21 came from this research.

28. From the earliest measurements of F. W. Taylor, it has been known that cutting fluids provide a cooling action for the tool. Because of the nature of the process, few usable cutting fluids provide a lubrication action to the tool/chip interface but this

29. Carbide tools are made in press and sinter operations. The compositions of the carbide constituents and the binder are important in determining tool mechanical properties and hence performance when cutting different work materials.

Powder metallurgy techniques are described in Chapter 16.

30.High-speed steel tools are coated to increase their useful life by covering them with a more highly wear resistant material. Physical vapor deposition is used since it is a relatively low temperature process and so has little effect on changing the HSS substrate material. Subsequent heat treatment to restore HSS properties after coating may not be required.

31. The is no universal cutting tool material since the requirements for the cutter vary widely with the material being machined and the kind of machining process being used.

At one extreme is the cutting of tough work material in an intermittent or interrupted cutting process such as milling. In this situation tool material resistance to impact loading and thermal cycling is required. High cutting speed is secondary to simply accomplishing the process and so high speed steel tools may be used in preference to other tool materials that have higher hot hardness but are more susceptible to chipping and fracture. At the other extreme are smooth, continuous machining processes such as finish lathe turning of low strength materials with small feed rate and depth of cut. In this situation, high hardness, high wear resistance tool materials can be used at high cutting speed. e.g., diamond tooling. The factors that make these tools materials susceptible to failure do not exist.

32. 18-4-1 or T1 high-speed steel is composed of iron, carbon and 18% tungsten, 4% chromium and 1% vanadium.

33. The most notable mechanical property of high-speed steel compared to other cutting tool materials is its higher toughness. It can also be more easily ground and so complex tool shapes can be produced. These characteristics make high speed steel tools useful for severe cutting situations requiring form tools, e.g., interrupted cutting processes such as milling using form cutters and gear cutting.

34. High hot hardness, high wear resistance cutting tool materials are usually brittle and so sensitive to changing forces and temperature, i.e., fluctuating forces and temperatures

cause varying stress fields and can lead to chipping and fracture. Non-rigid machine tools can cause dynamic, as opposed to constant level, forces and so adversely affect tool life.

35. While hardness is one indication of wear resistance, it is not the only one, and may be only an indirect indication of the resistance of the material to a particular wear mechanism.

Perhaps the most obvious shortcoming of hardness as a measure of wear resistance is in the chipping/fracture of cutting tools. Hard brittle materials are susceptible to chipping at the tool edge. So the tool material may be hard but still exhibit high wear rate if the work material, machining process and cutting conditions result in local, small-scale fracture and edge wear.

Also at a local level, hard inclusions in the nominally soft workpiece may abrade the tool and cause wear of the macroscopically much harder tool.

At high cutting speed, even with soft work material, high temperature is produced in the chip formation zone. The high temperature can result in diffusion of certain phases of the tool and tool wear. More specifically, for cemented carbide cutting tool materials the binder material may diffuse out of the tool exposing the brittle carbide structure to fracture and wear. This same type of tool weakening and wear can be due to chemical effects. In cutting green (moist) wood chemical action may remove the carbide tool binder. Then even relatively small cutting forces may cause fracture of the carbide phase.

36.A honed edge, or the chamfer shown in Figure 22-11, is the result of removing a small region at the tool cutting edge. The intent is to make the tool stronger. Much as negative rake angle increases tool strength by decreasing the wedge angle (θ in Figure 22-12) and changing the force at the tool edge to a more compressive stress pattern, honing has the same goals.

Problems:

1. With tool life equation $V T^n = K$ and K a constant,
can choose two data points and set the values for K equal,
Using the 3 min and 60 min tool life data points

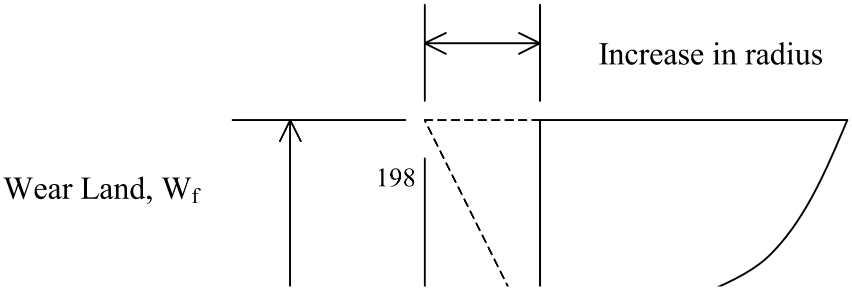
$$(V T^n)_3 = (V T^n)_{60}$$

$$(40.6) (3)^n = (26.8) (60)^n$$

$n = 0.14$

V Tn = (40.6) (3).14 = 47.4 = K
Values for n in Table 22-6 indicate material is high speed steel, but there is a low value for K

2.



Increase in radius = (Wf)(tan 5^o) = (0.020 in)(tan 5^o)= 0.002 in
Increase in diameter = -.004 in

There may be other significant effects on machined diameter, e.g., workpiece and tooling deflection.

3.

A =	side rake angle
B =	side relief angle
C =	end relief angel
D =	back relief angle
E =	nose radius
F =	side cutting edge angle
G =	end cutting edge angle

4. $V T^n = K$
For sand casting – diamond
$731 (20)^n = 642 (30)^n$
$731 (20)^n = 514 (60)^n$
$642 (30)^n = 514 (60)^n$
gives n = 0.32 and $K = 731 (20)^{0.32} = 1907$

For permanent mold casting – diamond
$591 (20)^n = 517 (30)^n$
$591 (20)^n = 411 (60)^n$
$517 (30)^n = 411 (60)^n$
gives n = 0.33 and $K = 517 (30)^{0.33} = 1588$

For PMC – diamond will coolant
$608 (20)^n = 554 (30)^n$
$608 (20)^n = 472 (60)^n$

$554\ (30)^n = 472\ (60)^n$

gives $n = 0.23$ and $K = 472\ (60)^{0.23} = 1210$

For sand casting – WC – K-20

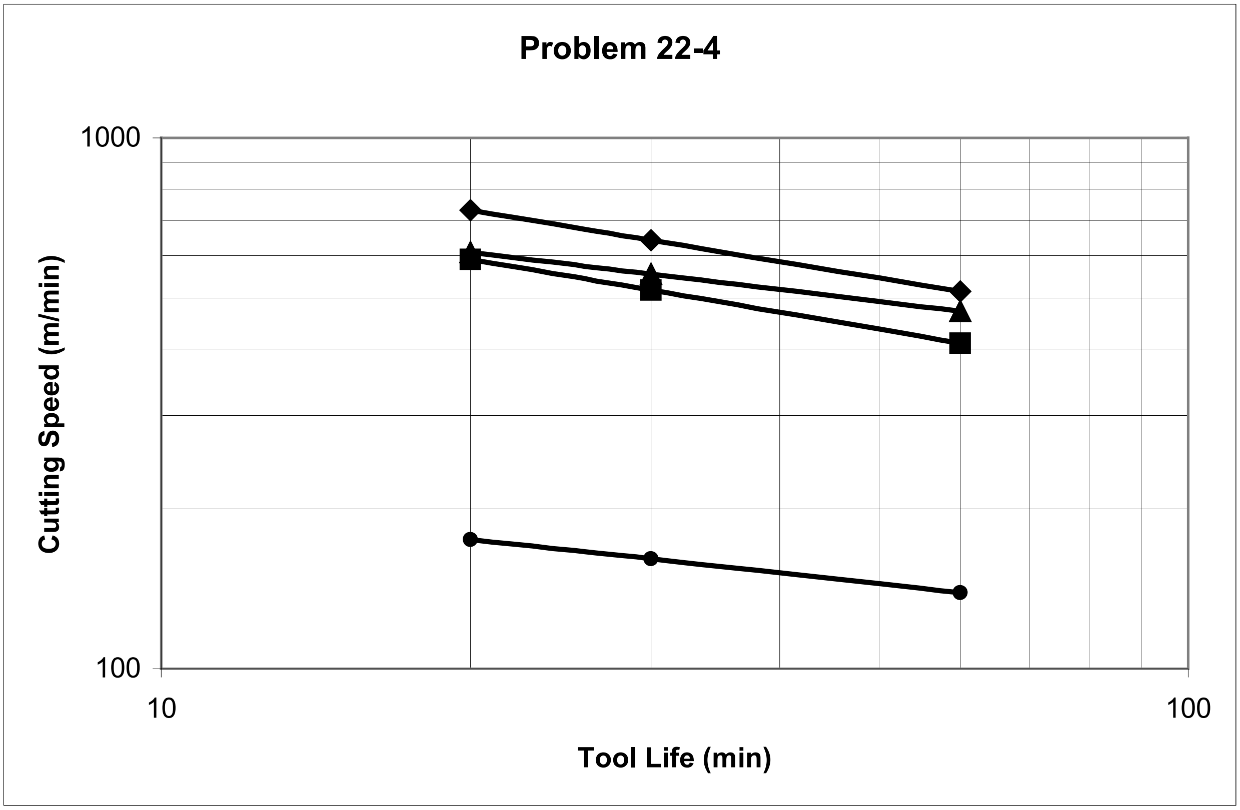
$175\ (20)^n = 161\ (30)^n$

$175\ (20)^n = 139\ (60)^n$

$161\ (30)^n = 139\ (60)^n$

gives $n = 0.21$ and $K = 161\ (30)^{0.21} = 329$

Problem 22-4								
		V (m/min) for tool life T (min) of				Log of V and T values		
Work	Tool	20	30	60		1.30	1.48	1.78
Sand Casting	Diamond	731	642	514		2.86	2.81	2.71
Mold Casting	Diamond	591	517	411		2.77	2.71	2.61
PMC	Diamond	608	554	472		2.78	2.74	2.67
Sand Casting	WC-K-20	175	161	139		2.24	2.21	2.14



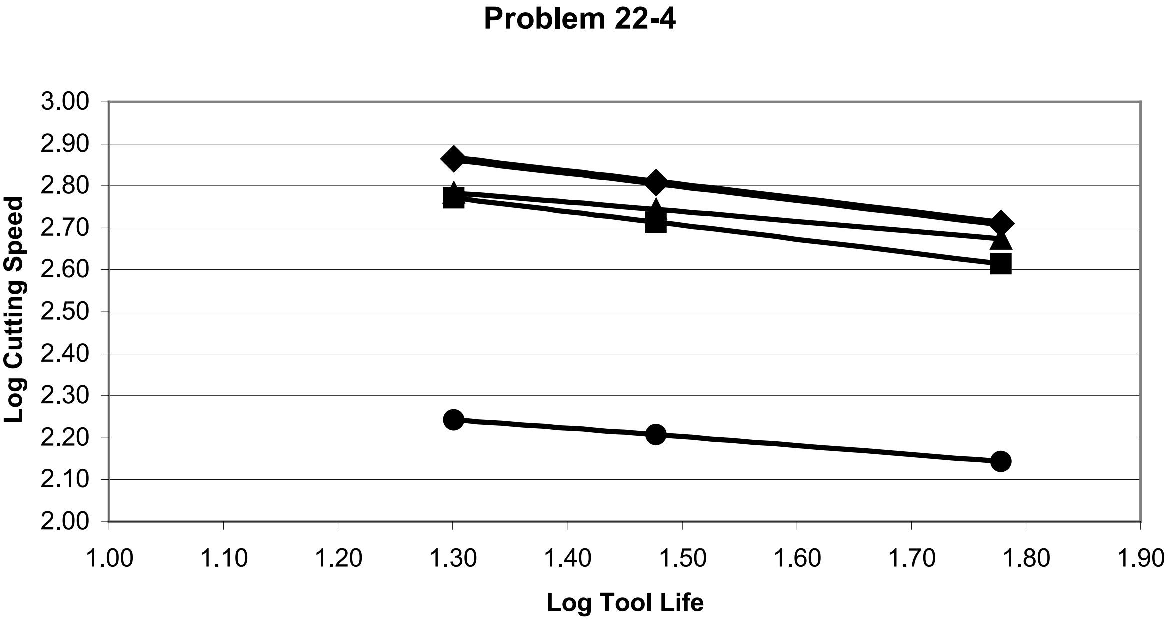
Slope		
for example		
Sand Casting	WC-K20	n = (log(330) - log(140)) / (log(60) - log(1))
		n = (2.519 - 2.146) / (1.778 - 0)
		n = 0.21
Sand casting	Diamond	n = (log(1900)-log(510)) / (log(60) - log(1))
		n = (3.279 - 2.708) / (1.778 - 0)
		n = 0.32

with the T = 1 intercepts, that are the values for K, determined by extaoplating the following plot

		V (m/min) for tool life T (min) of				Log of V and T values		
Work	Tool	20	30	60		1.30	1.48	1.78
Sand Casting	Diamond	731	642	514		2.86	2.81	2.71
Mold Casting	Diamond	591	517	411		2.77	2.71	2.61
PMC	Diamond	608	554	472		2.78	2.74	2.67
Sand Casting	WC-K-20	175	161	139		2.24	2.21	2.14

		V (m/min) for tool life T (min) of				Log of V and T values		
Work	Tool	20	30	60		1.30	1.48	1.78
Sand Casting	Diamond	731	642	514		2.86	2.81	2.71
Mold Casting	Diamond	591	517	411		2.77	2.71	2.61
PMC	Diamond	608	554	472		2.78	2.74	2.67
Sand Casting	WC-K-20	175	161	139		2.24	2.21	2.14

Or
plotting log T vs log V

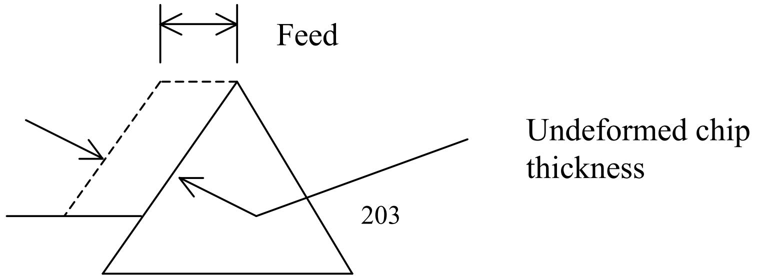


Slope		
Sand Casting	Diamond	n = (2.87 - 2.71) / (1.78 - 1.30) = 0.33
PMC	Diamond	n = (2.78 - 2.67) / (1.78 - 1.30) = 0.23
PMC	D + fluid	n = (2.77 - 2.61) / (1.78 - 1.30) = 0.33
Sand Casting	Diamond	n = (2.25 - 2.14) / (1.78 - 1.30) = 0.23

K		
for example		
Sand Casting	Diamond	extrapolate lowest line to Log Tool Life = 1, T = 10
	Log Cutting Speed = 2.3, V = 199	
	VTn = K = 199 (10)0.23 = 338	

5. a. cos(SCEA) = = 0.250 in / 0.289 in = 0.865 => SCEA = 30.1°

b)



Undeformed chip thickness = (feed distance)(cos(SCEA)
Undeformed chip thickness = (0.010 in)(cos(30.1^{o}) = 0.009 in

c) When SCEA goes from 0o to a different value the orthogonal, essentially two-dimensional deformation and force situation changes to three-dimensional. A radial force arises producing work and tooling deflection and may cause chatter. A SCEA increases the chip becomes thinner, more heat is dissipated and notching wear at the work outer diameter is decreased.

6.

	SiN	PCBN
Tips/part	12	12
Tool life parts/tool	200	4700
Cost/tip	\$1.25	\$28.50
Tool cost/part	(12)(\$1.25)/200 = \$0.075	(12)(\$28.50)/4700 = \$0.073
Tool cost/yr	(\$0.075)(312,000 = 23,400	(\$0.073)(312,000) = \$22,776

There are costs with making change and these may very well be greater than the \$624 tool cost savings. However, There be other than cost advantages to adopting the new tools, e.g., part surface finish, less tool change time.

b. If there is to be a change it will be based on tool cost and other, important, factors. The finished cylinder bores are critical elements of the part. Changes in the product – over its entire life – that are related to changing tooling have to be evaluated. For example, changing cutting tools may affect bore surface finish and surface integrity and so affect engine performance in terms of power produced and cylinder bore wear.

7. The tool life equation is $V T^n = K$ and so the straight line relation is on a log-log plot, e.g., Figure 22-16 and n and K have constant values.

Given 2 in diameter the cutting speeds and tool lives are

Spindle Speed (rpm)	Cutting Speed, V (ft/min)	Tool Life, T (min)
284	149	10
132	69	30

With the two (V,T) points the values of n and K can be calculated and used in the tool life equation to calculate the cutting speed for a tool life of 60 min

for constant K,
$69 (30)^n = 149 (10)^n$ and n = 0.7
with n = 0.7, K = 746.5

for 60 min life, $V T^n = K$ is V (60)0.7 = 746.5 and V = 42.5 ft/min

Solving the problem by plotting the given values on log-log paper or if linear graph paper is used the given point are

(V, T) point	(logV, logT) point
(149, 10)	(2.17, 1)
(69,30)	(1.84, 1.78

Drawing a line between the point and picking the point on the line corresponding to tool life of 60 min (log 60 = 1.78) gives a log cutting speed value of about 1.62 and a cutting speed of $(10)^{1.62} = 41.7$ ft/min

If the straight line relationship is interpreted erroneously as a linear relation between V and T rather than $V T^n = K$,
then

the slope of the line is $\Delta V / \Delta T = (69 - 149)$ ft/min / (30 – 10) min = - 4
extrapolating from the V = 149 ft/min, T = 10 min point to T = 60 min gives

V = 149 ft/min + (-4 ft/min/min)(60 – 10) min = - 51 ft/min

8. The machining process dependent variables are:
a) eqn(21-18)

Chip thickness ratio = $r_c = t / t_c = 0.010$ in / 0.022 in = 0.455

b) eqn(21-19)

Shear plane angle = $\phi = \tan^{-1}\{ r_c \cos\alpha / (1 - r_c \sin\alpha) \}$

$\phi = \tan^{-1}\{ 0.455 \cos 10^o / (1 - .455 \sin 10^o) \} = 25.9^o$

c) Friction angle = see below
d) Coefficient of friction = see below
e) Friction force = see below
f) Shear force = see below
g) Shear stress on shear plane = see below
h) eqn(21-21)

Shear velocity = Vs = V { $\cos\alpha / \cos(\varphi - \alpha)$

Vs = 500 ft/min { $\cos(10^o) / \cos(26^o - 10^o)$ = 512 ft/min

i) Shear strain eqn(21-31)

$\gamma = \cos\alpha / [\sin(\phi+\psi) \cos(\phi+\psi-\alpha)$

eqn(21-34) $\psi = 45^o - \phi + \alpha/2$

gives corrected eqn(21-35) as shown in the center of page 503

eqn(21-22) corrected

Shear strain = $\gamma = 2 \cos\alpha / (1 + \sin\alpha)$

$\gamma = 2 \cos(10^o) / (1 + \sin(10^o)) = 1.68$

j) Specific shear energy = see below

Parts c, d, e, f, g, j require information in addition to that given in Problem. Specifically,
- a value for cutting force can lead to solution,
- a value for material shear strength can lead to solution,
- some other possibilities that enable use of concepts in Section 21-6

For example, Figure 21-21 shows a value for shear strength of 1018 steel, using a value of τ_s = 75,000 lb/in2 for 1015 steel gives

(f) eqn(21-28) $F_s = \tau_s A_s$

eqn(21-29) $A_s = t\, w / \sin\phi = (.0100\text{in})(.100 \text{ in}) / \sin(26^o) = 0.0023 \text{ in}^2$

F_s = 75,000 lb/in2 (0.0023 in 2) = 171 lb

(e) eqn(21-23) $F = F_c \sin\alpha + F_t \cos\alpha$

eqn(21-26) $F_s = F_c \cos\phi - F_t \sin\phi$

$F_c = (F_s + F_t \sin\phi) / \cos\phi = (171 \text{ lb} + 140 \text{ lb} (.438)) / 0.899 = 258 \text{ lb}$

F = 183 lb

(c) eqn(21-22) β = tan-1(F/N)

N = Fc cosα - Ft sinα = 230 lb

β = 38.5o

(d) $\mu = \tan\beta = 0.796$

(j) eqn(21-16) $U_s = F_s V_s / V f d$

U_s = (171 lb)(512 ft/min)(12 in/ft) / (500 ft/min)(0.01 in)(0.1 in)(12 in/ft)

U_s = 175,104 inlb/in^3

9. Figure 21-32 shows that temperature increases with cutting speed and that wear increases with temperature. The general conclusion is that wear increases with cutting speed. With regard to the data in Problem 1, the data show that as cutting speed increases the tool life (given amount of wear) decreases.

10. $V T^n = K$

n = 0.25, K = 1300

using the units of minute for T and ft/min for cutting speed

Spindle speed = N rpm

V = (N rev/min) (26.25π in/rev) (ft / 12 in) = 6.88 N ft/min

T = work length / feed speed = 48 in / { .01 in/rev) (N rev/min) } = (4800 / N) min

$(6.88 N) (4800/N)^{.25} = 1300$

N = 64 rpm

V = (64 rev/min) (26.25π in/rev) (ft / 12 in) = 439 ft/min

11. For the turning operation described in Problem 10

Horsepower = F_c V + Ft V_{feed}

V = 500 ft/min = N rev/min (26.25 π in/rev)(ft/ 12 in)

N = 72.8 rpm

V_{feed} = 0.010 in/rev (72.8 rev/min)(ft/12 in) = 0.061 ft/min

F_c = 258 lb estimated in Problem 8

negligible with respect to cutting speed

HP = 258 lb (500 ft/min)(hp / 33,000 ftlb/min) = 3.9 hp

12. It's not clear that how a cutting force comparison can be discussed since it seems that only one tool geometry is specified, i.e., in Figure 22-D.

Case Study: no case study

CHAPTER 23

Review Questions

1. In turning, the work rotates and the tool is fed parallel to the axis of rotation. In facing the tool is fed in the radial direction, toward or away from the axis of rotation..

2. In turning cylindrical, conical, contoured, tapered, and knurled surfaces can be produced externally. Internal turning is called boring. In facing a flat surface is produced.

3. In form turning, the shape of the tool defines the shape of the surface and the tool is usually fed perpendicular (or plunged) to the axis of rotation. See Figure 23-28 for examples of form turning.

4. Facing employs a tool that is wider than the desired cut width and the workpiece is not separated into two parts by the process as is the case in a cutoff operation. In both cutoff and facing, the tool feeds perpendicular to the axis of rotation.

5. Knurling, a common lathe operation, usually does not make chips - it cold forms the pattern into the surface.

6. It is not possible to provide the proper rake angles on all portions of a complex form tool. Typically, small or even zero back angle tools are used, so the cutting forces will be large. In addition, small increases in depth of cut result in very large force increases because the cutting volume is large (long cutting edge in contact); so depth of cut must be set (and held) small to prevent large deflections and chatter during machining.

7. $MRR = 12\ V\ f_r\ d$ uses V which is the speed at the outer, unmachined surface of the workpiece to calculate material removal rate. In reality cutting speed varies with radial position and V is the maximum value. So, the calculated MRR using V does not include the variation of cutting speed in the calculation.

8. A hollow spindle permits long bar stock to be fed through it into the workholding device (chuck or collet) much more quickly than if individual piece parts are used. The drawbar for the collet also must pass through the spindle. See Figures 23-4 and 23-38.

9. The carriage supports the toolholder and provides the feed motion to the tool.

10.

11. Either the feed rod or the lead screw drives the carriage. The feed rod system usually has a friction clutch in which slippage can occur. The lead screw provides positive ratios between carriage movement and spindle rotation and no slippage is allowed. The lead screw is for thread turning.

12. Work in a lathe can be held between centers, held on mandrels which are then held

between centers, held in 3 or 4 jaw chucks, or held in collets. Workpieces can also be directly mounted on a faceplate attached to the spindle and are occasionally mounted on the carriage and even in the tailstock assembly (very rarely) .

13. A device called a dog is attached to the work and the tail of the dog fits into a hole in the faceplate, which is directly attached to the spindle. See Figure 23-30.

14. After the work has been turned, the surfaces will be tapered rather than cylindrical. See Figure 23-11.

15. Hot rolled stock usually has an oxide scale on it, which is rough. Clamping on nonround, rough surfaces like this can damage the collet jaws and destroy the accuracy of the collet.

16. A steady rest is mounted on the ways and is stationary while a follow rest is mounted on the carriage and thus translates with it as it carries the tool. Both are commonly used on long, cylindrical workpieces.

17. A four-jaw independent chuck can be adjusted to clamp work of almost any shape within its capacity. Such a chuck requires more time to adjust than a three-jaw chuck, and it is not self-centering .

18. Minimizing the overhang of the tool improves the rigidity of the setup and reduces the tendency of the tool to deflect which in turn reduces the tendency to chatter and vibrate. Remember, deflection is a function of length of overhang cubed in cantilever beams, so a small change in overhang length can greatly change deflection and vibration tendencies.

19. Figure 23-12. On a ram-type turret lathe the ram holding the turret moves on the saddle – ram and saddle can move independently. On a saddle-type turret lathe the turret is fixed to the saddle – there is no movable ram between the saddle and turret and so the saddle-type turret lathe is stiffer with respect to tool and tool holding structures..

20. Tapers may be turned by: (1) use of the compound rest, (2) set-over of the tailstock, (3) use of a taper attachment.

21. The material removal rate is a function of speed x feed x depth of cut. Assuming speed is kept constant, heavier depths of cut or heavier feeds will reduce the number of cuts or passes that have to be made, which reduces the number of adjustments or resettings of the tool which have to be made. Increasing either feed or depth of cut will increase the cutting force. Increasing depth of cut will have less effect on tool life than increasing the feed. Either way, the total machining time is usually less. In addition, the surface finish is usually better with the lighter feed.

22. The rpm of a facing cut is based on the largest diameter of the workpiece, utilizing

the correct (selected) cutting speed.

23. See response to question number 18 above. Boring tools have large overhangs and are thus more subject to deflection, vibration, and chatter problems. Reducing the feed (or the depth of cut) reduces the cutting forces and thereby the deflection problems .

24. As the cutting rate increases, the surface finish usually improves - See Figure 23-7. However, large nose radius tools tend to chatter more.

25. The BUE will cause the tool to make heavier depth of cuts than expected, so the part may come out undersize.

26. In tooling a multiple spindle screw machine, it is important to have the machining operations at each spindle require the same amount of time. As shown in Figure 23-18, this time balancing can be very difficult to do. There will be one operation having a processing time larger than any of the other operations. The 2nd position drill or the 4th position tap are probably the operations with the longest operation times (about 5-7 seconds) .

27. The C-axis is the rotational position of the spindle on the lathe. For turning centers that have capabilities in addition to turning the workpiece may have to be held stationary in a certain orientation – the C-axis position – so that the other type of machining process can be done. For example, if a turning center has milling capabilities a turned shaft with two slots can be produced in one setup. The shaft can be turned and then held in specified positions, C-axis positions, while the milling of the slots is done.

28. In drilling, the drill can drift or shift off center. This is due to the chisel end of the drill not cutting and the drill being deflected as it starts the cut. In boring, the hole is the result of the rotation of the workpiece about its axis, which remains fixed.

29. On vertical boring machines, the weight of the workpiece is down on, and supported by, the table; whereas, in a lathe, it must be supported and rotated about a horizontal axis. Large, heavy workpieces will deflect the spindle, causing a loss in accuracy and precision.

30. On a horizontal boring machine, the workpiece does not rotate. In other words, workpiece rotation limits the number of surfaces which can be machined in a single setup. Thus, horizontal boring machines are more flexible. This machine was one of the first to be converted to NC. On this machine: (1) Several types of machining operations can be performed with a single setup, and (2) the workpiece does not move, thus it is easy to clamp and hold large workpieces. Finally, chip disposal is easier than on vertical spindle machines (for boring blind holes for example) .

31. Figure 32-14.

32. In a collet.

33. Figures 23-2, 23-11, 23-30, 23-38

34. Figures 23-11, 23-31

35. a. Three-jaw chuck; Figures 23-6, 23-14, 23-34: Figure 23-33
b. Collet; 23-17, 23-36
c. Faceplate; Figures 23-30, 23-38
d. Four-jaw chuck; Figure 23-5: Figure 23-33

36. Three form tools are used in this setup. The shaving tool is a form tool.

37. Since the intent of most operations is to machine a complete part in one setup all the machining operations have to be completed on one machine. If one tool fails the part cannot be completed and so the tool has to be replaced. The question then is whether to replace all the tools at this time. The general answer is that if the tool failed unexpectedly, i.e., after a very short time the other tools are expected to keep performing adequately and so only the failed tool is replaced. To do otherwise is disposing of useable tooling. The other extreme is if one tool fails at about the same time as the other tools are approaching the end of their expected lives. Then all tools are changes. The large middle ground is difficult to quantify since tool life is a stochastic variable, Figures 22-15, 22-18.

38. The tools to be used are shown in the turret in Figure 23-29. The last operation is to separate the final part from the remaining stock and so cutoff operation with tool 9 is the last one.

There may be rare exceptions but usually turrets are indexed sequentially from one tool holder to the very next one. This being the case the questions are what is the first turret operation, whether the turret rotates clockwise or counter-clockwise and whether there are operations between those performed using the tools in the turret.

The workpiece has to be positioned, so

1. Stock stop used to set extension of work out of collet

   An accurate initial diameter is needed so

2. Turn B using tool 3 which may include turning the entire part length

   Diameter D is needed and Figure indicates it is produced by

3. Turn D using turrep position 2

   An accurate initial diameter is needed for tread production so

4. Turn F using turret position 3

   The end face needs to be chamfered and center drilled and this will also aid in starting threading so

5. End face and chamfer – turret position 4
6. Center drill – turret 6

   Thread the end before reducing final part diameter since work will be stiffer so

7. Thread – turret position 7

   Machine diameters furthest from supported end first since work is stiffer and

8. Turn C and E with tool 5
9. Form cut with tool 8

10. Cutoff with tool 9.

Problems:

1. V = N rev/min (π 3 in/rev)(ft / 12 in) = 200 ft/min
N = 255 rpm

2. CT = (L + A) / (feed x N)
CT = (8 in + 1 in) / {(255 rev/min)(0.020 in/rev) = 1.76 min

3. Material Removal Rate – exact:
i. MRR = Volume removed / time

Volume = π/4 (work length)($d_o^2 - d_f^2$)
change in diameter = 2 (depth of cut) = 0.25 in
V = π/4 (8 in){ $(3 \text{ in})^2 - (2.75)^2$) } = 9.03 in3
time = distance / feed speed
feed speed = N rev/min (0.020 in/rev)
V = 200 ft/min = N rev/min (π 3 in/rev)(ft/ 12 in)
N = 254.6 rpm
feed speed = 5.09 in/min
t = 8 in / 5.09 in/min = 1.57 min

MRR = 5.75 in^3/min = 94,225 mm^3/min

ii. Or
using do – ½(depth of cut) to calculate cutting speed
MRR = V f d
V = 254.6 rev/min (π 3 in/rev) = 2350 in/min
MRR = 2350 in/min (0.020 in)(0.125 in) = 5.875 in^3/min = 96,274 mm^3/min

Material Removal Rate – approximate:
MRR = V f d = 200 ft/min (0.020 in)(0.125 in)(12 in / ft)
MRR = 6 in^3/min = 98,332 mm^3/min

4. a). Engine lathe cost TC_{EL} = (0 .5 Q + 0.5) 18 + 0
Turret lathe cost TC_{TL} = (0.083 Q + 3) 20 + 300
Equate TCEL = TCTL at BEQ
(0.5 Q + .5) 18 = (0.083 Q + 3) 20 + 300
9 Q + 9 = 1.67Q + 60 + 300
Q = 351 / 7.33 =41.9 or42 units

b). 0.5 (18) + (0.5 x 18) / 41.9 = 9 + .21 = $9.21/part

5. The feed given in the problem (for boring) is 0.5 mm/rev or

about 0.02 ipr. The depth of cut is (112) x (89-76) or 6.5 mm or
0.255 inches. Assuming that for 1340 steel, the BHN would be in
the low range (175 to 225), Figure 42-11 on page 1179 recommends
a cutting speed of 80 sfpm or 24.4 m/min.

Drilling RPM for 18 mm drill = (24.4 x 1000)/(18 x 3.14) = 431
Drilling RPM for 76 mm drill = (24.4 x 1000)/(76 x 3.14) = 102.2
Boring RPM = (24.4 x 1000)/(89 x 3.14) = 87.3
Drilling time for 18 mm drill = (200 + 18/2)/(431 x 0.25) = 1.94 min.
Drilling time for 76 mm drill = (200 + 76/2)/(102.2 x 0.64) -3.64 min.
Boring time = 200/(87.3 x 0.5) = 4.58 min.
Center drill time = 0.5 min.
Four changes of speed and tool settings require 4 x 1 mm = 4 min.

6. a) Taking “fixed cost” completely literally, i.e., not varying with production quantity, the fixed cost is the constant cost per unit part of the curves. Estimating costs from the log Cost per unit axis
Engine lathe; 30 - 40
NC lathe; 6 - 7
Single spindle automatic; 2 - 3

7. The derivation of the approximate equation 23-5 for the MRR for turning requires an assumption regarding the diameters of the parts being turned. The derivation is:
$\text{MRR} = 12 (D_1^2 - D_2^2)\ fr\ V / 4 D_1$
$\text{MRR} = 12 \{ (D_1 - D_2) / 2 \} \{ (D1 + D2) / 2\ D1 \}\ fr\ V$
$V \simeq 12\ V f t$
where $(D_1 - D_2) / 2 = t$ and
$(D_1 + D_2)/ 2 D_1 = (D_1 + D_1 - 2t) / 2 D_1 = 1 - t / D_1 \simeq 1$ for $t / D1 \simeq 0$
which assumes t, the depth of cut, is small and negligible compared to the uncut diameter, D_1, so that $t / D_1 \simeq 0$.

Case Study: New “Estimating the Machining Time for Turning”

Total machining time is
CTT = (machining time for one pass)(number of cutting passes) + tool change time
The problem comes down to determining the machining time for one pass and the number of passes required. The machining time for one pass will be determined by the feed rate, f, along with the length of the workpiece, L, and the allowance, A. The number of passes necessary will be determined by the depth of cut, doc. There are three concerns that set limits on feed rate and depth of cut and they are available power, workpiece deflection and tool wear.

Cutting time for one pass over the forging is CT = (L + Allowance) / feed speed
the feed speed is (spindle speed rev/min)(feed rate in/rev) = N f

A starting place is to choose a tool life based either on desired tool cost if more than one tool can be used or life long enough to complete the machining operation with one tool. This tool life will give a cutting speed and cutting speed is needed in the analysis to follow. After the results are calculated the tool life chosen can be reassessed and is it is not consistent with the results obtained, the analysis can be repeated with a different tool life.

Tool life = 30 min
- tool life equation $VT^n = K$
- using given data in part 1 and *noting feed rate = 0.020 ipr and* $\alpha = 10^o$

  $(VT^n)_{60} = K = (VT^n)_{85}$

  $60 (100)^n = 85 (10)^n$

  $K = 120$, $n = 0.15$

For 30 min tool life: $V (30)^{0.15} = 120$

$V = 72$ ft/min

Power Available constraint:

power available = power required

50 hp (0.75) = HPs (MRR)

HPs from Table 21-3 and BHN = 300 – 400

for steel with BHN = 300 the larger unit power is 1.87 hp/in^3/min

say HPs = 2 hp/in^3/min

V = 72 ft/min = 864 in/min

37.5 hp = (2 hp/in^3/min)(f)(doc)(864 in/min)

(f)(doc) = 0.022 in^2

- this is a large area, e.g., feed rate of 0.020 ipr and depth of cut = 1.1 in
- and so power will not be a limiting factor

The power required can also be calculated using the cutting force, Fc, and thrust force, Ft,

power available = Fc V + Ft Vfeed

The machining forces are calculated below.

Deflection constraint:
- the radial force is said to cause deflection and the machining process models can be used to relate feed and depth of cut to cutting force Fc and thrust force Ft
- two machining process models are available; the specific power model used above and the machining forces model
- the cutting forces model will be used since material shear strength data and measured chip deformation (chip thickness) information are available
- model workpiece supported between centers as a simply supported beam
- deflection will be maximum when force applied is at midlength and diameter is minimum so D = 6 in
- deflection, δ (= 0.005) in of a simply supported, circular cross section beam with load P applied at mid length is

$\delta = PL^3 / 48\ EI$

$E = 30E6\ lb/in^2$ is typical value for steel

$I = \pi\ D^4 / 64 = 63.6\ in^4$

$0.005\ in = Fr\ (\ 96\ in\ )^3 / [\ (\ 48\ )(\ 30E6\ lb/in^2\ )(\ 63.6\ in^4\ )\ ]$

Fr = 518 lb

and with the given force relationships

Ft = 2 Fr = 2 (518 lb) = 1036 lb

Fc = 2 Ft = 2 (1036 lb) = 2072 lb

The cutting force and thrust force are functions of feed rate and depth of cut and the shear strength is known

eqn(21-30) $tw = (\ Fc \sin\phi \cos\phi - Ft \sin^2\phi\ ) / \tau$

shear angle was measure – chip thickness ratio – *at feed rate = 0.020 ipr*

at V = 20 ft/min, rc = 0.4: at V = 80 ft/min, rc = 0.6

at V = 72 ft/min, rc = 0.4 + [(0.6 – 0.4) / (80 – 20)][72 – 20] = 0.57

$\tan\phi = rc \cos\alpha / (\ 1 - rc \sin\alpha\ ) = [\ (\ 0.57\ )(\ .985\ )\ ] / [\ 1 - (\ 0.57\ )(\ 0.174\ )\ ]$

$\phi = 32^o$

$tw = [\ 2072\ lb\ (\ 0.53\ )(0.85\ ) - 1036\ lb\ (\ 0.53\ )^2\ ] / 125{,}000\ lb/inb^2 = 0.0051\ in^2$

the data was developed for *feed of 0.020 ipr* so

t = doc = 0.26 in

For the limiting doc = 0.26 in based on workpiece deflection the number of passes is

NP = (change in radius) / depth of cut = [(10 – 6) / 2] in / 0.26 in

NP = 8

The feed speed depends on spindle speed and if the cutting speed is to be maintained at 72 ft/min the spindle speed will have to be changed for the different machining passes. The average diameter during production is 8 in and the average spindle speed is

$V = 72\ ft/min = N\ rev/min\ (\ 8\pi\ in/rev\ )(\ ft/12\ in)$

N = 34.4 rpm

and the feed speed is

S = 34.4 rev/min (0.020 in/rev) = 0.7 in/min

For a half-inch allowance the machining time per pass is

CT = (96 in + 0.5 in) / 0.7 in/min = 137.9 min

It is reasonable to expect that the eight passes will be used to bring the diameter to close to the specified finished diameter and then a finishing cut made. If the finishing cut is made with a feed rate of 0.005 ipr the feed speed is on fourth of the roughing feed speed and the machining time for the finish cut is

CTF = (96 in + 0.5 in) / [(0.7 in/min) / 4] = 551.4 min

For the eight roughing passes and one finish pass the total machining time is

CTT = 8 (137.9 min) + 551.4 min = 1654.6 min

This time is far in excess of the starting estimate of 30-minute tool life and so re-evaluation of the analysis procedure is not needed.

For the 30 minute tool life there will be 1655 min / 30 min/tool = 55 tool changes and a tool change time of

TCT = 55 (time to change tool)

should be added to the total machining time.

CHAPTER 24

Review Questions

1. The flutes form the rake angle of the cutting edges, permit coolant to get to the cutting edges, and serve as channels (elevators) through which the chips are lifted out of the hole.

2. The rake angle of the drill is determined by the helix angle of the drill at the outer extremities - the tips - and gradually changes to a zero rake angle at the inner extremities- the chisel edge. The center core drill shown in Figure 24-4 has a small, uniform rake angle.

3. The helix angle is mostly determined by the material being drilled .

4. The smaller hole provides a guide for the cone portion of the point of the larger drill, of sufficient size so the chisel point of the latter does not contract the workpiece at the start and thus cannot cause the drill to wander. In addition, larger drills can drill faster if the central region of the hole is drilled out first as the negative point is removed from the operation, lowering the cutting torque and thrust considerably. Of course, an extra operation is needed (i.e. drilling the smaller hole first) .

5. <u>Area of the hole</u> times <u>the feed rate</u>, where (f_r)N is the feed rate.

6. Spade drills typically are operated at slower speeds (lower rpms) and higher feeds than twist drills.

7. The hole will generally be oversize as the drill will not be cutting properly and will probably use more torque and thrust.

8. The drill selected to machine the hole generally has a diameter equal to the nominal hole size, so unless the drill has excessively worn, the hole will typically be equal to the nominal size or greater.

9. Two primary functions of a combination center drill are:
(a) To start the hole accurately at the desired location, and
(b) to provide a tapered guide for the drill to be used.

10. The margins bear or rub against the drilled hole and help to guide the drill and prevent it from bending. This rubbing action also produces heat which expands the drill and increases the rubbing and friction which can increase the torque. Proper lubrication is advised to reduce the friction at the walls of the hole.

11. Drift is a particular problem with small drills and deep holes. If the rake angles or the lengths of the cutting edges between the two sides are not equal (this is usually due to improper regrinding of the drill), a force imbalance can cause the drill to drift off line. Hard spots in the workpiece can also cause the drill to move off line, as can a large void

or other material nonhomogeneities.

12. The holes provide a way to get cutting fluid to the cutting zone and so aid in cooling and lubricating the chip formation zone. Such drills are usually employed for long, deep holes.

13. The deeper the hole, the greater the surface area of the drill in contact with the hole wall (the margin) and in contact with the chips coming out the flute. The chips can also pack in the flute and increase the friction and thus the torque.

14. Cutting fluids have lubricants to reduce the rubbing friction between the drill margins, and the chips, as they contact the walls of the hole.

15. Figures 24-6, 24-11, 24-12

16. A gang-drilling machine has several independent spindles mounted on a common base, and usually has a common table. A multiple-spindle drilling machine has several spindles driven and fed in unison by a single powered head.

17. The thrust force (the force 900 to the cutting force or torque) increases with increasing feed. See Figure 24-4.

18. Holding the workpiece by hand may result in broken hands, fingers, or even arms as the workpiece may catch on the drill, particularly at breakthrough, causing the workpiece to rotate at the drill rpm.

19. Centering insures that the drill will start at the right location and not walk off the desired spot. Drilling creates the hole itself. Boring produces a sized and properly aligned hole over the entire length, correcting for any drift problems. Reaming provides for final finish and exact hole size.

20. The slot-point drill reduces the thrust significantly compared to other drills by eliminating the chisel end of the drill. The material in the center of the hole is left undrilled and is periodically fractured away as the drill advances. See Figure 24-4.

21. Spot facing produces a smooth surface normal to the hole axis, as a bearing surface, usually for a bolt head, washer, or nut.

22. Counterboring produces a second hole of larger diameter and with a smooth bearing surface as its bottom, which is normal to the axis of the hole. See Figure 24-22.

23. Reaming provides for excellent hole finish and more exact size.

24. Shell reamers are cheaper, because the arbor is made of ordinary steel and may be used with more than one shell. Only the shells are made from HSS or coated HSS.

25. First, the geometry of a drill for plastics will be very different than a drill for cast iron. It will have much larger helix angles and therefore larger rakes. Also, plastic is a very poor heat conductor compared to cast iron so the frictional heat will remain in the drill, causing it to overheat.

26. The drill should be withdrawn from the hole at frequent intervals to remove the chips and permit the drill to cool. This procedure is called pecking. Ample coolant should be used. See also Figure 29-15.

27. A spade drill requires a much smaller amount of the expensive cutting tool material, and it can be made more rigid than a comparable twist drill. Also, the different point geometries allow these drills to start more accurately. They are really more like milling cutters than drills, and are used for large holes that are not too deep (there are no flutes to carry the chips out of a deep hole) .

28. The drill bit is repeatedly withdrawn from the hole during the drilling process in order to clear the flute of chips. This procedure is invoked whenever the hole depth to drill diameter exceeds 3 to 1. See also Figure 29-15.

29. Recall the equation which relates rpm to cutting speed:

$$V= \pi D N / 12$$

Write the N term as the ratio of drill rate (in./min.) divided by the feed rate (in./rev.)

$N = f_m / f_t$. Therefore, $V = \pi D fm /(12 ft)$

In order to keep the cutting velocity at the drill tips constant (keep V constant), while maintaining the same penetration rate(keep fm constant), the feed rate must increase in proportion to the drill diameter, D.

$$D / f_t = 12 VI (\pi f_m)$$

30. If the feed is too large, one could experience drill fracture up the middle of the drill, chipping of the cutting edge, and rough walls on the drilled hole. See Table 24-7.

Problems:

1. The selection of proper speeds and feeds is the first step in any process analysis or planning. Someone has to decide the cutting parameters. Since this is an indexable-insert drill, Table 24-1 can be used. Otherwise, standard references like the 1(machinability Data Handbook can be used. For 1020 cold rolled steel, the recommended speeds and feeds are 400-550 sfpm and 0.004-0.007 ipr respectively. The allowance would typically be D/2. You might want to use a spade drill here as it is less expensive and ideal for shallow, large-diameter holes - See Figure 24-13.

2. Problem 1 is solved here using a cutting speed of 410 sfpm and a feed of 0.005 ipr. The allowance used is one half of the drill diameter.

CT = (Hole depth + Allowance) / fr N

$CT = (2 +0.75) \text{ in} / \{ (0.005 \text{ in/rev}) [(12)(410)] / [\pi 1.5] \text{ rev/min}\}$
$CT = 2.75 \text{ in} / 5.22 \text{ in/min} = 0.527 \text{ min}$

3. Cutting speed = 200 fpm
N = (12 x 200)1 3.14 x 1.5 = 509 rpm
$MRR = \pi D^2 /4 N f_r$
MRR = (3.14 x 1.52)14 x 509x 0.010
MRR = 1.76 x 509 x 0.010
MRR = 8.99 cu.in./min. or 9 in^3/min

4. HP = (0.9 hp/in^3/min)(9.0 in^3/min) = 8.1 horsepower

5. 1 hp = 0.7457 kW so 1.5 kW -= 2 hp
CS = 200 fpm
N = 509 rpm
$MRR = \pi D^2 /4 N f_r$
$MRR = [3.14 (2)^2 / [4 (509)(0.010)$

Also, $HP = HP_s (MRR)$
So, $MRR = HP/HP_s = (2) (75) / 0.70 = 2.14$
Therefore, $2.14 = 3.14 \times 509 f_r$
$f_r = 0.0013$
f_r (max) = 0.0013 ipr
The process is severely limited to light feeds.

6. $MRR = (\pi D^2 L/4) / (L / frN) = (\pi D^2 / 4) (f_r N)$
$MRR = (\pi D^2 /4) f_r (12 V / \pi D)$
$MRR = 3 D f_r V$

7. Yes. $f_r N$ = feed rate in inches/minute

8. The time to change the drill is spread over the total number of holes drilled between tool changes. The units are time per hole.

9. Spade drill:
Feed rate = 204 x 0.009 = 1.836 in./min.
Holes/mm = 1.836 *1* 3 in/hole = 0.612
Cost/hole = (45/60)1.612 + 160.90/ X (where X = holes/tool)

Indexable-insert drill
Feed rate = 891 x 0.007 = 6.237 in./min.
Holes/mm = 6.237 1 3 in/hole = 2.079
Cost/hole = (45/60)12.079 + 285.80/ X

Equating:
1.225+ 160.90/X = 0.36 + 285.90/X

BEQ:
X= (2.85.80 - 160.90)/(1.225-0.36)
X = 124.90 I 0.865 = 144

If you were doing more than 144 holes, the extra cost of the indexable-insert drill may be justified.

Why is it a “reasonable assumption” to assume that both tools make the same number of holes? The cutting speeds selected here are from tables of recommended speeds, and these tables typically recommend speeds that give 60 minutes of tool life.

Of course, the decision to change from one process to another is made on the basis of many factors in addition to tool cost.

10. a). The tolerances between the holes is based on ± 1 degree Converting degrees into inches, ± 1 degree = (3.14 x 6)/360 = 0.05 inches.

b) Yes, a multiple spindle drill setup can meet this tolerance specification, as such a setup would have a process capability for hole location of ~ 0.030 to 0.050 inches, assuming good drills are being used.

c). Using a drill jig would improve the situation by an order of magnitude to * 0.003 to * 0.005 inches.

Case Study: “Bolt Down Leg on a Casting”

1). The machining difficulty was in starting the drill for machining the bolt hole on the inclined, rough cast iron surface. The drill point would tend to “walk” down the surface, and drill breakage would result due to bending of the drill bit.

2) Assuming the fixture used is accurate, the varying distance between holes is due to the drill walking to a location other than the specified hole location.

3). The failures were in the form of cracks, at location as shown in Figure CS-24. These failures were caused by sharp corners (produced by the counterboring operation) which created a stress concentration when the leg was placed in service and received a moment bending load. The sharp corner was placed in tension, and cast iron is weak in tension. NOTE: This problem could be further aggravated if white cast iron were produced in this region as a result of rapid cooling rates in the thinner leg segments.

4). One solution would be to redesign the part so that the present curved surface is flat. This will eliminate the counterbore and sloped surface from the processing. Another alternative would be to use a start drill, drill and counterbore sequence with the counterbore enlarged somewhat and given a large radius to eliminate the sharp corner. If possible, drilling from the bottom would eliminate the drill “walking”.

5). To stop failures in the field, it will be necessary to eliminate the sharp corner. The same oversize counterbore operation can be manually performed on units in the field if they have not been installed. Those that have been installed and failed must be replaced since cast iron cannot readily be repaired. The company should replace these at no cost to the customer. Other installed units should be repaired (and/or replaced) as rapidly as possible, particularly if failures in the field could lead to personal injury.

CHAPTER 25

Review Questions

1. Since multiple-edge cutters are used material removal rate can be high in milling. If sufficient power and tool strength is available along with allowable surface finish requirements, large feed rates and depths of cut are possible for the multiple cutting edges.

2. In peripheral milling the surface produced is parallel to the cutter axis of rotation, Figure 25-1. In face milling, Figure 25-2, the generated surface is perpendicular to the cutter axis. For mass-production machining material removal rate is the primary concern. Assuming sufficient power is available, wide peripheral milling cutters or large diameter face milling cutters can be used to achieve high material removal rate.

3. If the volume of metal removed is the same and the only difference is the direction of rotation, one would think the power (FcV) would be the same. In climb milling, a component of the cutting force is in the same direction as the feed force which lowers the power requirements on the feed motor.

4. Casting surfaces can be quite hard (due to rapid cooling) or contain hard spots (rapid cooling around grains of sand) as well as abrasive grains (in sand castings). These factors can lead to more rapid tool wear when the cutter tooth comes down into the surface from above versus from below as in up milling.

5. The material removal rate is given by equation (25-5)

$$MRR = W f_m DOC$$

and depends on the width of the cutter of workpiece, W, the depth of cut DOC, and the cutting time, T = length of cut / machining time. Machining time depends on the table speed.

Material removal rate in milling can be viewed as the rate at which the cross section of material being removed is advancing through the workpiece. The area being removed is

(depth of cut)(width of cut)

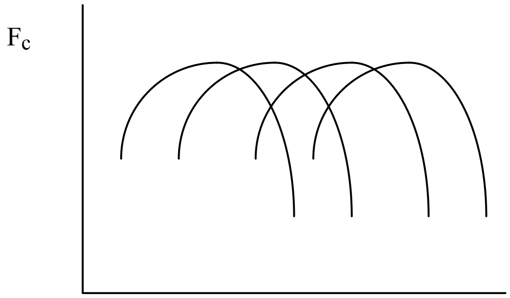
and it is being removed at a speed equal to the speed of the cutter through the workpiece or the

table speed.

6. You would have end milling, and you would be milling a slot.

7. Helical toothed cutters enter the workpiece progressively. Thus, the impact of initial tooth contact is less, and, overall, the cutting forces are smoothed out as two or three teeth are engaged in the work at the same time.

8. Imagine all the F_c patterns superimposed on each other which forms a steady F_c with small scallops.



9. No. The cutting edge on the insert shown in Figure 25-7can produce only a flat, horizontal surface. Production of a T-slot requires machining of horizontal and vertical surfaces.

10. The teeth are staggered so that the teeth can be given a side rake angle in addition to a back rake. This reduces the impact at entry and the cutting forces overall.

11. The table on a plain column-and-knee milling machine cannot be swiveled to permit cutting a helix, as required for the flutes of a twist drill. A special attachment to hold a ball end mill and a universal dividing head can be used as shown in Figure 25-17.

12. The block has to be mounted on the machine table, either directly clamped of in a vise or fixture. This means that the two sides of the block available for simultaneous milling are perpendicular to the machine table. So, two side milling cutters, Figure 25-8 could be mounted on the arbor of the horizontal milling machine as shown in Figure 25-9 and two sides of the block machined.

13. The most distinctive feature of the column-and-knee type milling machine is the combination of the column that supports a movable knee. The knee then supports the saddle and table. In contrast, in a bed-type mill the table is supported by a stationary part of the machine frame.

14. The table can move horizontally, left, and right. The table sits in a saddle, which can move horizontally, in and out. The saddle sits on the knee which can raise and lower the saddle-table assembly.

15. The rate ring limits the amount of deflection of the stylus. See Figures 25-16.

16. The vertical spindle Bridgeport was (and still is) a very versatile machine, and it was very accurate and precise.

17. The dividing head uses a worm-gear reduction assembly. See Figure 25-17. When you turn the crank one revolution, the spindle on the other end rotates 1/40 of a revolution. The index plate is designed such that a workpiece can be rotated through almost any desired number of equal arcs.

18. Connecting the input end of a universal dividing head to the feed screw of the milling machine causes the workpiece to be rotated a controlled amount as the table moves longitudinally. see Figure 25-17.

19. The hole-circle plate (or the index plate) is to control the rotation of the workpiece through a desired angle. See Question 20.

20. The only hole circle that can be used is the 27-hole circle. All others do not give a whole number of holes. The calculation is (40 x 27)118 = 60 holes. Thus a tooth gap would be milled and then the gear blank rotated by cranking through 60 holes or about 2.22 revolutions of the crank, and then the next tooth gap milled. The setup is shown in Figure 31-7 for cutting helical gears.

21. As in all machining processes, the cutting speed (V) is selected based on the cutting tool material and work material. The feed (f_t) is also selected in terms of how much each tooth will remove during each pass over the work -- the feed per tooth (See Table 25-1). The RPM is computed from the selected speed by:

$N = (12 \times V)/(3.14 \times D)$ where D is the cutter diameter

Then, the table speed is calculated from:
$f_m = f_t \, n \, N$ where n is the number of teeth in the cutter .

22. See answer to question 24. The important aspect of milling feed is the amount of material removed per cutting edge and this depends on spindle speed, table speed and number of teeth.

23. The large cutting forces in slab milling must be considered. These forces tend to dislodge the part in slab up milling. In vertical spindle milling, the chip engagement (chip thickness) tends to stay more uniform and overall the cutting forces are not as large.

24. A cutting speed of 50 to 100 fpm and a feed per tooth of 0.005 to 0.010 ipt are quite reasonable values. The student must go to a handbook or similar source to find the values. See also Table 25-1.

Problems:

1. $V = \pi.D\,N / 12$, so
$N = 12\,V / (\pi D) = [\,12\,(200)\,] / (3.14 \times 8)$
$N = 95.5$rpm
$f_m = n\,N\,f_t = 10\,(95.5)(0.01) = 9.55$ ipm

2. $N = 12\,(70) / [\,(3.14)(6)\,] = 44.5$ rpm

$f_m = n\ N\ f_t = 8\ (\ 44.5\ )\ (\ 0.012\ \text{ipt}\ ) = 4.28\ \text{ipm}$

CT $(L + All) / f_m = (12 + 3 + 3) / 4.28 = 4.2$ min.

3. MRR = Vol / CT = $W\ t\ f_t = 5\ (\ 0.35\ )\ (\ 4.28\ ) = 7.49$ cu.in./min.

4. HP = MRR (HP_s)= 7.49 (0.67) = 5 horsepower

5. The axially symmetric sections of the part would be made in lathe turning operations. The left end face would probably be produced in a facing cut on the lathe.

Flat surfaces can be milled and for the slot some options are:

Process	Tool	Cutting Conditions	
Slotting Figure 25-8	width equal to slot width	- spindle speed - depth of cut - table speed	- slotting cutters stiffer than end mills - slotting typically done in one pass
End milling Figure 25-3	diameter equal to or less than slot width	- spindle speed - axial depth of cut - table speed - radial depth of cut for finishing pass if diameter less than slot width	- end milling may require more than one pass
End milling on a turning center Figure 23-14	same as end milling		- use lathe C-axis Question 27, Chapter 23 - turning and slotting on one machine

6. The first step in the problem is the selection of a cutting speed. From Table 25-1, the student might select anything from 40-130 sfpm. Let's say 120 sfpm is selected.

For face milling:

RPM of cutter = [(120)(12)] / [(3.14)(8) = 57.3 rev/mm

Table feed, $f_m = n\ N\ f_t$ = (10)(57.3)(0.010) = 5.73 in/mm

CT = Machining time where A = D/2

$= (L + A) / f_m = (18 + 4) / 5.73 = 3.83$ mm/part

Setup time (a one time operation) = 60.0

min.

Load and unload fixture (very conservative) = 2 min

Total time for one part is = 65.83 min

Cost to make one = (60.00 / 60)(33.25 / 1) + (33.25)(5.83) / 60 = \$37.03/part

Cost to make 10 = (60.00 / 60)(33.25 / 10) + (33.25)(5.83) / 60= \$6.55/part

Cost to make 100 = … = \$3.56/part

For shaping, use V= 120 sfpm (high but used for comparison):

$V = 2\ 1\ Ns / 12\ R_s$

where is the fraction of the total stoke during which cutting occurs and is typically about $R_s = 200^o / 360^o = 5/9$, Equation (26-1)Figure 26-1

l = 6 (Equation 26-3)

$N_s = 66.6$ This is RPM of the bull wheel (See Figure 26-1)

CT = 18/ [(66.6)(0.015)] = 18 min/part (no allowance)

Cost to make one = (10 / 60)(25.25 / 1) + [(25.25)(18.00)] / 60 = \$12.77/part

Cost to make 10 = = \$7.99/part

Cost to make 100 = ... = \$7.61/part

The shaper is cheaper when the lot size is very small. At some higher number of parts, the milling machine will be the better choice. Note that the reduction or elimination of setup time could make milling the choice even for a lot size of one.

7. For milling, the percentage of time spent in nonmachining activities is

[60 + (2)(10)] / { [(5.83)(10)] + 60 } = 80 / 118.3 =or 67.6%

For shaping, the percentage of time spent in nonmachining activities is

[(10 + (2.0)(10)] / [(18.0)(10) + 10] = 30/191 or15.8%

8. Figure 25-10 and equation (25-2)

$f_m = ft\ N_s\ n$

$V = 125$ ft/min = Ns rev/min (π 5 in/rev)(ft/12 in)

Ns = 95.5 rpm

f_m = 0.006 in/tooth (95.5 rev/min)(8 teeth/rev) = 4.58 in/min

9. MRR = W d fm = (2)(0.5)(4.58) = 4.58 cu.in./min.

Up milling is shown in Figure 21-5.

10. $N = 12\,V / \pi\,D = (\,12\,)(\,500\,) / (\,3.14\,)(\,6\,) = 318$ rpm

$f_m = n\,N\,ft = (\,8\,)(\,318\,)(\,0.010\,) = 25.44$ inch/min

$CT = (L + \text{Allowances}) / f_m$ where Allow $= \{\,35\,(\,6 - .35\,)\,\}^{1/2}$
$CT = (12 + 1.4) / 25.44 = 0.53$ min

This cutting time is considerably less due to the high cutting speed for carbide cutting tools. The MRR is greater than for face milling with HSS tools.

Case Study: no case study

CHAPTER 26

Review Questions

1. The feed is built into the teeth of the broach -- the rise per tooth is the feed. It is also as close to orthogonal machining as one finds in industry.

2. The saw blade has no “step” or rise per tooth between successive teeth, so a saw blade is not a broach.

3. These machines use straight line movement and the feed is built into the tool, so the machine tools are much simpler, mechanically speaking.

4. Why broaching is suited for mass production -- Accuracy and precision are built into the process. No machine adjustment is needed after the initial setup. The rapid, single stroke or one pass completion of parts leads to easy A(2) or A(3) levels of automation. Roughing and finishing are built into the same tool.

5. The pitch or the distance between each tooth. This is needed to determine how long the broach must be to remove the material. See question 6.

6. Because all metal removal (depth of cut) is built into the tool, the design of the tool must relate to the amount of material to be removed, chip thickness per tooth, tooth-spacing (pitch and gullet size), and the length of available stroke in the machine.

7. Methods for reducing force and power requirements in broaching are rotor-tooth design, double-cut construction, and progressive-tooth design .

8. The rotor-tooth broach would be longer.

9. In designing a broach, the distance between the teeth (the pitch) and the shape of the gullet (the radius) must be such that the chip can be fully contained and allowed to curl properly, so that the chips do not rub the machined surface.

10. Since the entire surface is machined in one pass, the operation is very fast without resorting to high cutting speeds. High speed would consume more power and also generate more heat, thereby greatly shortening the life of the broach. Because these tools are usually quite expensive, they must have a long life to make the cost per part low and the entire process economical.

11. Shell-type construction reduces the cost of the broach because the main shaft can be made of inexpensive steel, and also the shaft can be used with various sizes and types of shells. Also, worn or broken teeth can be removed and replaced and the entire broach does not have to be replaced.

12. Because the cutting speeds are low, carbides are not needed. In addition, the cutting

forces tend to put the broach tooth geometries in tension, where carbide is not as strong and reliable as steel. Carbides and ceramics can be used for the burnishing rings (i.e. finishing teeth).

13. TiN-coated HSS broaching tools will cut with less power and lower forces because of the lower tool/chip interface friction condition. The lower interface friction condition produces larger shear angles and lower shear forces. The TiN-coated tools also last longer.

14. It is easier to feed pull-up machines, and the work falls free after the operation is completed.

15. The roughing teeth are shorter and varying in height. In finishing broaches the finish teeth are of the same height.

16. No. There would be no place for the chips to go, and the first tooth on the broach would have to be full size, permitting no feed being built into the tool.

17. Such sockets usually have a recess, larger than the finished size of the broached hole, beyond the end of the surface to be broached. Such recesses can be made by forging, casting, or machining.

18. Sawing is relatively efficient because only a small amount of material is formed into chips.

19. (1) Tooth spacing controls the size of the teeth, (2) the spacing determines the space into which the chips must be contained, (3) tooth spacing determines how many teeth are in contact with the work (cutting) at a given time. Tooth spacing is the same as pitch in broaching.

20. The tooth gullet is the space between the teeth. It must be large enough to hold all the chips from a single pass over the workpiece.

21. “Set” is the manner in which the teeth are offset from the centerline of the saw blade so as to produce a cut that is slightly wider than the thickness of the blade. The width of the cut is called the "kerf". See Figure 26-12 and 26-13.

22. Set is the offset of the tooth corner from the plane of the saw surface, Figure 26-12. Cutting at the tooth corners determines the kerf and so kerf is determined by saw thickness and set. In the ideal case for a straight set saw (Figure 26-13) the kerf is equal to the saw plate thickness plus twice the tooth set.

23. If the band were hardened throughout its width, it would be brittle and would break when flexing around the guide wheels.

24. Circular saws are limited in the depth of cut that can be made with them. Also they

are more expensive than bandsaws. Advantages: they can be made stronger, more accurate cuts can be made, and they have teeth made from a variety of cutting materials.

25. Bandsawing machines can operate at higher cutting speeds and cut continuously (no reciprocating) and are thus able to make the same cuts faster than hack saws.

26. A hole is drilled into the workpiece. The bandsaw blade is broken, inserted into the workpiece, and welded. The cuts (holes) are then made. The blade is broken and removed. This process is good for small volumes of parts.

27. The machining time Tm is the distance the saw edge moves divided by the rate of movement.

Tm = distance / speed

For a horizontal saw cutting a 3 inch diameter round section with downfeed rate of f_d

$Tm = 3 \text{ in} / f_d$

The downfeed rate is probably not known with any precision.

Attaching a value to the feed rate is difficult. If there is a power feed on the saw then the feed rate can be set to a specified value. Establishing the value is not straightforward. The cutting speed along with the feed rate will determine cutting forces, cutting zone temperature and tool wear. Starting with a desired tool life the effects of cutting speed and feed rate would have to be determined and the feed rate set. The length of cut along the work varies over time since the saw is moving through a circular cross section. This means that the best feed rate will vary during the process.

If the feed is provided by gravity (or gravity and an additional load) the estimation of the feed rate is even more complicated. A force balance can be set up in which the downward gravitational force is balanced by the cutting forces. In a two-dimensional model the cutting force and thrust force act to separate the work material and balance the gravitational force. It seems unlikely that the force situation could be modeled accurately enough to be able to predict the rate of advance of the cutting edges in the feed direction into the work material. And, the net force and perhaps forces at each tooth vary during cutting since the length of work being cut varies since the workpiece has a circular cross section.

28. If feed is by gravity, the feed force is constant. As the cut proceeds, the length of the cut increases. The force resisting the feed increases in proportion to the length of the cut. Thus, the feed rate slows down and speeds up in proportion to the diameter of the round bar.

29. The file is much wider than the saw blade and the teeth may have negative rakes, but these are the only real differences.

30. A safe edge on a file means that the file has no teeth on the edge. The user is less likely to be injured while using it and metal won't be filed from undesired locations.

31. On a band filing machine, the cutting motion is continuous, i.e. no reciprocation.

32. The teeth on a rasp-cut file are formed by being plastically deformed outward from the body of the file, whereas those of other types are formed by cutting.

33. In a shaper, the tool reciprocates and the work feeds perpendicularly to the tool motion. In a planer, the work reciprocates and the tools feed perpendicular to the work movement. Both make straight line cuts. Shapers are best suited for flat surfaces on small workpieces in small quantities as in the tool room or for special one-of-a-kind jobs. Planers are used for large workpieces. Because the workpieces machined on planers are large and heavy, it is difficult to reciprocate the work and table rapidly and to block the workpiece so as to hold them against the high acceleration and deceleration forces occurring at the ends of the strokes. It is good practice to cut on a shaper with as little overhang of the ram arm as possible. The arm is a moving cantilever beam and the cutting forces will greatly increase the amount of deflection in the arm as the length of overhang is increased. The planer does not have the cantilever beam design of the shaper, so it can make long straight cuts without suffering deflection problems, and therefore can take advantage of the cutting time saved.

34. Shaper feed is in millimeters or inches per stroke, while milling is in inches per tooth. In shaping, the cutting time is relatively slow and the setups, while usually simple, can take as long as the setup on a milling machine, which will have a faster cutting time. Thus, milling is generally able to show an economic advantage over shaping and has about the same or better precision. See Problem 6 in Chapter 25.

35. On planers, two tables are often used, so one is being used while the other is machining. On planers, the setups and cuts are designed so that cuts are made during both the forward and return strokes, while on shapers, cuts are made only on the forward stroke and feed occurs after the tool has returned. (On both shapers and planers, feed is in inches per stroke.) on planers and shapers, the table cannot be reciprocated at high speeds, so cutting speeds are relatively low and cutting time is large. On planers, simultaneous cuts can reduce the cutting time. These methods cannot be used on a shaper.

Problems:

1. The length of the cut times the feed is 12 x 0.0047 = 0.0564 cu.in. per gullet. This would be the minimum cross section of the gullet. The gullet would have a larger cross section than this to allow the chip to curl.

2. The formula used to estimate the pitch is an empirical expression based on English units, the metric units must not be used. $P = (Lw)^{1/2} =$).35 (17.75 $)^{1/2}$ = 1.47 inches. The number of teeth needed is 0.25 / 0.004 = 62.5 teeth. The length of the roughing section is then 63 (147) = 92.6 inches.

3. For gray cast iron, HP_s = 0.5 HP/ cu. in./ min

10 m/min = 32.75 ft/min
The horsepower needed per tooth:
HP = HP_s K MRR = .5 (12) (0.004) (3) (32.75)
HP = 4.716 horsepower

The number of teeth in contact: = 17.75 / 1.47 = 12

The maximum HP is = 12 x 4.716 = 56.59 hp, a rather large value, suggesting that the broach be redesigned if the machine does not have sufficient horsepower.

4. The approximate force per tooth can be estimated by:
HP = Fc V/ 33,000. Therefore, $F_c \simeq$ 4.716 **(** 33,000) / 32.75 = 4752 lbs per tooth.
For 12 teeth, this requires 57,024 pounds. This is very large. The student should be concerned.

5. The cutting speed selected should be around 55 m/min. = 180 ft/mm. The pitch is 0.05 inch or 0.00417 ft.
The number of teeth which pass over the workpiece per minute =180 / 0.00417 = 43165.5 teeth/min.
The CT = 6/ (43,165.5)(0.0001) = 1.39 min with no allowances.

6. Allowable pull = (A_{min})(Y.S.) / S where S = factor of safety
Allowable pull = ((πD^2 / 4 - DpW)(200,000)/ 1.25
where DpW = the area of the slot in the pull end.

7. First determine the Stroke Ratio, R_s = 200 / 360 = 0.55
N = 12 V R_s *I* 2 1 where we let 1 = 2 L to allow for overrun at both ends of the stroke and allow the ram to reach full cutting speed before it enters the workpiece
N = 12 **(** 25)(0.55) / (2)(4) = 165/ 8 = 20.6 rpm or 20.6 bull wheel strokes per minute

Cutting time = CT = W/(N_s f_c) = 7/(20.6 x.1) = 3.39 min.
Note that shapers are rather slow.

Metal removal rate = MRR = L w t / CT = [(4)(7)(0 .25)] / 13.39 = 2.06 cu. in./min.

8. R_s = 0.55; N_s = 11.78 for 1 = 7 inches; CT = 3.39 minutes Thus, this setup does not take less time, but requires a much greater overhang on the ram and a possible loss of accuracy and precision due to deflection.

N_s = 12 V R_s / (2 1) = (12)(25) (0.55) / (2)(7) = 11.78
CT = w / (N_s f_c) = 3.39 min

9. Let V_{avg} = average velocity of the ram produced by N rpm of the crank with a R_s stroke ratio.
V_{avg} = distance / time = length of stroke / time of stroke
V_{avg} = 1 in / [(1/Ns)(R_s) min

Since $V = 2\ V_{avg}$

$V = (2)(1)(Ns)$ ft / $(12)(R_s)$ min

10. For $R_s = 220 / 360 = 0.611$

$N_s = [(12)(120)(0.61)] / [(2)(10)] = 43.92$ strokes/min

or $N_s = [(6.11.1)(36.6)] / [(2)(254)] = 44.03$ (metric units)

where $611.1 = R$ (1000 mm/meter)

so, $N_s = 44$ strokes/min

11. $N_s = (12\ V\ Rc) / (2\ 1)$ but $R_5 = 2/3$ for hydraulic shapers with a 2:1 cut to return ratio and = L + 1 inch allowance instead of 2.

Therefore:

$N_s = 8\ V / 1 = [(8)(150)] / (8 + 1) = 133.3$ strokes/min

$CT = W/(Ns\ f_c) = 10 / [(133.3)(0.020) = 3.75$ min.

12. MRR = L W t / CT = (10)(8)(0.25) / (3.75) = 5.33 cu.in./min.

13. Assuming gray cast iron has a specific horsepower of 0.30 HP/ cu.in./min,

$HP = HP_s$ (MRR) = (0.30 hp/in^3/min)(5.33 cu.in./min) = 1.59 HP

14. Power available = Power required for machining

10 hp (0.75) = (0.67 hp / in3/min) (material removal rate)

7.5 hp = (0.67 hp / in3/min)(0.25 in)(180 ft/min)(12 in/ft)(doc)

doc = 0.021 in

15. Planing: Problem Definition: For a one tool planer, cutting occurs and then a return stroke, say at the same speed. The planing action starts off the edge of the workpiece (say 25 mm, which is related to the tool size) and moves off the other edge. So the "surface machined" is (25 + 305 + 25) mm wide. The tool moves the length of the work piece (305 mm) and returns so there are two stokes per each cutting pass. Tool acceleration to cutting speed and deceleration and reversal times will be ignored. There is an allowance at both ends, say 1/10(workpiece length) = 30.5 mm. The length of travel is then 2(366 mm) per cutting stroke. The tool is fed across the workpiece at 6.35 mm/stroke. Cutting speed is 180 ft/min = 55 m/min.

Machining time =(time per tool pass)(number of tool passes)

Process parameters

work length plus allowance = 366 mm

tool travel per feed step = 2(366 mm) = 732 mm

time per feed step = time per stroke = travel / cutting speed

= 0.732 m / 55 m/min = 0.013 min = 0.8 sec

number of feed steps = (width of cut surface + allowance) / feed per stroke

number of feed steps = (355 mm / 6.35 mm/stroke) = 56 strokes

Tc = (56 feed steps)(0.8 sec/feed step) = 45 sec

Milling: Process: A more than 305 mm = 12 in long peripheral milling cutter seems unreasonable, so a face milling operation, Figure 25-2 is planned. The realistic choice is probably use of a large diameter, carbide insert face mill, Figure 25-7. The work can be machined on both forward and return passes.

Since the problem asks for comparison of machining times for high speed steel, an 8-cutting edges, 4 inch diameter face mill will be used with HSS inserts. The central issue is choice of bite per tooth. Table 25-1 suggests feed of 0.005 – 0.015 in/tooth and cutting speed of 60 – 100 ft/min. Choosing central values of chip load of 0.010 in/tooth and cutting speed of 80 ft/min and

- mill step over distance is typically 1/3 –1/2 cutter diameter, choose 1/3 diameter,
- indexing (step over) time between cutting passes is at rapid traverse speed and will be ignored,
- allowances at each end of work are 1.5(cutter diameter),
- cutter starts off end of work by 1.5(diameter) and is set for initial pass so cutter axis is set for a 1/3(diameter) first pass and 8 passes are required, i.e., 12 in / (4/3) in/pass less the starting point position that is one step over,
- to pass completely off of work 3 additional passes are need, i.e., 1/3(diameter) step over,

T_c = length of tool travel / table speed

length of tool travel = (length per pass)(number of passes)

length per pass = work length + 2 (allowance)

length per pass = 12 in + 2 [1.5 (cutter diameter)

length per pass = 12 in + 2 [6 in] = 24 in

number of passes = 11

length of tool travel = (24 in/pass)(11 machining passes) = 264 in

table feed speed, v, for the selected bite per tooth

For the 8-edge cutter and bite per tooth = 0.010 in/tooth

(table speed)(time for 1/8 revolution) = 0.010 in/tooth

$(v) [(1/8 \text{ rev/tooth}) / (N \text{ rev/min})] = 0.010$ in/tooth

$V = N \text{ rev/min} (\pi 4 \text{ in/rev})(\text{ft}/12 \text{ in}) = 80$ ft/min

$N = 76.4$ rpm

$v [(1/8 \text{ rev/tooth}) / 76.4 \text{ rev/min})] = 0.010$ in/tooth

$v = 6.1$ in/min

Time per pass = 24 in / 6.1 in/min = 4 min which is much larger than the planing stroke time of 0.8 sec.

T_c = 264 in / 6.1 in/min = 43.3 min

Case Study: “The Socket with the Triangular Hole”

After getting over your initial reaction to "who the heck designed this part?" and "I don't think that this part can be made!", you would find that there are really many ways to make the part. Clearly, it could be made by powder metallurgy or investment casting. It could be made in two pieces -- a flat disk and cylinder with a broached triangular hole -- with an appropriate joining process, perhaps friction welding. The hole could be machined into the cylinder by EDM, ECM, or ultrasonic machining. With the latter three approaches, a hole should initially be drilled of a diameter about 5 and 1/2 mm in the center of the cylinder. Two EDM tools are used: a triangular hollow tool followed by a solid triangular tool to finish the hole to size. One might want to follow initial drilling with end milling, to make the initial hole flat bottomed. Drilling and milling before EDM, ECM, or ultrasonic will greatly enhance the overall processing time.

If you can get the designer to relent a bit on the 0.8 mm radius, you can use the Watts method of drilling angular holes. The Watts method consists of a Watts Patented Pull-floating Chuck, Angular Drill, and Guide Plate and is kind of a Wankel engine that machines. Triangular, square, and hexagonal holes

can be drilled on conventional lathe, mill, or drill press equipment. Again, a regular round hole is drilled first in harder metals as a lead hole, but this probably won't be necessary of aluminum is selected as the metal for the part. These tools are sold by the Watts Bros. Tool Works, Inc., Wilmerding, PA.

It may be possible to make this part by backward impact extrusion, since the material is aluminum and the part is not that large. The final selection as to which processes are most economical would likely come down to impact extrusion, powder metallurgy, and investment casting. The quantity here is quite large and all of these processes can be automated. Die life may be a problem for impact extrusion because of the small radius that will have to be placed on the punches to get those 0.8 mm corners .

CHAPTER 27

Review Questions

1. Abrasive machining processes. Grinding, honing, lapping, and ultrasonic machining are four processes that use abrasive grits for cutting tools.

2. Attrition is caused by the dulling of the edges and flattening of the grits, and the glazing of the wheel surface that is caused by the abrasive wear action of the grits. The grits are pulled out of the surface of the wheel as the forces on the worn grits increase.

3. Friability is the ability of the grits to fracture and expose new cutting edges, which results in more cutting surfaces continuously becoming available.

4. The smaller the grit size, the better the surface finish.

5. Both are quite hard, but aluminum oxide is tougher than silicon carbide, and is less reactive with materials. Therefore, it is the more general purpose abrasive.

6. CBN is harder and does not react with certain work materials at the elevated temperatures of grinding (particularly steel).

7. The common bonding agents are vitreous ceramics, plastics, rubber, and silicate of soda.

8. Grade expresses the strength of bonding material. It controls how freely grits will pull out of the wheel – the stronger the bond, the more difficult it is for grits to pull out of the wheel.

9. Structure refers to the spacing - how far apart are the abrasive grains. An open structure has widely-spaced grains compared to a dense structure. Either structure could use a high strength bonding material.

10. In crush dressing, the grains in an abrasive wheel are crushed, oz broken, by means of a hardened roller, to expose sharp edges and, usually, to impart a desired contour to the wheel. It is the easiest practical way to impart a desired contour to an abrasive wheel. See Figure 27-14.

11. A glazed wheel is one in which the grits are worn flat and polished; whereas, a loaded wheel is one in which chip material has packed in between the grains so that the entire surface of the wheel is smooth, rather than just the tops of the grains.

12. Grinding is a mixture of cutting, plowing, and rubbing processes, all occurring at different places at the same time. Grits with large negative rakes may just plow a groove in the surface rather than form a chip. Other grits may simply rub or burnish the surface (depth of cut very small or cutting edges very rounded or worn) . The grits that are

making chips do so in exactly the same manner as a single point cutting tool.

13. In dressing a grinding wheel, dulled abrasive grains are broken (thereby exposing sharp edges) or are pulled from the wheel to expose new grains.

14. In abrasive machining, heavy feeds and large abrasive grits are used to rapidly remove material. Cutting dominates the process but, fundamentally, it is not really different from grinding.

15. The grinding ratio is the ratio of the volume of metal removed versus the volume of wheel lost (abrasive material used) or worn away (attrition).

16. Feed is controlled by tilting the regulating wheel. The angle of inclination provides a force in the feed direction. The part feeds at
$F = dN \sin\theta$ (Equation 27-1)

17. There must be spacing between the grains to make room for the chips. To a certain extent, spacing or structure, along with the grain size, also dictates the surface finish.

18. The cutting fluid carries away the chips and keeps the workpiece and grinding wheel cool. The very high grinding speeds convert considerable energy into heat energy. The grinding area is very limited and the localized heating can easily damage the workpiece .

19. The wheel is fed radially into the rotating workpiece.

20. The dust resulting from grinding contains fine, hard abrasive particles which can become airborn and get embedded in the softer, moving parts of other machines, causing these parts to act as laps, which thereafter would ruin the accuracy of the machines. In manufacturing cells, where grinders are often placed near other machines, it is important to put good dust control devices on the grinders and use lots of cutting fluids.

21. The purpose is to produce a surface which is free of residual stresses or a surface in which tensile and compressive stresses are nicely balanced. Cutting results in residual tension, while rubbing and burnishing produce residual compression.

22. Wheel speed is reduced, the down feed is reduced, and sulpherized cutting oil is used for low stress grinding. See Figure 27-11.

23. The larger the grains, the fewer that can be packed into a given area, so on the average, fewer grains will contact the workpiece during a pass.

24. Centerless grinders are faster, have better work support, require very little operator skill, have the possibility of continuous infeed, give excellent size control, and can be automated with regard to part loading and unloading. wheel adjustment for wheel wear can be automatic as well.

25. Electron microscopes are roughly analogous to light microscopes with electrons, rather than light, used to create the image. This requires an electron source, electromagnetic lenses and operation in vacuum. In scanning electron microscopy secondary electrons emitted from the surface under observation are used to form the image. An explanation of these general ideas is provided at *www.mos.org/sin/sem/intro.html*

26. The grinding forces are much lower than the forces used in milling and usually are directed downward into the vacuum chuck. Killing has larger forces, and the force may be directed up, away from the vacuum check, as in up milling.

27. The typical grinding operation makes many passes at very small depths of cut and relatively large feeds. In creep feed grinding the depth of cut is large, the feed is very slow, and the cut is often made in one pass over the workpiece. Creep feed grinding is grinding at very slow feed rates. See Figure 27-20.

28. In lapping, the abrasive grits become embedded in the soft material of the lap. This is referred to as "charging the lap". The material to be lapped is machined or rubbed by the abrasive grits, not the soft material of the lap.

29. In honing stones, additional materials, such as sulfur, resins, or wax are added to the bonding agents to modify the cutting operations. The grits themselves are very fine or small.

30. "Charging" a lap is loading it up with abrasive materials.

31. Honing is intended to smooth and size the hole, not to alter the position or angle of the axis, so a rigid setup is not what is desired in this tool.

32. In most coated abrasive belts, the abrasive grains do not pull out so as to expose new, sharp grains. They thus have no self-sharpening action.

33. The chips are small, of the same order of size as the abrasive grits. So, the bottoms of the individual chip slid on one abrasive grit. If the bottom of the chip appears smooth it is because the abrasive grain surface was smooth or the resolution of the microscope was insufficient to show the features on the chip bottom surface.

With the 4800x magnification including enlargement of the photograph from the original micrograph the chip thickness is a measured chip thickness on the photograph divided by 4800. The upper left potion of the chip labeled “T” shows the top and side of the chip. The chip thickness in the photograph is about 7 mm and so the actual chip thickness is about 0.002 mm = 2 μm.

34. The angle is a function of the rate of rotation (rpm) of the honing head versus the rate of oscillation.

35. Four major causes of grinding accidents are:
a) operating at too high of a rpm.
b) operating a wheel that has been dropped or struck so as to produce a crack
c) operating the wheel improperly
d) operating the wheel with the safety guards removed.

36. A surface grinder resembles a horizontal spindle milling machine.

37. A residual stress is a stress that is left in a piece of material after external loading is removed from the material.

38. Infeed and crossfeed usually refer to surface grinding operations, Figure 27-19. Infeed is the distance that the wheel is advanced into the workpiece in the direction perpendicular to the work surface. Crossfeed is the distance that the wheel is traversed parallel to the work surface and perpendicular to the infeed and grinding directions between grinding passes.

Problems:

1. a) The wear of the stairs is produced by the hard particles of material embedded in the soles of people's shoes. The leather or rubber soles are softer but act as laps, charged with fine grits of abrasives. The bottom of the stairs are nearest the outside.
b) The grits get dull as the stairs are ascended so less stair wear occurs at the top than the bottom. Grits are removed from the soles while ascending. Soles get charged while walking outside the building, not inside the building.

2. The small particle will tend to have fewer defects (dislocations) per unit volume and will thus act stronger. The small particle may also be more work hardened than the bulk material.

3. In surface grinding, the MRR is controlled by the table feed, V_w. See Table 27-5.

For a 1-inch wide wheel removing 0.004 inches of metal,
MRR = (12) (150) (0.004) (1) = 7.2 in^3/min.if the entire face of the wheel were engaged.

However, the wheel is crossfed over the workpiece at a rate of 0.060 in per pass, so the MRR = (7.2)(0.060) = 0.43 in^3/min.

Generally speaking, MRR's in grinding are an order of magnitude less than other multiple-tooth machining processes.

Case Study: “Aluminum Retainer Rings”

Several possibilities exist here:

One method might be to purchase tubing with the correct internal diameter or wall thickness (if possible) and slice the rings of f the tube with a sawing or cutoff operation. This would be followed by a milling operation to cut the opening in the ring. A tumbling operation might be needed to eliminate sharp edges and burrs on the ring. If tubing of the proper size cannot be located and additional machining of the OD and ID are needed, this method will not be the most economical.

A very economical procedure would be to purchase this material (5052 aluminum half hard) in a wire form, and convert the wire into a rectangular shape by pulling it through a device called a Turks Head. A Turks Head is a roll forming device with four rollers which form the four sides of the needed rectangle. The wire would thus be given the 1.60 x 2.36 cross section. Next, a round mandrel would be made. The mandrel diameter would be something less than the 89,71 ring diameter. The rectangular wire would be wound up on the mandrel like a big spring, forming a continuous coil. This operation would be done on a lathe and could provide the pulling means to pull the round wire through the Turks Head. The mandrel, with the coil clamped in place, is then placed in a milling machine and a slitting saw is used to form the individual rings. Some calculations (regarding springback) and experimentation would be necessary to determine the correct diameter of the mandrel and the width of the slitting saw so that, when the coil is cut, the individual rings will come out with the appropriate diameter with the correct opening.

If an extrusion press is available, the square wire can be formed by extrusion, since a rectangular extrusion is fairly easy to do in aluminum, and the dies might not be overly expensive. However, if the die costs exceed $500, it would be advisable to go to the Turks Head method, as Turks Heads do not cost much more than this and can be adjusted and used for other applications at a later time.

CHAPTER 28

Review Questions

1. Four types of NTM processes are: chemical, electrochemical, mechanical, and thermal.

2. The materials used in the future will be harder and stronger, making traditional machining more difficult. A large amount of energy in metal cutting goes into heat which can cause damage to the material of the part. Delicate workpieces are extremely difficult to machine by traditional methods.

3. Material removal rates on Nontraditional machining processes are typically much lower than in conventional metal cutting with some notable exceptions. The exceptions are when MRR = volume removed / time = (penetration rate)(area being machined) becomes large due to very high penetration rates or, more likely working of a large area. For example,
- in cutting operations where penetration rates may be comparable to or larger than mechanical processes such as sawing, and
- in processes with small penetration rates but that act over large areas such as is possible in electrochemical milling.

Material removal measures are given in Table 28-1.

	Feed rate (mm/min)	
Process		
Chemical milling Photochemical milling	0.013 – 0.076	MRR = (penetration rate)*(area)
Electrochemical machining	2.5 – 12.7	MRR = (penetration rate)*(area)
Abrasive-jet machining	76	
Abrasive waterjet machining	15 - 450	MRR = (penetration rate)*(area) area ~ kerf -> small
Ultrasonic machining	0.5 – 3.8	small penetration, small area
Waterjet machining	250- 200,000	high penetration, small area
Electrical-discharge machining	0.5	MRR = (penetration rate)*(area)
Electon-beam machining	30 - 1500	very small area
Laser-beam machining	100 - 2500	small area
Plasma arc cutting	250 - 5000	high penetration, kerf can be large
Wire electrical discharge machining	100 - 250	MRR = (penetration rate)*(area) area = wire-work area -> small

4. The six basic steps are: (1) preparation of the artwork, (2) photographic production of

the negative, (3) application of the emulsion to the workpiece, (4) exposing the workpiece to light passing through the negative, (5) developing the exposed workpiece, and (6) application of the reagent to the workpiece.
In chemical milling, one often wants to selectively etch certain parts of the material. The material is coated with a coating, called a resist, which, when exposed to certain wavelengths of light, chemically changes and hardens or sets. The unexposed region can be washed away, leaving an exposed region which can be chemically milled or etched. The resist or mask protects the rest of the surface. This technique allows for complex, minute, detailed masks to be developed. The technique is used in microelectronics.

5. Spraying continuously washes away the debris and keeps the process progressing evenly.

6. Very thin parts can be blanked.
Parts with varying thickness can be blanked.
Many parts can be blanked at the same time.
No press or expensive die sets are needed.
No tools to wear out.

7. The area having the greatest depth is exposed to the reagent first. Next the resist is removed from the area having the next greatest depth, and the work is again exposed to the reagent. This step-by-step procedure is repeated as often as desired.

8. No. The ratio of the depth to width is too great.

9. The width of the groove = width of the maskant + (213) depth. The width of the mask should therefore be 21 mm.

10. Yes, but not very satisfactorily. There would be too much variation in the geometry and metallurgy in and adjacent to the weld.

11. Tapered sections are produced by slowly withdrawing the workpiece vertically from the chemical bath.

12. Deburring by vaporizing burrs and fins on cast and machined parts.

13. ECM is not really related to chemical machining since ECM is a deplating process that utilizes an electrolytic circuit with an external power supply.

14. Hardness is not a factor in ECM and should have no effect on MRR.

15. The current density in a material is obviously a function of the geometry of the part. Small projections, corners, and things like burrs will have a current density which is higher than the bulk regions. The MRR is a function of the current density. The higher the current density, the faster the MRR. Thus, geometries like burrs preferentially etch faster.

16. There is no tool wear to speak of in ECM as the tool is protected cathodically during the process. There may be some chemical reaction between the tool and the electrolyte when the power is off, depending upon the materials involved.

17. Shaped-tube electrolytic machining is similar to electrochemical machining and electrostream drilling in that the same material removal process is used – electrochemical action. It is different in the tooling used to deliver the electrolyte to the material removal area. In STEM the electrolyte is delivered in a very controlled way to the working area by use of a tube.

18. ECG is not suitable for grinding ceramics because they are not conductors. Ultrasonics can be effectively used to machine ceramics, but the process is quite slow (low MRR).

19. The MRR in ECM depends mainly upon the current density which is influenced by the geometry of the tool. For example, the current density at sharp corners will be greater than flat surfaces, so corners will cut faster.

20. The amount of material removed is a function of exposure time. As the tool advances down into the work, the sides of the tool would continue to machine the sides of the hole, giving it a taper (largest at the top) which in this case is not desired. Thus, the tool is insulated to prevent the passage of current.

21. In ultrasonic machining small parts of the work material are removed by coalescence of fractures cause by the impact of the abrasives on the work, and a small amount of ductile chip formation where very small depths of cut (deformation zone size) occur. If chips are viewed as the result of (ductile) shear deformation as in metal cutting then ultrasonic machining is chipless. If chips are viewed as an identifiable particle from the workpiece then ultrasonic machining produces chips.

22. The acceleration is greatest at the ends of the stroke so the forces acting on the grits in the slurry are greatest here as well. Actually, the grits in the slurry are driven by the wave action of the vibrating tool against the workpiece. The tool acts to focus this wave action into the desired regions.

23. The surface is heated by the sparks to either melt or even vaporize metal. The melted metal is washed away by the dielectric. The sparks cut small, spherical shaped, cups into the surface. The surface is covered with recast (melted and resolidified) metal. Thus, there will always be a hard, brittle, surface layer on EDM part surfaces.

24. The moving wire electrode can cut straight or angled slots through plates under CNC control. The thin wire allows relatively complex geometries to be cut into dies and stripper plates, for example, with virtually the same program being used to make parts which will later mate with the die set. The principal advantage is that it can produce "saw-like" cuts in hard, delicate materials which would be difficult to bandsaw. There are

no tool forces on the wire. A hole can be drilled in the part and the wire passed through the hole.

25. The effect would not be great. The MRR is controlled by adjusting the amperage (higher amperage, higher MRR) while the surface finish is controlled by the frequency of the spark (higher frequency with amperage constant yields smaller craters and smoother finish).

26. ECM is probably preferred to EDM in this case because the recast layer produced by EDM may serve as a source for fatigue cracks in the already brittle base material.

27. Of the four processes, laser beam machining is the easiest to automate into large volume production provided the laser can do the job. Lasers leave recast surfaces like EDM. Both ECM and EDM can be automated but are more oriented toward batch processes. If the parts are small and a large number can be loaded into a machine at the same time, EDM or ECM could be used, with ECM holes having less damage and EDM usually having slightly faster MRRs in most materials. LBM and EBM have very low MRRs which may exclude them from large volume production.

28. Again, LBM is good for small holes in hard metals and since they are being used for venting, the recast layer should not be a problem. The low MRR rate may make for long machining cycles, so ECM may be preferred. EDM is not preferred for small holes.

29. Specific power may be high for LBM because the spot area or volume is very small and the coherent beam energy is very large.

30. The spark in an EDM process literally blasts molten metal out of the crater. These globs of material try to assume the lowest energy state which is spherical. They cool from the outside to the inside, so the inside can form a shrink cavity, making the spheres hollow. The spheres may also trap gases to make them hollow.

31. In waterjet cutting a high speed stream of water is used. This requires machines to generate high pressure, pumps to move the fluid, the flow of water through piping at high speed, and a high speed stream leaving a nozzle (Figure 28-16). These are all sources of noise.

32. In abrasive waterjet cutting nozzle wear occurs due to the interactions of the abrasives and the nozzle. Wear can be minimized if abrasive-nozzle contact is minimized (few particles and low contact stress) and if the speed of the abrasives through the nozzle is small. One way to accomplish decreased nozzle wear in to use controlled streams of water to keep the abrasives away from the nozzle wall and to inject the abrasive particles into the central part of the water streams.

33. Abrasive flow machining appears to be useful for finishing internal passages in engine blocks AFM is useful for finishing complex, internal, difficult-to-access regions of parts. However, the AFM process will become very complicated since there are so

many openings that need to be closed, different kinds and size passages and so large variations in media pressure and long passages and so large media pressure drops in cylinder blocks.

34.Thermal deburring is a process in which a hot, corrosive gas is directed onto a burr and the burr is removed by vaporization. Part of the deburring process is due to chemical action, oxidation of metals, breakdown of the chemical bonds of thermosetting plastics. While thermoplastics have low thermal conductivity the increase in temperature will have a less severe effect on the material. Thermoplastics are characterized by a glass transition temperature that indicates gradual changes in molecular behavior. Rather that breaking the material down chemically thermal deburring is expected to cause a softening of the material, and not only in the burr but also in the surrounding material.

Problems: no problems

Case Study: no case study

CHAPTER 29

Review Questions

1. The work holding device locates the part in the machine tool with respect to the cutting tools and holds the part (clamps it) so it does not move due to cutting forces or inertial forces.

2. A jig determines location dimensions while a fixture does not. A fixture is a special workholding device -- that is, specially designed to accomplish a specific job. Jigs have the layout of geometric shapes built into them, and thus they automatically transfer this layout to the workpiece as operations are performed with their use.

3. The definition was incorrect, in that some jigs do not hold the work (as in clamp-on jigs), and some jigs do not guide the tool (as in welding jigs). Welding jigs are used to locate one (or more) parts with respect to another part and hold them in the right orientation and location while welding is performed.

4. A vise is a general purpose workholding device and is not a specially designed workholding device. This answer may sound picky but it is important to distinguish between a vice used in general purpose milling and a fixture used in a milling machine. Why? The latter may have many special features designed into it to enhance or speed up production, reduce setup time, or reduce time to load or unload parts. The fixture may have a pokayoke built into it, meaning that it cannot be operated if parts are loaded into it incorrectly (pokayokes prevent defects from occurring - See Chapter 43).

5. Some basic factors in designing jigs and fixtures are: (1) clamping the work to resist the cutting forces; (2) supporting the work during cutting so that it does not deflect under the load of the cutting forces; (3) location to provide the desired dimensional control; (4) guidance of the tool, if required; (5) provision for chip removal or clearance during or after operation; and (6) rapid, easy, safe operation.

6. The critical surfaces (often 3 perpendicular planes) are surfaces on the part that are vital to the parts function or operation. Other surfaces are dimensioned from the critical surfaces, and these surfaces are established early in the processing sequence.

7. The clamping forces can distort the workpiece. The workpiece is machined in the distorted configuration. When the clamping forces are removed, the workpiece returns to its unstressed shape, but now the machined surface is distorted and the dimensions produced by the machining operations will be incorrect .

8. Three points are required to locate the workpiece in one plane. Two points are required to locate the workpiece in a second plane, perpendicular to the first plane. One point is required to locate the workpiece in a third plane, perpendicular to the first two.

9. Supporting the work against the cutting forces of the process often requires that

additional points or bearing supports be placed in the three perpendicular surfaces, beyond the 3-2-1 points .

10. Reasons for not having the drill bushings actually touch the workpiece include:
(1) Chips may become tangled in the drill bushing if there isn't sufficient clearance between the bushing and the workpiece,
(2) the end of the bushing may contact an oversize workpiece and not permit the piece to be located or held properly, and
(3) the chips will be passed through the bushing and may wear and score it.

11. Down milling pushes the workpiece down into the location surfaces, which are solid, unmoving surfaces; up milling tends to lift the workpiece out of the fixture, so clamping forces must be greater to hold the workpiece against the location points during machining.

12. Flexibility means versatility. Workholding devices can be made move flexible by making them modular, i.e., made of combinations of standard elements that are combined in different ways for use in making different parts.

13. Forces acting against the floor caused the jig to deflect, which, in turn, caused the jig to twist. By having a rigid jig with only three points of support, the jig would not twist.

14. If a machine is costly and has a high production rate, time lost in setting up and clamping a workpiece is very costly. Thus a small amount of time saved each cycle by use of a fixture easily repay the cost of the fixture. A machine that is not costly or highly productive may not offer sufficient return to pay for the same fixture.

15. Jigs that can be flipped over to permit drilling from more than one side are called roll-over jigs. They: (1) usually eliminate the cost of a second jig, (2) reduce the amount of clamping time, and (3) may reduce possible clamping error due to clamping stresses.

16. The spherical washer permits minor deviations in the parallel surface to readily be absorbed. The strap clamp does not have to be exactly parallel to the surface holding the D stud. This allows for variations in the thickness of the workpiece .

17. Strap clamps, C clamps and toggle clamps are all commonly used.

18. The strap clamps can be bought in different sizes. The letters are used in a table in the clamp catalog to define the sizes but the basic design of the clamp does not change, just the size.

19. There is no control over how many points the part will rest on if it is set on the flat plate. Plates are not perfectly flat. Using locator buttons assures that the number and location of part support points are known.

20. The X plane is the largest plane and would ordinarily take 3 buttons. However, this

would place the thrust of the drilling process for the two mounting holes outside the area defined by the three buttons. Therefore, 4 buttons are used in the X plane and the drilling thrust is inside the region defined by these 4 points. The bottom of the bearing block would be milled flat and true prior to insertion in the jig.

21. The Z location buttons establish the "A" dimension.

22. The front and back could be straddle milled first, then the base milled perpendicular to the front or back and finally the right end. The end is milled solely for the purpose of establishing dimension "B" and "C: The right end must rest against button"Y" in the jig. The base could be milled first and then the front and back milled, using the base as a locating surface .

23. The surfaces which locate the holes are milled first to properly establish dimensions "A", "B", and "C". It is more difficult to locate surfaces to be milled from surfaces that were drilled than it is to locate (and drill) holes with respect to milled surfaces. While the drawing does not say so specifically, the holes are perpendicular to the flat bottom.

24. Drill bushings (K) must be removable so the holes can be countersunk with the workpiece still in the jig. Drill bushings are made removable for any number of reasons. You may want to replace it if it wears. You may want to remove it so that the drilled hole can be reamed, tapped, or countersunk --the reamer, tap, or countersink being larger than the drill diameter. You may be drilling two holes of different diameter in the same location, so you need two different drill bushings.

Problems:

1. Same as 8th edition Chapter 28

   1. $(\$5.75 + \$4.50)(2.25) - (\$4.50 + \$4.50)(1.25) = (\$3.000 / N)(1 + (3)(0.1)/2$

   $N = 292+$ or 293 pieces

2. The cost of the jig is:

$$C_t = [\$100 + (4)(12)] / N + [\$600 / N][1 + (3)(16)/2]$$

Assuming the design and assembly costs are one-time costs and the modular elements are written off over three years;

$$C_t = \$148 / N + (600 / N)(1.24)$$

$$(8.00 + 8.75)(.5) - (6.50 + 8.75)(0.2) = 148 / N + (600 / N)(1.24)$$

$$8.375 - 3.05 = 148 / N + 744 / N$$

$$N = 892 / 5.325 = 167.51$$

The modular fixture has a lower breakeven quantity.

3. The cutting force, F_c of 1800 lb. is assumed to be going to the left, and the thrust force of 900 lb. is assumed to be going down. The clamping forces, F_R and F_L are required so that the clamps can be designed.

For a static condition, the sum of forces in the X-direction (horizontal) equals zero, the sum of forces in the Y-direction (vertical) equals zero, and the sum of moments around any point is zero.

$F_x = R_1 + \mu(F_L + F_R + 1500 + 900) - 1800 = 0$
$F_y = R_2 + R_3 - F_L - F_R - 900 - 1500 = 0$

M_A = moment about point A on left side
$= (900 \text{ x } 5) + (1500 \text{ x } 15) + (F_R \text{ x } 30) + (R_3 \text{ x } 30) - (1800 \text{ x } 34) = 0$

Let $R_3 = 0$ (assume part is barely touching) and
$F_L = 0$ (assume there is no tendency to lift on the left side).

So:
if $R_3 = 0$; $F_L = 0$

$2F_x = R_1 + 0.19 (FR = 1500 + 900) - 1800 = 0$

$2Fy = R_2 - F_R - 900 - 1500 = 0$

$M_A = 4500 + 1500(15) + F_R\, 30 - 1800(34) = 0$

$F_R = [1800(34) + 900 + 1500(15)] / 30 = 1140$ lb

$R_2 = 1140 + 900 + 1500 = 3540$ lb.

$R_1 = 1800 - .19 (1140 + 1500 + 900) = 1127.4$ lb.

4. Current cost to drill holes
1 minute machining time + 0.5 minute unload/load time = 1.5 min/part
40 parts/hr
(\$42 / hr) / (40 parts/hr) = \$1.05 / part
With toggle clamp
experiment shows advancing screw about ½ in takes about 4 sec
and working toggle takes less than 1 sec
=> part in and out of jig about 30 sec – 2(4 sec) for one screw at a time
new unload/load time is 22 sec part handling + 2 sec clamping = 24 sec
1 minute drilling time + (24/60) unload/load time = 1.4 min/part
43 parts/hr
(\$42 / hr) / 43 parts/hr) = \$0.98 / part

Cost change = \$0.07 /part

Cost to implement change
  cost per clamp = \$3.85 – catalog data
  cost to modify jig = (shop cost)(shop time) = (\$70 /hr)(7 hr) = \$490
    current University shop rate
    University shop estimate of construction time
  design cost = ?
  lost production time while jig is modified = 7 hrs + transportation and queue time = ?

Considering only purchase of clamps and jig modification cost the number of parts that must be drilled to recoup cost is (\$490 + \$7.70) / \$0.07 / part = 7,110 parts

Case Study: “Overhead Crane Installation”

This study actually involves two location problems: the location of the holes with respect to themselves and the location of the hole patterns with respect to each other. The former problem can be solved by making a simple ring jig. The jig can be secured to the column using magnets or a hole can be drilled at the point (+) on the column, tapped, and used to hold the jig plate while the bolt holes are drilled. The holes can be drilled with a hand electric drill.

The second problem, locating the drill jig properly on each column so that the hole pattern centers all come out on the same plane, is a bit more difficult. Here is one possible solution. A fine cross (+) is placed on the jig. On the day that the job is to be done, a surveyor's transit or level is set up in the center of the eight columns at the required height. A painter's scaffold should provide adequate height. When the transit is properly leveled, each column can be "shot" so that, when the jig is mounted on each column for hole drilling, the jig will always be at the same height with respect to all other columns (without regard to the floor itself).

The equipment needed would be: a drill jig, magnet, drills, portable electric drill with long extension cord, scaffold, and surveyor's level.

CHAPTER 30

Review Questions

1.The major diameter is the over-all, outside diameter of the thread. The pitch diameter is a smaller, theoretical diameter upon which all the design elements of a thread are based.

2. The pitch and lead are the same for a single-pitch thread.

3. The helix angle is the angle between the slope of the screw thread and a line perpendicular to the axis of the screw.

4. Pipe threads are made on a taper so that as the threaded joint is tightened it will form a liquid-tight joint.

5. The basic methods for making external threads are: machining (grinding), forming, and casting. In plastics, threads can be molded.

6. 1/4"-20 UNC-3A designated an external thread of the Unified, or American, form, 1/4" nominal diameter, having 20 threads per inch, and a Class 3 fit.

7. M20 x 2.5-6g6g designates a metric thread; the nominal size is 20 mm; the pitch is 2.5 mm; #6 tolerance grade and "g" tolerance position on the crest diameter. The x means "by".

8. Fine-series threads are being used less because of the wide availability and use of self-locking plastic inserts on fasteners and special locking coatings.

9. Pitch is controlled by controlling the longitudinal motion of the lathe carriage relative to the rotation of the spindle, by means of the lead screw and clamp nut. Comment on threading on a lathe: Cutting threads on a lathe is a slow and expensive process. The design should specify standard threads which can be made by the most economical process whenever possible. Can thread rolling be used? If machined threads are needed and if the threads are of standard diameter, they can be cut with a die. Dies come in standard sizes. Nonstandard size threads would require operator controlled functions and great time delay in the cycle to make the threads. This is typically how they are made on the engine lathe, but engine lathe work is only for very small lots. The use of a die allows the turret lathe operations to be performed rapidly, without adjustment. An NC lathe can do threads quickly and repeatably.

10. The threading dial assures that the cutting tool will exactly

"track" in the previous thread groove during successive cuts.

11 Figures 23-8 (not labeled) & 23-9 show threading dials.

12.The lead is built into the cutting die. It twists itself on to the shaft just like a nut.

13. The purpose of a self-opening die head is to permit the die head to be withdrawn linearly from the completed thread without having to be unscrewed from it.

14. The shape of a taper tap aids in properly aligning the tap in the hole. It is much more difficult to align a plug tap properly if it is not preceded by a taper tap.

15. If full threads are specified to the bottom of a dead-end hole, it is necessary to follow the usual plug tap with a bottoming tap, which must be used with care to avoid breaking off the tap in the hole.

16. A fluteless tap produ6es threads by plastic flow of the material, requiring a ductile material. Gray cast iron is brittle, and therefore does not plastically flow. Threads in gray cast iron must be machined.

17. If possible, have the hole drilled deeper than actually needed so that it can be threaded to the desired depth without having to use a bottoming tap.

18. A spiral-point tap projects the chips ahead of the tap, thereby avoiding chips from becoming entangled in the cutting tap. (Another reason to drill the hole deeper than the threaded portion.)

19. No, a fluteless tap forms threads progressively, thus requiring several partially formed threads ahead of the fully formed threads, therefore it can not be used to thread a dead-end hole to the bottom.

20. Yes, it is not only desirable but necessary in most materials that the cutting fluid be a good lubricant. There will be large friction forces between the teeth of the tap and the tapped hole as the tap progresses. A lubricant will also reduce the friction between the chips and the work material and the tap.

21. Threads are milled (machined) using form cutters - either single or multiple-form cutters are used. Because the cutter has multiple teeth, the thread can be fully machined in one pass of the cutter past the rotating workpiece. So this process is faster than thread turning, which

uses a single point tool.

22. By grinding, threads can be made on hardened materials and the threads will be more precise (less variability) and have a better surface finish.

23. Thread rolling is much faster than any of the machining processes and the properties of the threads are improved -- stronger and smoother. The materials to be thread rolled must be ductile and full-form threads cannot be obtained by rolling. Also, the threads will not have any sharp radius. The surface of the bar must have a good surface finish.

24. Examine the thread. Machined surfaces are very different from rolled surfaces.

25. With the involute tooth form, there is only rolling contact between the gear tooth surfaces, thus eliminating sliding friction.

26. The diametral pitch of a gear is the ratio of the number of teeth to the pitch diameter, or is the number of teeth per inch of pitch diameter.

27. The module and the pitch diameter are the same.

28. See Figures 30-14 and 30-15.

29. (1) The actual tooth profile must coincide with the theoretical profile; (2) tooth spacing must be uniform and correct; (3) the actual pitch circle must be coincident with the theoretical circle and be concentric with the axis of rotation; (4) the face and flank surfaces must be smooth and adequately hard; (5) the shafts and bearings must assure that center-to-center distances are maintained under load. Notice that most of these requirements are determined solely by manufacturing of the gears.

30. The tooth engagement of helical gears is gradual, and more teeth are in contact at a given time. This tends to provide smoother and quieter operation. (Do you think that helical gears are used in car transmissions?)

31. Helical gears cause side thrust and are more difficult to manufacture than straight tooth gears.

32. A hob has to extend past the point being cut on the gear teeth. On herringbone gears this would cause the hob to extend, and cut into the teeth beyond the centerline of the gear.

33. Full-herringbone gears can be cut only on a Sykes gear generating machine .

34. A clearance groove is machined around the center of the gear

to provide clearance for the hob, or two helical gears, having opposite helix angles, may be machined separately and joined together.

35. A different, and very expensive, broach has to be made for each size and type of gear.

36. A crown gear will mate properly with any bevel gear having the same diametral pitch and tooth form.

37. Three basic processes for machining gears are: form cutting, generating, and template machining.

38. The Fellows gear shaper uses generation, meaning the tooth profile is made in progressive passes. See Figure 31-10.

39. The feed screw of the milling machine table is geared to the dividing head so as to cause the spindle of the dividing head, which holds and rotates the gear blank, to rotate in relationship to longitudinal movement of the table.

40. A hob has almost continuous cutting action, there are multiple teeth, and the action does not have to be stopped to index the gear blank.

41. The tooth profiles are produced by successive cuts of the cutter past a slowly rotating workpiece.

42. Cold-roll forming is a very rapid process, the faces of the resulting teeth are very smooth and somewhat hardened, and the gear may be stronger.

43. Cold-roll forming requires a ductile material; gray cast iron is not ductile.

44. Shaving cannot be used on hardened gears.

45. Cold-roll forming produces work hardening and thus provides a better wearing surface on the face of the teeth.

46. Cast iron is soft, and the lapping abrasive would become embedded in the gears, resulting in them not being lapped but rather the teeth would become laps.

47. Gear inspection checks: hardness; tooth thickness, spacing and depth; tooth profile; surface roughness; and noise.

48.Gear finishing is accomplished by gear shaving, roll finishing, grinding (good for hardened gears) and lapping for final finishing.

Problems:

1. For 30 fpm, the RPM will be N = (12 x 30)1(3.14 x 0.75) = 152.8rpm.
The cutting time CT = (2 + 0.75)/(0.1 x 152.8) =0.179 min.
where 10 thread per inch = 0.1 inches/thread or 0.1 inches per revolution and 0.75 inches is the allowance for overtravel to insure that full threads are cut.

2. The recommendation is based on the favorable cutting time of the chipless tap over the normal tapping process. The engine blocks may be made out of cast iron, in which case fluteless tapping will not work because cast iron is a brittle material. In addition, tapping deep, dead-end holes with fluteless taps is a difficult process. If these are aluminum engine blocks, then the suggestion should be given serious consideration. P.S. Do not forget to ask the operator and the foreman in the area what they would recommend, as they are going to have to implement any suggestions you make.

3. RPM of hob = (27.4 x 1000) / (76.2 x 3.14) = 114.5
RPM of gear blank = 114.5 / 36 = 3.18

4. Effective width = 76.2 + (2 x 38) = 153.2 mm
Time = 153.21(3.18 x 1.9) = 25.4 minutes

5. For the HSS cutter milling 4340 steel, selected values for
V = 100 fpm and f_t = 0.007inches per tooth would be reasonable.

f_m= n N Ft, where N = 12 V / (πD) = 12 x 1001(3.14 x 4) = 95.4
f_m= 11 x 95.4 x 0.007 = 7.35 ipm

CT = (L + A) / fm = (1 + 2~4) / fm for a 1 inch thick gear
CT = 3.4 / 7.35 = 0.46 min.
where A = allowance = $2L_A = 2 \{ t (D-t) \}^{1/2} = 2 \{ 0.6(3.0 - 0.6) \}^{1/2}$ for t=0.6, scaled from Figure 31-19

Each pass takes about 1/2 minute. From Figure 31-19 one can determine that there are 12 teeth which require 12 passes. Assuming that it takes 30 seconds to return the cutter to the start position and index the gear blank 30 degrees, the job would take about 12 minutes. Down milling will be used to get the best finish on the teeth.

6. The broach has 10 sets of progressive tooling, so assume the cost of the tooling is $2500. Assume labor costs $10 per hour and machine overhead is 100%. Assume the milling cutter cost is $100 or so. The milling time is 12 minutes per part versus 15 seconds per part for broaching.

Savings estimate (12-.25) x (20 / 60) = $3.91/part

Assuming all other costs remain the same,
Additional cost = $2500 - 100 = $2400 for the broach versus the milling cutter

BEQ = 2400 / 3.91 = 613 parts

If the company is making over 613 gears and has both machines, the switch is justified.

Comparing to shaping, assume a 1 minute cycle time for shaping.
Savings estimate (1-.25) x (20 / 60) = $0.25/part
BEQ = 2400/0.25 = 9600 parts

Broaching would only be preferred to shaping if there were over 9600 gears to be machined. The broach can easily cut that number of gears and the cost of TiN coating is also justified. For example, adding $100 to each broach,
BEQ = 3400/3.91 = 869 parts

7., 8. The gear manufacturing processes described in the chapter are listed in the table along with some important characteristics of each related to making 1.125 inch diameter, 70-30 brass gears.

Process			Consider for
Form Milling	standard cutters standard milling machine	slow	3
Broaching	complex machine complex tooling	short cycle time	10,000
Gear Generating			
- shaping	specialized machine can make multiple gears simultaneously	short cycle time	10,000
- hobbing	general purpose machine can be adapted specialize machine for high production		3, 10,000
Cold-Roll Forming	specialized machine high quality tooling	short cycle time high quality gears	10,000
Casting	probably requires finishing		
Blanking	for thin gears		NA
Powder Metallurgy	specialized equipment and materials		don't consider
Flame machining	little accuracy		NA

8. Above

9. The hole is larger than the internal thread minor diameter.

A closer look at machinists' handbooks will show not only 75% threads but also 60% threads that call for larger drill sizes than the 75% thread drill size which is still larger than the minor diameter.

While an oversimplification an explanation of thread strength is that it is determined by the shear of threads and so the width of the thread is the important issue and thread depth is secondary. With regard to thread manufacture there is work material deformation in addition to the metal removal. Too small a prepared hole will lead to very little room for deformed material flow, tap seizing and tap breakage. Machinists working on prototypes and special projects have been know to use drill sizes slightly larger than recommended for low stress applications so as to ease machining problems.

Case Study: "Vented Cap Screws"

The redesigned part would need a hole 0.024 inches in diameter, 1/2 inch deep. This is a hole diameter to hole depth ratio of 1 to 20, clearly not a conventional drilling process.

The hole or the slot, as designed, could be made by EDM or ultrasonic machining, or perhaps laser machining, depending upon the available equipment. If none of this equipment is available, ask the designer if the slot needs to be of uniform cross section throughout, or only in some region to control the pressure buildup. This is probably the case, and would allow the slot to be redesigned as shown in the sketch below. This design can be slot milled using a one-inch-diameter slot milling cutter.

CHAPTER 31

Review Questions

1. Some of the possible objectives of surface modification processes are: clean surfaces and remove surface defects, modify a product's appearance, improve resistance to wear or corrosion, reduce friction or adhesion, and conserve costly materials.

2. When selecting a surface modification process, one should consider the common factors of time, labor, equipment, and material handling. In addition, consideration should be given to such features as: the size of the part, the shape of the part, the quantity to be processed, the temperatures required for processing, the temperatures encountered during subsequent use, and any dimensional changes that might occur due to the treatment.

3. Two general concepts apply. One is the shape or geometry or topography of the machined surface. Machining processes produce surface profiles that are not exact replicas of the tool shape. The deformation of the work surface results in roughness at a more local level than the size of the cutting edge and nose radius. This is the roughness usually measured and referred to as “surface roughness.”

The other aspect of the machined surface is the modification of the structure, properties and residual stress state of the machined surface layer. These changes in material characteristics can affect the part performance in use. The term “surface integrity” refers to this aspect of machined surface characteristics.

4. Manufactured products frequently contain foreign material on the surfaces. Sand from casting molds and cores often adheres to surfaces. Scale can be produced when metals are processed at elevated temperatures. Oxides can form during storage.

5. Blasting or other abrasive cleaning operations utilize abrasives such as: sand, steel grit, metal shot, fine glass shot, walnut shells, dry-ice pellets, and even baking soda.

6. Barrel finishing operations are most effective when large quantities of small parts are to be processed.

7. In barrel finishing, the rotation of the barrel causes the material to rise until gravity causes the uppermost layer to cascade downward in a "landslide" movement. If the barrel is too full, the relative motion between the work and the abrasive will not adequate. Increasing the speed causes the material to rise higher in the barrel, but if the speed is too high, centrifugal forces cause the parts to adhere to the outside of the barrel, thereby eliminating the cascading action.

8. In barrel finishing, most of the finishing occurs when the parts slide down over the media. In vibratory finishing the entire load is in constant agitation, and there is virtually constant relative motion between the work and the media.

9. Synthetic abrasive media, formed by combining abrasive material and a binder, are manufactured, and have consistent and reproducible size and shape.

10. The compounds that are used in abrasive finishing operations can perform a variety of functions, including:
deburring, burnishing, abrasive cutting, cleaning, descaling, and corrosion inhibition.

11. The ideal geometry for belt sanding is a flat surface. The process is more difficult with curved surfaces, and is extremely difficult to apply when the geometry includes recesses or interior corners.

12. Electropolishing is the reverse of electroplating, since material is removed from the surface rather than being deposited.

13. Alkaline cleaning can remove a variety of soils, including oils, grease, wax, fine particles of metal, and dirt. The actual cleaning occurs through one or more of: (1) saponification, (2) displacement, (3) dispersion or emulsification, and (4) dissolution.

14. Solvent cleaning cannot be used to remove insoluble contaminants, such as metal oxides, sand, scale, and the inorganic fluxes used in welding, brazing and soldering.

15. Environmental issues have made vapor degreasing rather unattractive. The standard solvents have been identified as ozone-depleting compounds, and have been banned from use. Replacement solvents usually lack one or more of the qualities that are desirable for the process.

16. Acid pickling operations are generally used to remove oxides and dirt that remain on the surface of metals after other processing operations.

17. During milling of most of the slot the work material ahead of the cutter is supported by more work material ahead of the deformation zone. As the free surfaces of the workpiece are approached this support decreases. Very near the free surfaces the workpiece deformation zone is not strongly bounded. The deforming material is not cleanly sheared and deforming material can move into free space forming burrs.

18. During thermal energy deburring, the parts are loaded into a chamber, which is then filled with a combustible gas mixture. when the gas is ignited, the short-duration wavefront heats the small burrs to extremely high temperatures, while the rest of the part remains cool. The burrs are vaporized, including those in inaccessible or difficult-to-reach locations .

19. While both coating and cladding are deposition processes, coatings are deposited as a liquid or a gas (or from a liquid or gas medium), while the added material is solid during cladding.

20. Paints are used for a variety of reasons, including providing protection and decoration, filling or concealing surface irregularities, changing the surface friction, and modifying the light or heat absorption or radiation characteristics.

21. In a painted surface, the prime coat serves to promote adhesion, fill minor porosity or surface blemishes (leveling), and improve corrosion resistance. The more highly pigmented final coats are designed to provide color and appearance.

22. In airless spraying, mechanical pressure forces the paint through an orifice under pressure. The resultant velocity is sufficient to produce atomization and propel the particles toward the workpiece.

23. Industrial robots can mimic the movements of a human painter, while maintaining a uniform separation distance and minimizing waste. Monotonous and repetitious movements can be performed with consistent results, and the human operator is freed from an undesirable working environment.

24. Electrostatic spraying greatly reduces paint loss and the generation of airborne particles, and provides for more uniform coverage of the workpiece.

25. In electrostatic spray painting, the workpiece must act as one of the electrodes. Wood and plastic are not electrically conductive and cannot serve as an electrode.

26. The most common metallic coatings that are applied by hot dipping are: zinc, tin, aluminum, and terne (a lead-tin alloy).

27. The two most common types of chemical conversion coatings are chromate and phosphate.

28. Nonconductive materials, such as plastic, can be electroplated provided that they are first coated with an electrically-conductive material. Processes, such as the electroless deposition of nickel can be used.

29. Hard chrome plate offers Rockwell C hardnesses between 66 and 70, and can be used to build up worn parts, and coat tools and other products that can benefit from the reduced surface friction and good resistance to wear and corrosion.

30. Some of the process variables in an electroplating cell include: the electrolyte and the concentrations of the various dissolved components, the temperature of the bath, and the electrical voltage and current.

31. Ordinarily only one type of workpiece is plated at a time, since the details of solutions, immersion times, and current densities are usually changed with changes in workpiece size and shape.

32. In the electroforming process, the coating is stripped from the substrate and becomes

the final product. In electroplating, the coating and substrate remain intact.

33. when anodizing aluminum, if the oxide is not soluble in the anodizing solution, the oxide will grow until the resistance of the oxide prevents the current from flowing. If the oxide is partially soluble, dissolution competes with oxide growth and a porous coating is produced. As the coating thickens, the growth rate decreases until it achieves a steady state where the growth rate is equal to the rate of dissolution.

34. In color anodizing, a porous oxide is first produced, which is then immersed in a dye solution. The dye is then trapped in place by a sealing operation.

35. Electroless plating will provide uniform thickness on complex shapes and it requires much less energy. In addition, metallic platings can be directly applied to nonconducting surfaces.

36. When minute particles are codeposited with the electroless metal, electroless plating can be used to produce composite coatings. Commercial applications have used diamond, silicon carbide, aluminum oxide, and teflon particles dispersed in the metal matrix.

37. Mechanical plating is an adaptation of barrel finishing in which coatings are produced by cold-welding soft, malleable metal powder onto a substrate.

38. Porcelain enamel coatings can be used to impart resistance to corrosion and abrasion, decorative color, electrical insulation, and the ability to function in a high-temperature environment.

39. See the Case Study below.

40. Since machining processes are surface region removal processes there is a difference in the deformation or structure between the worked surface region and the underlying un-worked material so there is always residual stress of some level. In the chip formation type of machining such as turning and grinding deformation gradients can be high and residual stresses are high. In very mild machining operations such as electrochemical machining there are still differences between worked surfaces and the bulk of the material, although such differences can be very small.

41. The extent of deformation below machined surfaces depends on the magnitude of the forces acting and the direction of the forces. A way to understand the effect of tool rake angle on depth of subsurface effects is to consider the resultant force of the cutting forces, R, in Figure 21-20. The magnitude of r is

$$R = \{ F_c^2 + F_t^2 \}^{1/2}, \quad \text{eqn (21-25)}$$

and the direction of R with respect to the finished surface is

$$\eta = \beta - \alpha$$

For constant coefficient of friction, as rake angle α becomes more negative the direction of R rotates so that R is directed more into the work material.

As rake angle decreases the cutting forces increases. A qualitative explanation is,
- as α decreases the shear angle ϕ decreases, eqn(21-19)
- decreasing ϕ means that the shear plane length and area increase, Figure 21-17,
- the shear strain also increases as ϕ decreases, eqn(21-31)
- as the amount of deformation increases the cutting forces increases if the work shear strength is constant, increases or does not decrease enough to compensate for the increase in cutting forces due to increased deformation

42. Fatigue failure involves crack initiation and growth. Crack are more likely to initiate at surfaces than in interior region of manufactured parts because,
- the manufacture of surfaces results in surfaces that are not perfectly smooth and small sharp irregularities in surfaces act as stress raisers,
- in extreme cases the irregularities in the surface may be small cracks,
- manufacturing operations may produce tensile residual stress in the surface region that then can act in consort with applied tensile stress to raise the net stress acting,
- the change in stress state from the interior of the material to the plane stress state at the surface can result in stresses that aid crack initiation.

43. Stress raisers are changes in material shape, part geometry, that result in the local stress near the change in shape being increased. At changes in geometry the material remains continuous so the stress changes and increased local stress can result.

44. The two types of surface effects due to machining are surface profile effects and subsurface region effects – see Question 3.

45. The residual stress combines with the stress due to applied loading to give the net stress acting, locally, in the part. If tensile stresses result and are undesirable in use then the residual compressive stress acts to reduce the net tensile stress acting and can improve part performance.

Problems:

1. Because of the wide variety of finishes desired, a number of processes can be considered. Of particular importance is the need to retain the necessary mechanical properties that were set by the heat treatment. Exposure to high elevated temperatures will overtemper the hook, making it prone to possible unwanted deformation. In addition, the need to maintain sharpness of the points and barbs significantly restricts the thickness of any applied coatings. The shape and the presence of the barbs may well make any mass treatment process rather difficult.

The ideal process would produce a durable, thin, uniform-color coating under low temperature conditions. Among the attractive possibilities are chemical conversion treatments, the various PVD methods, and blackening or coloring treatments.

2. This is a rather open-ended problem offering a wide variety of base materials, sizes,

shapes and requirements. It is designed to expose the student to the wide variety of surface treatment methods that are encountered in everyday products.

The extent to which the problem is treated can vary greatly. For example, part k) - the automobile muffler offers the option of having to integrate surface treatment and manufacturing process. For example, spot or seam welds are quite difficult if the sheet material has an existing galvanized (zinc) coating. Low-carbon sheet steel, however, can be readily seam welded. Therefore, if the sheet material is pre-galvanized, then assembly might utilize some form of mechanical (such as roll-lock) seam. If uncoated material is selected with the intent of subsequent coating, the student should realize that the presence of inlet and outlet tubes, and internal components or baffles, would preclude the possibility of approaches such as hot-dip galvanizing after assembly.

Case Study: "Burrs on Tonto's Collar"

1). Here is a listing of deburring techniques commonly used in industry (as contributed by L.K. Gillespie and J.G. Bralla):

- Barrel tumbling. A large group of parts with burrs are placed in a rotating barrel with small pebble-like media, a fine abrasive powder, and water, and the barrel and its contents are slowly rotated until the burrs wear off, typically 4-12 hr.
- Centrifugal barrel tumbling, similar to barrel tumbling except that the barrel is placed at the end of a rotating arm. The addition of centrifugal force up to 25G to the weight of the parts in the barrel makes the process 25-50 times faster than conventional barrel tumbling.
- Spindle finishing, also similar to barrel tumbling except that the workpiece is fastened to the end of a rotating shaft and then placed in a barrel rotating in the opposite direction. The abrasive media gently wears off the burrs and produces a smooth radius on the edges. Although each part must be handled individually, deburring requires only 1-2 mm. per part.
- Vibratory deburring, also similar to barrel tumbling except that parts and media are vibrated rather than rotated.
- Abrasive-jet deburring. A high-velocity stream of small abrasive particles or miniature glass beads is sprayed at the burrs, and a combination of impact, abrasion, and peening actions breaks or wears away the burrs. Deburring takes from 30 sec to 5 mm, depending on workpiece size and complexity. This process is essentially a refined sand-blasting process.
- Water-jet deburring. A 0.25-mm-dia (0.010-in.-dia) jet of water at very high velocity cuts burrs and flash from the workpiece. In nonmetals, this process can deflash contours at a rate of 250 mm/s (600 ipm).
- Brush deburring. Motorized rotating brushes abrade burrs from parts at a rate from 10 sec to 5 mm per part. At least 50 different types of brushes are in common use.
- Sanding. Belt sanders deburr flat parts and disks, and flap wheels deburr contoured parts, at a rate of 600 stamped parts per hour. Although heavy burrs are

removed, the process itself often produces a very small burr.

- Mechanical deburring. A variety of specialized machines are equipped with chamfering tools, knives, or grinding wheels to mechanically remove cut burrs. Automotive gears, for example, can be deburred at a rate of 400 gears per hour.
- Abrasive-flow deburring. Hydraulic cylinders force an abrasive-laden putty-like material over burrs at a rate of 30 parts per hour. Deburring at up to 400 parts per hour is possible with automation. Some dimensional changes occur on surfaces contacting the putty-like material.
- Liquid-hone deburring. A 60-grit abrasive suspended in water is forced over burr-laden edges, removing very fine burrs in a 5-mm cycle and producing minimal edge radii.
- Chemical deburring. Buffered acids dissolve burrs from large groups of small parts in 5-30 mm, depending on the part. Because acids attack all surfaces, some dimensional changes of the entire part occur.
- Ultrasonic deburring. A combination of buffered acids and a fine abrasive media is ultrasonically agitated to wear and etch minute burrs, such as those produced in honing.
- Electropolish deburring. Reverse electroplating operation uses electrolysis in a mild acid solution to remove burrs from all surfaces, producing excellent surface finish.
- Electrochemical deburring, similar to electropolish deburring except that a salt solution and a shaped electrode are required. Stock is removed only at the edges, although some light etching occurs at other places on the part. Surface residues on the part have to be brushed or wiped off.

  Deburring typically requires 2 min per part, without automation.
- Thermal-energy deburring. A high-temperature wavefront -produced by igniting natural gas in a closed container -vaporizes burrs. The short-duration wavefront exposes components to only 95C (200F) while burrs are exposed to as much as 3300C (6000F). Up to 80 parts per hour can be deburred by this process.
- Manual deburring. Workers with special knives, files, scrapers, and other tools cut burrs from parts.

2). The screw machine operation has six steps:

I. Use form tool to turn the 12.7 mm diameter (The original diameter is 17.46 mm.)
II. Slot the end. (Rotation must be stopped to form the slot.)
III. Turn the 16 mm diameter. (The original diameter is 17.46 mm. This operation removes the slotting burrs.)
IV. Drill 6.4 mm hole. (This operation uses the part of the hole remaining from the previous part as a start.)
V. Thread the 12.7 mm diameter. (Use a thread-forming tool.)
VI. Cut off.

(Cut to the specified 12.7 mm length.)

Drilling and turning after slotting eliminates most of the burrs. This part takes about 20 seconds, so the machine can make 180 per hour. The total run takes about 138 hours or 17-18 days, assuming one 8-hour shift per day. The part would cost about 10 or 11 cents, exclusive of material to make on the screw machine.

3). The collars could also be made by powder metallurgy. It is likely that powder metallurgy would be somewhat cheaper for the quantity required, but much would depend on local conditions as to competition between suppliers.

The collars could also be made by on cold heading machines followed by thread rolling. Quantities may be a bit too small to justify the dies.

The collars could also be investment cast. The cost here would likely be higher than the other alternatives that can take advantage of the geometric symmetries.

The collars cannot be die cast because the melting temperature of the material (AISI 304 stainless steel) is too high.

CHAPTER 32

Review Questions

1. Table 32-1 shows human attributes replaced
A(0) - none
A(1) – energy – power other than human powers machine
A(2) – dexterity – machines manipulate material
A(3) – diligence – machine runs without attention, but not closed-loop
A(4) – judgement – closed-loop control in response to measurements

2.A(1) powered machines – power hand tools
A(2) machine runs itself over single cycle – cooking ovens, clothes and dish washing machines
A(3) automatic repeat of cycles – clocks repeat mechanical and electronic actions cyclically
A(4) closed-loop control – refrigerators, freezers, home furnaces acting on thermometer measurements

3. Windmills are A(4) self-adjusting machines since the direction is set into the wind in response to changing wind direction. Changes in wind direction act to produce changes in force on the windmill rudder and motion of the mill to a desired, defined direction.

4. Feedback control includes an active action in response to a change in system operation. So, the overflow plumbing in sinks is not a typical feedback control system since no active control action is taken to stop water flow – water flow is simply diverted not controlled. Modern temperature and pressure controlling shower valves do operate based on measured flow rate to control flow. The water level in toilets is measured with simple mechanical mechanisms and water flow is allowed to continue or stopped based on feedback information.

5. Line balancing refers to time balancing - making the time for each station in a transfer line as close to the same as possible. This requires the balancing of the specific operations that are done at each station so the machining time at each station is the same.

The operations shown in Figure 32-6 are five machining operations. If each operation requires the same amount of time, then all operations finish at the same time and indexing occurs. The next set of operations are carried out in the same time and indexing to the next operation occurs, etc. If individual operation times are not equal then the system must wait for the longest operation to be completed before indexing and the start of the next step.

6. The machining center can automatically change tools to permit operations and processes other than just milling to take place. Both machines can be numerically controlled. The machining center will often be able to change pallets automatically with one pallet being in the machine and the other pallet being outside the machine having a workpiece mounted on it. This reduces the machine down time by doing the setup

externally - the machine does not have to be stopped during setup, only during part exchange.

In 1958, Kearney and Trecker marketed a NC machine tool that could automatically change tools, thus making it a multiprocess machine tool and the first machining center.

7. Parsons conceived of the idea of a machine tool controlled by inputting numbers. He demonstrated his idea to the U.S. Air Force by having three men stand at the controls of a 3-axis milling machine with three more people calling out numbers to them simultaneously. The machine then produced a complex contour. The USAF gave Parson's company a grant to develop a NC machine. Parson subcontracted KIT and the rest is history.

8. DNC as first practiced means direct numerical control and described a system wherein numerical control machines where hardwired to a large digital computer. Programs were sent directly to the machine tool and paper tapes were not needed. Recently, DNC stands for distributed NC were programs are distributed to the on-board computers at the CNC machine tools. That is, the CNCs are networked to a large computer which provides enhanced memory and computational capacity.

9. An adaptive control system, A(S), must be able to evaluate the process, and modify the inputs in order to optimize the process in some way. In order to do this, the machine tool must have a computer, and that computer must have in it a mathematical model which describes "how the process works". The process is going to adapt itself to improve or optimize itself, or its cost, or some other feature. To be specific, the house thermostat controls the temperature in the house. To make this system A(S), it would have to adjust fuel and air mixtures to improve the heat yield and burn more efficiently. It may even be programmed to change from oil to gas, depending upon the cost of fuel, in order to optimize cost.

10. Feedforward is sensing something about the product on the input side of the process and altering the process to meet these changing input parameters. For example, in hot rolling, the temperature and size (thickness) of the plate entering the rolling stand influences the strength and needed opening between the rolls to accomplish the desired thickness on the output side.

11. The machine tool builders had to learn how to build more accurate and precise machine tools, removing friction and backlash from the mechanical drives, often through the implementation of ball lead screwdrivers. The machines also had to be made more rigid, so that elastic deflections were less of a problem. A good machinist could compensate for such problems on a regular machine tool.

12. Interpolation refers to the situation wherein paths not on the X-Y axes of movement of the table must be approximated with a series of connected short (X,Y) movements. The shorter the increment (the X or Y distance moved), the better will be the interpolation but the program will be longer.

13. Cutter offset refers to the condition where the path of tool centerline must be offset from the desired surface by half the diameter of the tool. This means that the geometry of the path will be different from that of the desired surface. In terms of Figure 32-A the cutter path when machining the bottom edge must be 0.75 in / 2 = 0.375 in away from the intended edge of the part, the tool path will be along the y = 1 in – 0.375 in = 0.625 in line. On the right edge the cutter must run along the x = 6 in + 0.375 I in = 6.375 in line to produce the desired part edge.

14. The operator performs part loading and unloading, inspection, deburring, part transportation, reorientation (turn part end for end), and process monitoring. Any function which requires thinking on the part of the operator will be difficult to automate. In addition to the above functions, the operator may perform setups, improve setups, control the process capability and maintain the machines. Therefore, he may be very multifunctional. The higher the level of function, the more difficult it will be to automate it.

15.Open-loop control means reliance on the machine to execute the commands precisely with no feedback information, e.g., no information as to actual position or velocity. In essence there must be no errors in the motions performed. This means more accurate, more precise machines and so removal of friction and backlash, stiffer drive components and structure. There is no provision in open-loop systems for adjustments either by the machinist as in use of manual machines or by the machine system as in closed-loop machines.

16. There is no reason why it cannot be open-loop. The problem is, however, in contouring, where one must control the velocities in the X and Y (and Z) simultaneously within a certain tolerance or variation. This is difficult to accomplish without feedback.

17.A shaper is not really a production-type machine and a broach is a straight-line cutting machine wherein the tool geometry dictates the geometry of the surface to be machined.

18. It takes too long to manually generate all the points needed to describe a contoured path, even in two dimensions. Suppose you have a one inch long curved path and the contouring requires a tolerance of 0.001 inches. This means you might have to generate 1000 sets of points to program the tool to travel one inch.

19. The feedback detection or sensor can be placed on the motor, on the ballscrew of the table or on the table itself. See Figure 32-9.

20. The machine tool has a point in space that is its zero point - where X,Y, and Z dimensions are zero. This point is fixed in the machine tool. The zero reference point is selected by the part programmer or machine tool operator as some point on the part from which all the part dimensions are made. See Figures 29-7 and 29-8 for examples.

21. An encoder is a feedback sensor (a device) which generates pulses as it rotates. The source of the pulses is often an interrupted light beam. See Figure 29-S and 29-10.

22. In continuous-path or contouring control, both velocity and position must be controlled at all times in order to keep the tool on the desired path. In three-dimensional contouring, the cutter is required to move in three directions simultaneously. That is, the movement is the resultant of X,Y, and Z components. The curved path is broken up into short straight segments or arcs.

23. Pecking is a software routine that is already programmed into the machine which permits the drill to be periodically raised out of the hole to clear the flutes of the drill or chips. See figure below.

24. Pocket milling is a form of contouring wherein a hole (usually square or rectangular) is milled into a solid block of metal. This is often done to reduce the weight of the finished product. The cutting tool first feeds down to the desired depth and then feeds in a contouring path to produce the pocket. End mills with spiral flutes are commonly used for pocket milling. See the following figure.

25. Recalling that process capability refers to the accuracy and precision of a process, suppose a part is being turned in a CNC machine. The probe can detect the current size of the part. The correct depth of cut necessary to bring the part to size can be calculated by the computer. This depth of cut will account for variations in tool size and tool wear and deflections in the machining system.

26. The preparatory or G functions (also called G words) precedes the dimension words and prepares the control system for the information that is to follow in the block of information. G codes range from GOO to G99.

27. Transfer lines rely on mechanical mechanisms to control and produce workpiece motion from one station to the next. Changing motions or speeds or reconfiguring the line requires changing the inherent characteristics of machines and structures. In flexible manufacturing systems changing system behavior and performance is produced by much simpler re-programming of more sophisticated devices, e.g., changing machine tool programs, rerouting AGV guides, re-programming robot and moving sections of conveyors.

28. Even if the basic structure of a transfer line is fixed - a given configuration of machines and the mechanisms used to transfer work between them – it is desirable to be able to change operating conditions of individual machines. Programmable machines and PLC’s provide a relatively easy means for controlling and changing the behavior of component machines in a transfer line. Not all transfer lines are necessarily the extreme lock-step, fixed time step stereotypes. Adjustments and changes can be made to individual stations and programmable machines and PLC’s are useful.

29. In finite element problem formulations a continuous field is modeled by a set of discrete elements. The behavior of each element is defined, elements combined to describe the entire domain of interest and the overall behavior calculated.

Finite element analysis in based on replacing the continuous description of a field, e.g., strain or temperature, with a local description for each of a number of elements making up the entire domain of interest. The specification of the behavior of the variable of interest in the individual elements and the continuity between elements is given in the "shape function." The use of discrete elements and an algebraic shape function results in a system of algebraic equations describing the field rather than a differential equation as in continuum models. The solution of the usually large system of algebraic equations is simpler than the solution of a complicated differential equation that results for complex geometry, material behavior, loading and boundary conditions.

30. The two types of computer-aided process planning are variant CAPP and generated CAPP. The difference between them is that
- in variant process planning the plan is developed from an existing plan for a similar part while
- in generated, or generative, process planning a new plan is developed based on part geometric characteristics, design rules and logic and process characteristics and capabilities.

31. Computer graphics can be used to verify the NC program. In addition, a sample part machined out of plastic or machinable wax can be used to check actual dimensions, although cutting forces and therefore defections may be different when cutting metals than when cutting plastics.

32. Robots are used in materials processing (mainly welding, painting, and machining like drilling and boring) and materials handling (load/unload castings, forgings, and plastic processing machines and machine tools for metal cutting in cells). Robots, as they become more precise with long term repeatability, are being used in electronic and mechanical assembly. Very shortly, we will be seeing dedicated robots attached to machine tools for the purpose of changing tools as well as loading and unloading functions.

33. The typical industrial robot has a manipulator arm, a hand, a power source, and a control system. Depending upon the level of the robot, it will have feedback devices in the various joints, in the manipulator arm and hand, and perhaps sensors for tactile or visual sensory systems.

34. Spherical, rectangular, cylindrical, and jointed-arm are common work envelopes.

35. Positional feedback can be obtained by resolvers or stepper motors or other feedback devices in the joints of the robot arm. Proximity sensors are being developed as well to give positional feedback to the controller. Robots with visual sensors are being introduced into industry in a limited fashion. Many of these systems use vision systems for finding the position or orientation of workpieces so that the robot knows where to go to fetch the part.

36. The rotary transfer device not only moves the part from machine to machine, but also

serves as the workholder. The robot does not serve as the workholder, only a material handler doing load/transport/unload functions. The rotary transfer machine is setup to run one part in large volume. The unmanned cell is designed to handle a family of parts in very small lots. The machines in the cell are computer NC while the machines in the transfer machine or automatic repeat cycle with no feedback - fixed or hard automation or programmable NC machines.

37. The human worker can think, has superior vision and tactile feel, and in addition can walk. The human can also detect odors and hear funny sounds coming from the machines. Compared to humans, robots are quite handicapped but are superior in their ability to work in hazardous or dangerous or nasty environments and are very repeatable, having less cycle time variability when the cycles are long.

38. Tactile sensing is giving machines the sense of feel. No examples readily come to mind.

39. Most robots in automobile body assembly lines are doing spot welding. Some are doing arc welding, other painting. These operations entail moving through well-defined, relatively simple paths. Production of these kinds of motions with robots is easy, inexpensive and replaces people in repetitious tasks in unpleasant environments.

40. Ultra high-speed machining centers have to produce high spindle speed, high feed rates and high rapid travel moves between cutting passes. This leads to the following requirements and the continued development of
- high speed, high stiffness spindles,
- high speed, high performance (acceleration, deceleration) drives,
- high performance controller (high bandwidth),
- high stiffness machine structures.

Problems:

1. The X and Y locations / dimensions for hole #2 are +6.7118 and +8.6563.
The X and Y dimensions / locations for hole #3 are +7.9445 and +4.0555

2. $2\pi r = 3600 = 2\pi\ 5$ in $= 31.42$ inch
$\cos(\theta/2) = (5 - T) / 5 = (5-0.001) / 5 = 4.999 / 5$
where θ = the span angle

Therefore, $\theta/2 = 1.1459^{o}$ and $\theta = 2.292^{o}$
$AB = (31.42) (2.292) / 360 = 0.2$ inches

3. $\text{Cos}(\theta/2) = (5 - T) / 5 = (5 - 0.0001) / 5 = 0.99998$
$\theta/2 =0.36^{o}$;
$\theta = 0.7247^{o}$
$AB = (31.42) (0.7247) / 360 = 0.060$ in

4.

PT	X	Y
1	0	-0.5
2	12.5	-0.5
3	12.5	12.5
4	-0.5	12.5
5	-0.5	-0.5
6	0	-0.5

5.

PT	X	Y
1	0	-0.5
5	-0.5	-0.5
4	-0.5	12.5
3	12.5	12.5
2	12.5	-0.5
1	0	-0.5

6. From the drawing:

- the center of the bolt hole circle is at X = 12 in, Y = 10 in, the radius of the bolt hole circle is 6 in and the angle between holes is 45^o.

The X and Y directions the distances, d, of the center of hole 6 from the center of the bolt hole circle are

in the X direction, $d_x = - (6 \text{ in}) \sin 45^o = -4.243$ in
in the Y direction, $d_y = - (6 \text{ in}) \cos 45^o = - 4.243$ in

And hole 6 center position with respect to the Zero Reference is

X = 12 in – 4.243 in = 7.757 in
Y = 10 in – 4.243 in = 5.757 in

Interpreting the English Program

```
INDEX/GO TO/ 18, 10, 1, 40
```

go to position x = 18 in, y = 10 in z = 1 in with respect to zero ref. i.e., center position of first hole

then instructions for drill in a hole and to copy the hole every 45^o for seven holes

```
GO DELTA/MINUS 1, 12
GO DELTA/ 1, 12
COPY/ 1 XY ROT, 45, 7
```

8. [NOTE: This case study was developed from real factory data for a real part. Therefore the findings represent the real situation in the job shop where the machines are often employed. In this environment, you assume that each machine has one operator doing the job.]

1. The fixed costs, which do not change with make quantity, are: engineering, tooling and setup. The variable costs are the run cost and the material cost (which was not listed).

2. In order to find the run cost, one has to compute the CT from the equations found in the chapter and then add to that the time needed for part loading/unloading, tool changing and adjusting, inspection, and so forth during each cycle. See references on cost estimating.

3. The nonmachining portions can be estimated from other similar jobs done on these machines, or one can use techniques like MTM. One cannot use time study, since these jobs are not yet setup and running.

4. This time estimate is multiplied by the labor cost per hour, which can include a factor for factory overhead.

7. The breakeven quantities are shown on the plots. The engine lathe performs best for quantities of about 1 -> 35, the NC lathe for 35 -> 350 and the 6 Spindle Automatic for quantities larger than about 359. The turret lathe is never an economical alternative, being technologically replaced by the NC lathe. We observe that the turret lathe had a very narrow region over which it was economical if one ignored the NC lathe curve. In addition, we observe that none of these processes display an economic minimum, but rather there are regions in which one process is economically preferred. As the build quantities increase and the processes become more automated, the cost per unit continues to decrease, approaching the variable cost per unit as a limit.

8. The turret lathe is never an option. However, if the NC lathe is removed from the solution, the turret lathe has breakeven quantities at about 50 units and 75 units (a very narrow range). Turret lathes are being used far less in production operations due to the greater flexibility, capability, and productivity of numerical control lathes.

9.Use 0.500 in end cutting end mill to cut keyway and to drill (plunge cut) holes
Spindle speed in rpm, feed rate in in/min

c. Holes are 0.500 inch deep – see line No2 in table

Case Study: “Steam Line Holes”

1. The holes (cuts or slits) in the outer casing occurred where the edges of the U-shaped supporting legs contacted the casing. Essentially the entire weight of the outer casing rested on the upper vertical leg during transportation. During operation, the weight of the inner line and the steam will rest on the two lower legs.

2. A design error as explained below.

3. The designer of this line was not sufficiently familiar with cold forming operations to realize that when flat bar stock is bent to form the U-shaped support legs, a sharp corner will be produced on each outer corner of the bent pieces due to the stretching-contraction of the bars about the center line. This will create a line contact where the legs contact the outer casing, and the weight of the casing will be great enough to cause the load per unit area to exceed the strength of the casing wall in these regions. This was a design error. (The designer never went out to look at the line being fabricated or he might have caught this condition at the plant.)

4. Two design modifications are suggested. Grind off the sharp corners of the legs and shape the contour of the leg to conform to the interior curvature of the outer casing. This will reduce the unit loads to an acceptable level. The second design modification might be to eliminate the legs altogether and let the steam line simply lie on the bottom of the return line with a layer of appropriate insulation material placed between the two. This eliminates the legs and their fabrication and installation altogether.

5. The line must be totally disassembled and these modifications made even though no damage was visible or detectable. An entire new outer casing should be obtained since it appears that the damage was caused during shipping, not installation. Once operational, however, similar damage to the outer casing will be produced by the bottom legs, unless modifications are made.

CHAPTER 33

Review Questions

1.A prototype is the first physical model of a part or product.

2.The prototype can be used to verify the form, fit and function of part. Adding importance to prototyping is that the prototype is the first physical realization of the part and so is important for product and manufacturing process development.

3. Prototyping is expensive because only a small number of parts are made leading to high cost per part. Also, the total cost is high because usually specialized tooling and equipment are used to produce the prototype, possibly by highly skilled personnel. And, since the prototype is important many aspects of manufacturing personnel from many manufacturing functions will be involved in evaluating the prototype.

4. Rapid prototyping is used in software development and in printer circuit board and microelectronic product and process development.

5. *i*. Desktop Manufacturing: many rapid prototyping machine are about of desktop size, at least in terms of the machine footprint.
ii. 3D Printing: Inkjet printers build essentially 2-d structures using a buildup of ink spots. Some rapid prototyping techniques build 3d structures by the buildup of 3d particles of material analogous to the ink spots.
iii. Freeform Fabrication: Since structures can be built up of particles (for example, 3D printing) or streams of material that hold their shape and quickly solidify, there is no mold needed to contain the material. During part production there is a free surface(s), no container, and the ability to direct the material and so "freeform" fabrication.
iv. Layered Manufacturing: Layers of the final part can be built up by depositing particles or streams, parts can be made from a set of layers, e.g., similar to gaskets with slightly different shape for each layer and a number of layers forming a prototype part.
v. Tool-less Manufacturing: If particles are used to buildup a prototype as in freeform fabrication described in part iii there is no typical or traditional tool in the process.

6.*i*. Preprocessing to convert the part design into a sequence of tool paths.
ii. The fabrication of the part
iii. Postprocessing possibly involving curing, cleaning the part, surface finishing, etc.

7. Freeform fabrication processes are additive in the sense that the part is built up by continually adding material to the forming part until it is complete

8. Concepts modelers produce parts for verification of general concepts such as form, shape appearance and fit into final products. The parts are less durable than parts produced on functional modelers that are more robust and are intended for some level of use such as measurement, testing and perhaps short term use of the part.

9. The four basic groups of freeform processes are
i. Photopolymer-based processes in which material addition is by light curing of selected regions of a polymer bath.
ii. Deposition-based in which material is directly deposited onto the forming part.
iii. Powder-bonding using various kinds of bonding mechanisms to form layers or three-dimensional shapes by selective bonding of powder particles.
iv. Lamination-based processes in which layers of material are bonded together, in contrast to some photopolymer-based process in which the individual layers are form sequentially.

10. In turning, a part is produced by material removal using relatively strong, rigid work and tool materials. In freeform fabrication processes the tool is usually less well-defined and controlled, part production is by the addition of small amounts of material per time and the work material is soft and even fluid in some cases. This results in parts produced in freeform fabrication processes having poorer accuracy, rougher surfaces and larger tolerances than turned parts. In addition production times are longer for freeform fabrication and the work materials that can be used are much more limited.

11. Tessellation refers to a simple shape such as a triangle used to numerically model a surface, and it also can mean the process of using the discrete surface elements to model a continuous surface.

12. Preprocessing involves creating a manufacturing part model from the design model, converting the part shape into a sequence of tool paths and generating machine tool code from the tool path information.

Postprocessing has to do with the part itself rather than preparing input data to fabricate the part. Postprocessing may involve curing, cleaning and surface finishing.

13. The three components of freeform fabrication build time are preprocessing time, fabrication time and postprocessing time. Fabrication time is the longest (50% - 90% of total time) since for most processes material addition rates are low. While not always the case, in many operations small increments of material are added in a sequential manner leading to long build times. In contrast, if all parts of the work are processed at one time, parallel processing, high part production rates can be obtained, e.g., conventional casting solidification and sintering and solid ground curing rapid prototyping.

14. A voxel is a volume element. Voxels are significant in freeform fabrication processes since many of the processes can be modeled using the concept of adding voxels to the emerging part. Part build rate is then related to voxel deposition rate and voxel size. Part surface geometry is determined by voxel shape and size. Voxel size and shape depend on the process parameters - operating conditions.

15. In freeform fabrication material is added sequentially to the emerging part. As layers are built up a stair-step surface is created and this stair-stepping is the dominant surface effect in freeform fabrication. Stair-stepping can be minimized by orienting the part so that adjacent layers match better, meaning that the part orientation might have to be

continually changed during production requiring sophisticated machines and controls. Decreasing added layer thickness will decrease step height, but at the cost of added production time.

16. Random noise shrinkage is the non-deterministic part of the shrinkage that occurs on solidification. Random noise shrinkage is due to random variability in phase change shrinkage.

Random noise shrinkage is a factor in determining prototype dimensions for two reasons. First, shrinkage occurs and so part dimensions change and the change in dimensions depends on the amount of shrinkage. Second, and an important implication, is that since random noise shrinkage is non-deterministic the amount of shrinkage cannot be predicted and so cannot be compensated for by process and prototype part design.

17. Starting with the belief that a known amount of shrinkage can be compensated for and so does not influence final part accuracy, only the random noise shrinkage determines prototype dimensional accuracy. However, equation (33-1) states that the degree of random noise shrinkage is linearly proportional to mean process shrinkage so the material with the largest shrinkage will present the most problems with random noise shrinkage. The material with the largest volumetric shrinkage in Table 33-2 is B F Goodrich / Laserite, LN-4000.

18. In addition to random noise shrinkage, the dimensional accuracy available in freeform fabrication processes depends on shrinkage anisotropy, temperature gradients and the resulting residual stresses and warping, and shrinkage variations over the part due to constraints imposed by part shape (variations in amount of shrinkage in different part sections that have different thicknesses for example).

19. In stereolithography patterning is accomplished by scanning a laser over a phtotocuring polymer so that the polymer solidifies along the laser path. Layering is accomplished by raising the liquid polymer level to above the previously formed solid layer and then patterning the liquid layer to produce the next solid layer.

20. In postprocessing of stereolithography parts the excess, non-polymerized material is cleaned off the part and then the part is post or final cured to assure complete polymerization.

21. Stereolithography layering processes are descending platform, ascending suspension, ascending surface and masked-lamp descending platform.

22. In stereolithography first the boundary the layer is exposed and so cured. This setting of the layer boundary is followed by hatching in which in which the remained of the layer is exposed and solidified.

23. In photopolymerization processes the idealized parallelepiped voxel will not be formed because

- laser beam intensity varies over the beam diameter so there is no sharp laser beam edge to form a sharp edge on the voxel,
- the absorption of laser energy in the polymerizing material decreases with depth into the polymer voxel and so the solidification process varies with depth.

24. If power is decreased less energy is available for curing and so the line of voxels will be thinner and less deep. If scanning speed is increased the energy input per time to any voxel is less and so the voxel (line) will be less wide and less high.

25. The advantages of stereolithograhphy processes include high, repeatable dimensional accuracy (0.03% over 60 mm) and good surface finish (below 16 μm). Disadvantages include the need for expensive, sometimes toxic or irritating, polymers, the need for supports which leads to more complicated part designs, more involved preprocessing and the need to remove supports from the finished part and the need for post or final curing of the part.

26. In solid ground curing the pattern of a photopolymer layer is produced by exposing the polymer through a photomask. The photomasks are used for individual layers then cleaned and re-made with a different pattern to be used in making another layer. Layering is composed of a number of steps. For each layer, unexposed resin is removed, liquid wax is applied to fills voids in the layer and then the layer is milled to final thickness. Another layer is then built onto the structure.

27. In photopolymerization certain parts of the entire polymer bath are polymerized and layers are formed. This leads to three general types of postprocessing operations; cleaning to remove excess polymer, surface finishing to remove unacceptable stair-stepping and final curing to improve part strength through complete polymerization.

28. Lamp photopolymerization can produce dimensionally accurate prototypes and relatively smooth surfaces if layer thickness is small. Complex parts can be produced with supports, e.g. pre-assembled structures.

The disadvantages include small material addition rates and so long build times, the need for specialized materials and usually postprocessing to produce acceptable surface quality. If large parts are required the machine can be very large and this is a move away from the ideal of having to invest little time and expense in making prototypes.

29. Solid ground curing does not require supports for the part being built up. This means more of the working area is available for producing parts.

30. In fused deposition model creation an extrusion head is robotically guided and the extruded material forms a layer pattern. Another layer is extruded onto the previous layer to build up the part.

31. Extruded deposition prototypes do not have smooth surfaces but are usually not postprocessed. Deposition conditions are usually set so that an acceptable, even if relatively rough, surface is produced.

32. Extruded deposition processes use much conventional technology (robots and thermoplastics) and so machines are inexpensive, do not require any special shielding and venting and operator skill is minimal.

Materials used have to be easy to extrude and so the limited number of useful materials is a disadvantage. The material used is in filament form and so more costly than might be expected when quoting typical thermoplastic resin cost. The process is slow and rough surfaces are produced.

33. In inkjet deposition the layer pattern is formed by scanning an inkjet printing head over a surface or support. The small droplets coalesce to form a layer. Layers are produced by additional scans over the emerging part and supporting structure.

34. Depending on prototype requirements, inkjet deposition can produce parts that require no postprocessing. If high surface quality, high accuracy, relatively strong parts are required each layer is treated to fill voids and/or milled before the next layer is laid down.

35. The major advantages of the inkjet deposition process arise due to the small drop size and droplet spacing available. High dimensional accuracy and the ability to produce small structures are results.

With the small droplet size the disadvantage of very long build time is typical of inkjet deposition. Materials that can be used are limited.

36. In selective laser sintering the pattern of each layer is produced by scanning a laser over a powder layer. Layering is accomplished by adding another layer of powder to the layer previous sintered, leveling the powder layer and scanning the laser over this next layer.

37. Scanned laser fusion and sintering produces parts with surface roughness typical of bonding powder particles together. Postprocessing involves cleaning the part and, depending on intended use, perhaps surface finishing by processes such as sanding.

38. Scanned laser fusion and sintering is complicated but high strength materials can be processed and so high strength, directly useable products can be produced, e.g., injection molding molds and die casting dies.

The sintering of powder particles leads to rough surfaces and voids and these can be major disadvantages. Since relatively high temperatures compared to other prototyping processes are needed for sintering, high power lasers and perhaps preheating of the powder are needed and these are disadvantages. The need to heat the powder to sintering temperature leads to slow scan rates and long build times. High temperature is also conducive to oxidation and material contamination and so neutral atmosphere may be required. Shrinkage can lead to poor dimensional accuracy. As in other layering processes, stair-stepping can be a problem depending on the surface smoothness required. Often a final densification heat treatment is needed.

39. Fusing of powder particles involves melting of at least part of the powder and re-solidification. Sintering is carried out below the material melting temperature. Particles bond due to atomic diffusion and viscous flow under pressure.

40. In scanned laser fusion and sintering of amorphous thermoplastics the particle surfaces soften and bond forming a solid structure possessing substantial porosity. In crystalline polymers (parts of the polymer having a well ordered or crystalline structure) melting and bonding of particles occurs. In scanned laser fusion and sintering of metal and ceramics the powder is coated with a binder material which acts to bond particles together when first exposed to the patterning laser. The green structure produced is further processed in final sintering and densification, to form the final strong, dense part.

41. In selective inkjet binding (three-dimensional printing) the pattern of the layer to be produced is formed by injection of a binder between powder particles by a scanning head moving over the powder surface. The injected binder bonds powder particles together and the bonded powder pattern and any unbonded powder serves as the surface for the next scan that produces the next layer of the emerging part.

42. Postprocessing operations are different for selective inkjet binding depending on the material used. Ceramics and metals can be sintered to achieve full strength. Further processing can include infiltration of relatively lower melting temperature metals in to the sintered part to increase density.

43. The initial, green part produced in selective inkjet binding is made from a powder and a binder and is formed at low temperature. This leads to the advantages of being able to process a variety of materials using a variety of binders. The result is the possibility of making high strength parts and using the binder as a component that stays in the part.

The disadvantages of selective inkjet binding are associated with the number of operations needed to produce the desirable part properties. The green part has to be produced and then heat treated and infiltrated to achieve high strength and high density.

44. The individual laminations are cut (usually by laser) in desired patterns from a solid sheet. Layering is by stacking and bonding the individual laminations, usually sequentially immediately after the laminations are produced.

45. Post processing of prototypes from lamination based freeform fabrication processes includes edge finishing and perhaps sealing of hygroscopic materials

46. Lamination-based processes offer the advantages of using easy to cut material (although this limits material selection), no need for complicated support structures and relatively simple machines. The laminates are not severely deformed as they are produced and so warping and residual stress in not a large problem in the assembled parts. Since large laminations can be produced easily, large parts can be produced.

The laminations are produced by material removal – cutting – and so as in all material removal processes material that cannot be used, and must be disposed of, is produced.

Only small batches of parts can be produced so build time is long. Build time is also increased if only thin laminations can be produced and used to build up the entire part.

47. Rapid tooling is immediately usable tooling that can be produced quickly and inexpensively. Tooling is often complex in shape. Since freeform fabrication processes can produce complex shapes in a large variety of materials they form a set of attractive processes for tooling production. This is especially true for tooling that does not have to be extremely hard and strong.

48. Rapid tooling can extend from soft tooling to prototype tooling to production tooling. Soft tooling is used for producing small quantities of parts from easy to work materials, for example molds for casting reacting or low temperature curing polymers. Prototype tooling is destined for the production of small numbers of parts. The parts may be prototypes of real products and so made from more difficult to work materials. Production tooling is used to produce high volumes of high quality parts and so the more complicated freeform fabrication processes such as those involving sintering will probably be used for making production tooling.

49. Engineering tooling assemblies, ETA, are assemblies in which the shaped surface of the tooling is not built into a large block. In contrast to forging dies for example in which the die cavity is sculpted from a die block, in a tooling assembly the contoured surface is formed as a thin shell and is supported by a backing material in a frame to produce the entire tooling assembly. ETA's are significant for several reasons. The contoured shell can be made using freeform fabrication processes that are inexpensive and fast. The backing material and frame are not expected to be expensive compared to standard tooling materials. It may be possible to construct a set of modular tooling with only the shaped part of the ETA produced for different parts.

50.Freeform fabrication can be used for making conceptual prototypes to demonstrate ideas, for functional prototypes that can be used for dimensional and performance evaluation and for the production of real products, e.g., hard tooling such as injection molding molds.

Problems: no problems

Case Study: Flywheel for a High-Speed Computer Printer

NOTE: This part is somewhat unique in the relative absence of mechanical requirements (strength, ductility, fracture resistance, etc.) and the need to concentrate high mass in a small part (i.e. the desire to use a heavy material).

1. While a prototype does not have to serve all the functions required of the production part, the important aspects of function should be reproduced in the prototype. The weight of the part is a major requirement and so is should be included in the prototype. This

removes polymers from consideration and focuses attention on the metallic powder-based rapid prototyping techniques. Selective laser sintering with its ability to use metals and to infiltrate parts to achieve high density is the choice.

2. The above requirements, coupled with the need for high dimensional precision tend to restrict the possibilities. Since all axial surfaces are parallel, and the presence of gear teeth and a non-circular section add complexity in this plane, powder metallurgy seems extremely attractive. The thickness of the part is rather high for powder metallurgy, but the mechanical properties are sufficiently low that the absence of high-density pressing should not be a major limitation. The processing of ferrous materials has become routine for powder metallurgy, and heavier copper-based alloys could be used if even greater mass is desired within a given shape. Machining from bar stock would be another alternative, especially in view of the specified precision. Casting processes could be considered, but those that are compatible with ferrous materials would likely require secondary processing to attain the desired dimensional precision.

Since the mechanical properties are largely unspecified, powder metallurgy part and process design is free to select a material based on minimization of expense and ease of fabrication. An unalloyed iron powder, possibly an iron-carbon to utilize the benefits of the graphite as a lubricant, would seem attractive. Another alternative might be the iron-copper powders, since copper additions enhance P/M fabrication and the copper will actually add additional mass, possibly off-setting the presence of voids within the P/M product. Fabrication by machining would probably utilize some form of free-machining steel bar. Casting processes would best utilize one of the more fracture-resistant cast irons, since the part is a spinning flywheel, and the brittleness of the cheapest gray cast iron may be a detriment.

The "best" alternative here appears to be powder metallurgy because of the suitability of the size and shape, the low or absent mechanical properties, the desirability of ferrous material, and the minimization of scrap and labor (compared to machining). Fabrication would be by the conventional press-and-sinter method.

Consideration might be given to the need for enhanced corrosion or wear resistance. The part contains numerous small gear-type teeth -- might they experience wear? If ferrous material is used, is corrosion a possibility? If either of these become a concern, surface modification, such as the popular steam treatment of ferrous powder metallurgy products might be considered. Such a treatment would enhance surface properties without significantly altering the surface dimensions or finish.

CHAPTER 34

Review Questions

1. Electronics is primarily concerned with producing desired functions through production and manipulation of electrical signals by controlling the flow of electrons.

2.Integrated circuits have all the electrical components and interconnections on a single piece of material. This provides the advantages of a single structure and low cost per functional element since the cost of producing larger integrated circuits does not rise rapidly with the number of elements produced.

Electronic assemblies are combinations of electrical devices, including integrated circuits. Electronic assemblies can have greater flexibility in that elements can be combined to produce more and different functions or applications.

The less complex and less flexible (although still able to perform a variety of tasks) integrated circuits are less expensive that the more expensive, but more flexible assemblies.

3. The three levels of electronic manufacturing are;
i. integrated circuit manufacturing,
ii. integrated chip packaging for connection that leads to,
iii. printed circuit board fabrication and assembly.

4. A semiconductor is a material that can be either an electrical conductor or insulator depending on the impurity atoms in the overall atomic structure.

5. Three common semiconductor materials are silicon, gallium arsenide and germanium.

6. Doping is the introduction of impurity atoms into a semiconductor material to produced desired electrical behavior.

7. In n-type semiconductors electrical conduction is by the movement of electrons, negative charge carriers. In p-type semiconductors electrical conduction results from the movement of positive charge carriers – the movement of holes representing a lack of electrons in the valence level of the atoms.

8. The lack of a full complement of electrons in the valence level of the atoms in a semiconductor represents a positive or p-type charge carrier called a hole.

9. Silicon is the most important semiconductor used today because;
i. it is plentiful
ii. it is readily produced in single crystal form needed for electronic manufacture,
iii. the native oxide that forms is useful in electronic device manufacture.

10. A p-n junction is the interface region between a p-type semiconductor region and a n-type region. A p-n junction can be used as an electrical circuit element by controlling charge carrier flow across it – Question 11.

11. In a semiconductor p-n junction the electrons and holes that are characteristic on the n-type and p-type materials on either side of the junction combine to form region with no mobile charge carriers – the depletion region. The difference in potential across the junction is the potential barrier. Electron flow across the junction can be controlled by the imposition of an external potential and switching flow on and off can be the basis for an electronic device. The manufacture of such devices is outlined in Question 12

12. The steps in producing a bipolar diode are (Figure 34-2)
- production of a silicon wafer by cutting, lapping and polishing a section of a large crystal,
- growing an oxide layer on the wafer in an oven (this oxide layer will be used as a mask in the doping process),
- producing a lithography mask over the oxide layer,
- etching of the oxide layer,
- removal of the lithography mask,
- doping, (another doped layer(s)r will be produced above the first one),
- removal of the oxide mask,
- growing of another oxide layer,
- Patterning of the next layer,
- doping,
- deposition of a conducting metal layer to connect the semiconductor layers produced,
- create masks for lithography of metal film to produce leads and contacts,
- etching of metal layer to produce pattern,
- apply passive, protective coating.

13. ULSI is ultra-high-scale integration of electrical elements to form a device. ULSI and very-large-scale integration, VLSI, differ in the number of components per circuit.

14. Level of integration of electronic components required increased miniaturization of integrated circuit components. Initially new technologies were required, recently better control over processes has led to advances.

15. A silicon boule is a single crystal silicon ingot.

16. Impurity additions while growing a single crystal can serve as initial sites for the congregation and segregation of any additional impurities that may enter the process, see Question 20.

17. The electrical properties of the single crystal depend on crystal orientation and type of dopant used. The single crystal ingot is ground to cylindrical form for use. To provide an indication of crystal orientation and dopant type a flats are ground on the cylindrical

surface. The primary, largest, flat indicates crystal orientation. After processing the grinding affected region is removed chemically – a low stress process.

18. Smaller single crystal ingots have flats ground on them to indicate crystal orientation and type of doping. Grinding easily identifiable easily produced flats on large diameter ingots reduces the surface area available on this high cost stock and so to increase available area for devices notches are used.

19. Since high-precision planar devices are to be produced on the wafer, the wafer surface has to be flat and smooth. Geometric concerns in wafer production are the roughness of the wafer surface and the flatness of the wafer.

20. In wafer production gettering is the intentional addition of hard to move impurities into the wafer material in areas away from regions to be used for component production. The intent is to trap other impurities and defects at the gettering sites, Question 16.

21. Silicon wafers can be doped by;
i. alloying during production of the bulk material.
However to produce desirable, useful structure, composition gradients and behavior for electronic devices selective doping is required. Selective doping can be done by;
i. thermal diffusion,
ii. ion implantation.

22. For doping of semiconductor material ion implantation offers better control of the depth of dopant penetration and so dopant concentration and concentration gradient than thermal diffusion. Also, ion implantation provides better control over the impurities that may work their way into the diffusion process.

23. Ion implantation takes place as the high kinetic energy diffusing species impact with and enters the semiconductor. Mechanical damage results and this affects electrical and chemical properties. To remove or minimize the damage annealing processes are used.

24. In annealing, and other thermally driven processes, the effects produced depend on temperature and time of the workpiece at elevated temperature. In annealing of doped semiconductors the high temperature drives the decrease in mechanical damage but also increases energy available for movement and redistribution of dopant atoms. Rapid thermal processing technologies are advantageous since their use results in less change in the electrical properties of the material being processed.

25. In microelectronics manufacturing silicon dioxide is used as;
i. a dielectric material component of electronic elements, e.g., the gate in field effect transistors,
ii. an insulating material between electron element components such as isolation layers between metal conductors.

26. In wet oxidation the furnace atmosphere contains oxygen and water vapor. The diffusion rate of water molecules into the forming diffusion mask is greater that for oxygen molecules and so diffusion layers grow faster in wet oxidation processes. Two advantages of this faster growth rate are less processing time for a given layer thickness and the ability to grow thicker layers in reasonable time.

27. The lateral geometry, or pattern of the planar structures in integrated circuits, are produced by lithography and etching. Question 12 outlines the general steps in which lithography is used to produce patterns on a surface and etching is used to remove material to produce the patters in a material.

28. The most complicated, expensive and critical step microelectronics manufacture is lithography. Large numbers of very precise, high resolution patterns must be produced.

29. For pattern transfer in microelectronic manufacturing photolithography is most widely used. Additional lithography methods are;
i. X-ray lithography,
ii. electron-beam lithography,
iii. ion-beam lithography

In the different lithography processes different physical phenomena are used and so different equipment must be used. Electromagnetic radiation and particles are used and these are controlled and patterned differently.

30. To produce a photoresist mask on a silicon substrate a mask layer must be formed and a pattern produced on it. The steps are
the creation of a photomask,
- a thin film of opaque material is deposited on an optical purity, high stability quartz plate to be used in creating the photomask,
- the thin film is patterned by etching to form the photomask,

the creation of the photoresist
- liquid photoresist material is applied to the silicon substrate,
- the coated substrate is soft baked to evaporate solvents and case photoresist-substate adhesion,
- the photoresist is exposed to electromagnetic radiation through the photomask producing a stable, “hardened” pattern on the photoresist,
- the substrate is moved, indexed, stepped below the photomask to expose and pattern sequential areas of the photoresist,
- the photoresist is developed, the exposed areas of the photoresist remain and the unexposed areas are removed,
- the patterned photoresist on the substarate is hard baked to remove all solvents and harden the photoresist.

31. The two major classifications of photoresist materials are positive photoresists and negative photoresists. With negative photoresists the incident radiation in photoresist film production cause cross-linking in the polymer and making the photoresist less soluble in the developer.

32. A photoresist should
i. be resistant to down stream etching and diffusion or implantation, i.e., after it is applied and hard baked,
ii. have high resolution,
iii. have high sensitivity,
iv. adhere well to the substrate.
Resolution and sensitivity determine the accuracy and precision of the patterns that can be produced.

33. The two standard, and therefore important, wavelengths in photolithography using a mercury arc lamp are
i. the 436 nm, blue, g-line,
ii. the 365 nm, UV, I-line.

34. The three types of exposure methods used in photolithography are
i. contact printing which gives very high resolution,
ii. proximity printing which has higher throughput than the other methods,
iii. projection printing which result in no process induced resist-mask damage.

35. Wet etching uses a liquid chemical to remove material. Dry etching used a physical means to remove material, e.g., a plasma.

36. Undercutting is the removal of material under the photoresist, in the lateral direction for the typical horizontal photoresist-substrate configuration. Undercutting increases with time and so the lateral extent of undercutting varies with depth below the substrate surface. A quantitative measure of the amount of undercut is the etch bias, Figure 34-10.

37. If the photoresist-substrate is underetched the desired pattern is not produced and defects such as exposure or unexposure of doped and electrical contact regions occur and faults such as opens in doped regions and shorts in electrical result.

Overetching results in larger than allowable undercutting (Question 36) and possible damage as change in properties of the substrate and mask.

38. *i*. Etchant composition is the material content of the etchant and determines what interactions occur between it and the substrate and mask.
ii Etchant concentration is the relative proportion of the constituents of the etchant.

Important parameters of the etching process are etchant temperature and workpiece immersion time.

39.

Process	Etch mechanism	Advantages
Plasma etching (gaseous phase chemical etching)	partially ionized gas chemically reacts with the target surface removing material and producing gaseous by-products	high etch rate relatively simple process - low excitation energy - low radiation damage
Reactive ion etching (ion-assisted etching)	physical interaction between ions and target increasing rate of chemical action	etch rate higher than in sputter etching little undercutting in some situations
Sputter etching (ion milling)	impact between ions and target physically remove material	little undercutting

40. Thin films are layers of material less than about 1 μm thick. Thin film are important in microelectronic manufacturing because
- many of the structures and devices produced are built up as a series of thin films,
- thin films are used in many manufacturing processes, e.g., the photoresist in lithography.

41.

Type of Process	Mechanism	Advantages
Evaporative	condensation of metal vapor on substrate	simple - machines and equipment non-severe processing conditions
Sputtering	ions impact on charge material ejecting atoms toward and to the wafer	good step coverage can deposit metals, alloy, dielectrics

42.

Form of CVD	Applications
Atmospheric pressure CVD	producing microelectronic device layers, e.g., - passivation layers - smoothing and gettering layers e.g. producing components of devices - polysilicon gate electrodes
Low pressure CVD	producing microelectronic device components, e.g., - polysilicon gate electrodes
Plasma enhanced CVD	depositing passivating and protective layers on devices

43. In atmospheric chemical vapor deposition undesirable gas-phase reactions are controlled by using dilute gases. In low pressure chemical vapor deposition undesirable gas-phase reactions are controlled by using gas pressure.

44. Reactor designs are based on the fundamental physical process that controls and limits the deposition process. The reactions that occur at the deposition surface depend on the rate of reaction and the availability of reacting material. In atmospheric pressure chemical vapor deposition a large amount of the reacting gas is available at the surface and so the rate of deposition is controlled by the reaction rate – it is reaction rate limited. In low pressure chemical vapor deposition the availability of reacting material at the deposition surface controls the rate of reaction – it is mass transport rate to the surface limited.

For the reaction rate limited low pressure chemical vapor deposition process the important reactor characteristics are assuring uniform temperature over the entire gas mass in the reactor. This means and tight control over reactor temperature leading to heated wall reactors. For mass flow rate limited processes the control issue is assuring an adequate, uniform flow of gas over the entire deposition area. The flow of the reacting gas controls reactor design – nonuniform temperature in the reactor also can influence flow.

45. Two types of chemical vapor deposition reactor design are cold wall and heated wall reactors.
Hot-wall reactors keep the entire reaction zone at a uniform temperature providing good process temperature and flow control resulting in the advantage of uniformity of the deposited layer. The disadvantages of hot-wall reactors arise from deposition on the reactor walls. This may cause contamination of ongoing processes as aged deposits flake off the wall providing contaminants for the new or different material films. If reactors are dedicated to certain materials flexibility in types of materials that can be deposited is lost.

Cold-wall reactors are simpler than hot-wall reactors and so less expensive and easier to operate and maintain. The major disadvantage of them is the relatively less well controlled process temperature uniformity compared to hot-wall reactors. This leads to less temperature control and less uniform deposited layers.

46. The plasma enhanced chemical vapor deposition process an be run at lower temperatures than other chemical deposition processes. This has the advantage of allowing the desired reactions to occur while minimizing the effect of other temperature dependent processes, e.g., allowing deposition with minimizing diffusion of previously deposited material.

47. Epitaxy is the growth of a single crystal thin film on a surface with the film having the same crystal orientation as the surface. Epitaxial layers can be produced with fewer defects than doped layers, higher purity, more uniform dopant distribution and sharper transitions so that their use produces better electronic performance. Also, epitaxial layers can be used to ease geometric transitions between device layers since they maintain their desirable characteristics as layer thickness increases.

48. Contacts are the access points between the first metal layer of conduction lines and the underlying semiconductor. Vias are access points for contacts between the different layers of conduction lines.

49. Planarizarion is the production of a flat or planar surface on one or more of the layers that are built up during the production of integrated circuits. Plararization is needed because as the layers are produced distinct topography associated with each layer forms. If the topography becomes too uneven the structure and performance of subsequent layers becomes problematic. Non-flat surface can lead to short in the conducting layers and other problems.

50.Interconnect layers can be plararized by;
i. using a layer material that flows easily and inherently forms a planar surface, e.g., p-glass,
ii. etching with an etchant that preferentially etches high regions of the surface,
iii. chemical mechanical polishing which uses a combination of mechanical and chemical actions to remove material.

51. Electromigration is the movement of atoms over time due to an applied current. Electromigration is a concern in integrated circuit processing and use since the size and shape of conducting paths change. As conductor size and spacing are decreased the effects of electromigration increase and can even cause open circuits and short circuits

52. Wafer testing is intended to remove any defective dies or chips from the production stream. That is, defective dies are identified and removed and so resources are not spent on packaging dies that will not function.

53. A chip is an individual integrated circuit that is cut from the wafer on which many chips are produced.

54. Driving the increase in component density and die area is the desire to increase the number of chips produced on each wafer. This drives down the cost per chip.

55. Very small scale, or point, defects have large detrimental effects on integrated circuit yield. These small defects can be cause by atmospheric particles and to minimize this source of product contamination manufacturing is conducted in clean rooms.

56. Integrated circuit packages are made up of;
i. components to distribute electronic signals and power and provide interfacing to test equipment and the entire system in which the circuit will reside,
ii. components to protect the devices and circuitry.

57. In through-hole connections discrete electronic components are inserted into metal plated holes in the printed circuit board. Through hole technology provides the advantages of high joint strength and the ability to use many different kinds of components.

With surface mount technology electronic components are placed onto solder paste pads on the printed circuit board and soldered. Compared to through hole technology surface mount techniques provide the advantages of easily automated production and higher circuit board density. This leads to cost-effective manufacturing.

58. The two main classes of through-hole packages are dual in-line packages (DIP) and pin grid arrays (PGA).

59. The four types of surface mount lead geometries are;
i. butt lead or I-lead that has the advantages of cost savings if through-hole components have to be converted for use in surface mount processes,
ii. gull wing leads that provide the advantages of thinner packages, smaller leads, fine pitch, compatibility with most re-flow soldering processes, and that they can be self-aligning during soldering,
iii. J-leads have the advantages of ruggedness, easy inspection since solder joint are more visible and easier cleaning since the components have higher stand offs from the circuit board,
iv. solder balls used in ball grid arrays have the advantages of high lead density, self-aligning and they are less susceptible to deviations in parallelism between the component and board.

60. The major steps in conventional integrated circuit packaging are
- attachment of the die to the package,
- sealing of the package using either premolded or postmolded packages,
- formation of leads.

61. Three techniques for attaching and electrically connecting dies to integrated circuit packages are;
i. wire bonding or chip-and-wire attachment using an adhesive to attach the chip to the package and a wire to connect bonding pads on the chip and package,

ii. tape-automated bonding in which a polymer tape holding the lead circuitry is aligned with the die and bonded using raised temperature and applied pressure,
iii. flip-chip technology in which the chip and package bonding pads face each other.

62. Direct chip attachment or chip-on-board or direct mounting is a process in which the chip is directly attached to the circuit board. It differs from other integrated circuit packaging in that the chip itself is assembled onto the circuit board rather than a packaged chip. Disadvantages of this process are that it involves the shipping and handling of bare chips and the need for equipment to handle die-attachment while manufacturers have package-level equipment.

63. Chip scale packages are packages that add no more than 20% of additional board area to the chip. Chip scale packages are physical packages, not attachment methods. Direct chip attachment interconnection techniques are used with chip scale packages.

64. Multichip modules are chip carriers that package of more than one chip through direct chip attachment to fine line, thin film conductors within a ceramic carrier. They are advantageous in integrated circuit packaging because reduced distances between integrated circuits is possible

65. Printed circuit boards are the carriers that hold and connect the elements of a circuit. Printed circuit boards consist of a board composed of
i. laminated dielectric sheets comprising the base,
ii. metallic circuits or tracks for connecting the electronic components to be placed on the base
iii. pads of conducting material that serve as junctions for circuit elements.

66. Three alternative materials for the dielectric components of printed circuit boards are
i. epoxy-impregnated fiberglass which is the least expensive of the alternatives,
ii. polyamide which can be mechanically flexible and so can be made into flexible circuits,
iii. alumina or other ceramic which can be used to minimize thermal shock because of relatively high thermal conductivity compared to the other materials.

67. Plated through holes are holes that are plated with electrically conducting materials and serve as insertion points for circuit components. Via holes are plated holes that are connect the circuit on one side of the board to the circuit on the other side of the board.

68. Printed circuit boards are composed of layers of circuits. The circuits on different layers or different sides of an individual layer are connected by vias. Blind or partially buried vias extend from one side of the board to a layer in the interior of the board, they do not extent to the other free side of the board. Buried vias connect layers with in the interior of the board, they to not extent to either free side of the board. Through vias extend from the outermost circuit track on one side of the board to the outermost track on the other side of the board.

69. The four major steps in producing a multilayer printed circuit board are
i. production of circuits on inner layer laminations, (Question 70),
ii. lamination of layers,
iii. drilling and preparation of via holes,
iv. production of circuits on outer layers.

70. The two methods of circuitization of inner layers of printed circuit boards are
i. Subtractive circuitization in which
- the starting structure is a double sided copper coated laminate, panel,
- to which a dry photoresist is applied,
- followed by photolithographic exposure and development to produce the circuit pattern,
- and etching of the copper coating to produce the circuit,
- and stripping of the photoresist,
- then drilling of registration holes used in board assembly.

This process is less involved and more economical than the alternative additive circuitization.

ii. Additive circuitization is different than subtractive circuitization in that the circuit is formed by producing the circuit pattern directly by material deposition rather than by etching the circuit into a metal layer. Additive circuitization involves
- starting with a laminate in which registration holes have been drilled,
- drilling of any required via holes,
- exposing and developing an etch mask that exposes the underlying dielectric,
- preparing the dielectric for electroless deposition by adsorbing a catalyst on to it, the buttercoating or seeding process,
- deposition of a thin layer of electroless copper on the seeded dielectric,
- electroplating of thicker layers
- stripping of the resist.

This process provides higher resolution circuitry (finer lines and higher density) than subtractive circuitization.

71. Built-up multilayers are circuit boards that are produced by deposition and processing of one dielectric layer at a time. Vias are plated passageways used to connect one circuit layer to another. Microvias are via holes that are smaller than the approximately 200 micrometers diameter holes than can be produced by conventional mechanical drilling.

Laminates start with a dielectric layer and produce the circuit on it. Built-up multilayer manufacturing includes the deposition and processing of the dielectric as an integral, controllable part of the process.

Microvias are different from vias in size and production methods. Vias are larger than microvias and are usually produced by mechanical drilling and limited in size by the minimum drill size of about 200 micrometers. Micro vias are smaller than drilled vias and are produced by photoimaging, laser ablation and plasma etching.

72. The four major steps in assembling a through hole printed wiring assembly are
i. insertion of the circuit components,
ii. clinching and trimming of leads,

iii. soldering,
iv. postsolder cleaning.

73. Leads are trimmed and clinched after through hole insertion to decrease the effective size of them and so decrease the possibility of bridging of adjacent solder joints. Solder joint bridging produces electrical shorts in the circuit.

74. Four major steps in assembling surface mount printed wiring assemblies are
i. application of solder paste to the lands on the printed circuit board by screening, stenciling or dispensing,
ii. placement of the surface mount components,
iii. reflow of solder paste in an oven (or, less commonly, vapor phase soldering or condensation soldering),
iv. cleaning

75. Four methods for feeding components to robotic manipulators in pick-and-place robots are
i. tape or reel feeding which is widely used and most appropriate to high volume placement or where protective handling to minimize lead damage is needed,
ii. bulk feeding as with vibratory bowls is useful for prototyping of production processes,
iii. tube or stick feeders which are primarily used in smaller volume assemblers,
iv. waffle packs that hold different kinds of chips in specific locations so that pick-and-place robots can be programmed for positioning to pick the correct chip.

76. Startup and operation cost of surface mount assembly processes is most affected by the component placement step in the process.

Large costs are associated with component placement since the equipment cost is high (high startup costs) and this stage in the assembly process is the source of most product defects.

77. The four necessary zones in a surface mount solder reflow thermal profile (time-temperature trajectory) are
i. preheating to drive off nonflux volatiles from the solder paste,
ii. soaking to bring the entire assembly up to a temperature just below reflow temperature of the paste,
iii. a rapid rise in temperature to bring the solder paste temperature to above the reflow temperature for fluxing and wetting,
iv. cooling of the assembly.

Problems: no problems

CHAPTER 35

Review Questions

1. Manufacture as a joined structure composed of several pieces is favored when the product needs to be large, composed of several parts with different properties or have a complex shape.

2.Consolidatin processes are those in which different material bodies are joined to produce the part or product. Examples of consolidation processes are welding of relatively large pieces together to form a part, powder metallurgy with the sintering of particles together and additive rapid prototyping techniques such as inkjet and 3-D printing.

3. Welding is the permanent joining of two material bodies by coalescence produced by temperature, pressure and metallurgical conditions.

4. The ideal metallurgical bond requires: (1) perfectly smooth, flat or matching surfaces, (2) clean surfaces, free from oxides, absorbed gases, grease, and other contaminants, (3) metals with no internal impurities, and (4) two metals that are both single crystals with identical crystallographic structure and orientation.

5. Surface roughness is overcome either by force, causing plastic deformation of the asperities, or by melting the two surfaces so that fusion occurs. In solid state welding, contaminated layers are removed by mechanical or chemical cleaning prior to welding or by causing sufficient metal to flow along the interface so that they are squeezed out of the weld. In fusion welding, the contaminants are removed by fluxing agents. Welding in a vacuum also serves to remove contaminants.

6. When high temperatures are used in welding, the metals may be adversely affected by the surrounding environment. If actual melting occurs, serious modification of the metal may result. The metallurgical structure and properties of the metal can also be adversely affected by the heating and cooling cycle of the weld process.

7. Thermal cutting is the separation of a piece of material into two pieces by the imposition of localized thermal energy such as with a flame, electric arc, laser beam, electron beam or the impingement of an oxygen stream onto a hot material.

8. Some common weld defects are cracks, cavities, inclusions, incomplete fusion between the weld and base materials, incomplete penetration of the weld into the materials to be joined, unacceptable weld shape, surface defects due to arc strikes, blemishes due to spatter, metallurgical changes that are detrimental to product performance and warping and distortion.

9. The four basic types of fusion welds are bead welds, groove welds, fillet welds, and plug welds, as illustrated in Figure 35-3.

10.Fillet welds are used for tee, lap, and corner joints. These configurations are shown in Figure 35-6.

11. The cost of making a weld is affected by the required edge preparation, the amount of weld metal that must be deposited, the type of process and equipment that must be used, and the speed and ease with which the welding can be accomplished.

12. When two pieces are welded together, they become one piece. Cracks in one segment can then cross the weld and continue propagation throughout the structure. Also, one segment constrains the others, so that properties such as fracture resistance and ductility can change appreciably.

13. The notch-ductility characteristics of metal can change markedly with a change in the size of the piece. While a small piece, such as a Charpy impact specimen, exhibits ductile behavior and good energy absorption down to low temperatures, a large structure of the same metal exhibits brittle behavior at higher temperatures. Because of the added constraint of mass, deformation and fracture modes that may absorb energy may be forbidden, resulting in a product with reduced fracture resistance, reduced ductility, and an elevated ductile-to-brittle transition temperature.

14. Excessive rigidity in a welded structure can restrict the material's ability to redistribute stresses, and thereby avoid failure. Structures and joints should be designed to have some flexibility.

15. In a fusion weld, a pool of molten metal is created, contained, and solidified within a metal mold formed by the segments being welded. This is actually a casting in a metal mold and has all of the structural and property features of such a casting.

16. The chemistry of a weld fusion zone may be complex because it is a combination of the filler metal and melted-back metal from the material being welded. See Figure 35-9.

17. Since the solidified weld will be in an as-cast condition, its properties and characteristics will not be those of the same metal in the wrought state. Therefore, electrode or filler metals are usually not selected on the basis of matching chemistry, but on the basis of having properties in the as-solidified or as-deposited condition that equal or exceed those of the base metal.

18. Fusion weldments may exhibit all of the problems and defects observed with castings, including: gas porosity, inclusions, blowholes, cracks, and shrinkage. Rapid solidification and cooling may lead to: inability to expel dissolved gases, chemical segregation, grain-size variation, grain shape problems, and orientation effects.

19. In the heat-affected zone, temperature and its duration vary widely with location. This variation in thermal history produces a variety of microstructures and a range of properties.

20. Structure and property variations in heat-affected zones can include: phase transformations, grain growth, precipitation (or overaging), embrittlement, and even cracking.

21. Due to possible changes in structure, the heat-affected zone may no longer possess the desirable properties of the parent metal, and, since it was not molten, it does not have the selected properties of the weld metal. Consequently, it is often the weakest area of the weld in the as-welded condition. Except when there are obvious defects in the weld deposit, most welding failures originate in the heat-affected zone.

22. Low heat input rate to welding processes heat a large area of the workpieces and so produce high total heat content, slow cooling rates, large heat affected zone. The resulting structures can have low strength and hardness and high ductility (analogous to annealing). Residual stresses are expected to be lower than high heal input rate processes that produce localized, small, high temperature zones interacting with surrounding cooler zones.

23. When attempting to heat-treat products after welding, numerous problems can arise in producing controlled heating and cooling in the often large, complex-shaped structures that are typically produced by welding. Furnaces, quench tanks, and related equipment may not be available to handle the full size of the welded assembly.

24. Pre- and post-heating operations can reduce the variation (and sharpness in the variation) in microstructure. The cooling rate in both the weld deposit and adjacent heat-affected zone is reduced, producing more gradual changes in microstructure.

25. In brazing and soldering, the base and filler metals are usually of radically different chemistry. The elevated temperatures of joining can promote interdiffusion. Intermetallic phases can form at the interface and alter the properties of the joint - usually imparting loss of both strength and ductility .

26. Residual stresses can produce several kinds of undesirable effects including
- residual stress states that act in combination with applied stresses to raise the effect stress acting in a part to above the failure stress,
- change of part shape, warping, as the residual stresses produced during processing of a held or fixed part rearrange themselves when the part is released from the fixture,
- change in dimensions locally.

27. Reaction-type residual stress is caused by restraining the parts during welding. If the parts are not free to move in response to loads applied during welding when the entire structure is assembled there is rearrangement of the stress state. Reaction stresses result.

28. The magnitude of the reaction stresses is an inverse function of the length between the weld joint and the point of fixed constraint.

29. The amount of distortion in a welded structure can frequently be reduced by: forming the weld with the least amount of weld metal necessary to make the joint; use faster welding speeds to reduce the amount of heating of adjacent metal; use the minimum number of welding passes; permit the base metal segments to have as much freedom of motion as possible; and, weld to the point of greatest freedom (as from the center to the edge) . Weld surfaces can be peened to induce offsetting compression.

30. If plastic flow can occur in response to residual stresses the effects of the residual stress is mitigated. A plastic flow zone forms, plastic flow occurs, stress is relieved or surrounded by an elastic zone constraining the plastic zone. Residual stresses will have harmful effects if the residual stress acts along with a stress raiser such as a notch and if the structure is very rigid and no or very little plastic flow can occur.

31. When welded structures are subsequently machined, the material removal frequently unbalances the residual stress equilibrium, and the material distorts to achieve a new balance of forces. In essence, it distorts during machining. Weldments that are to undergo appreciable machining should be given a stress-relief heat treatment prior to the machining operation.

32. The cracking of weldments can be reduced by designing joints to keep restraint to a minimum, and selecting metals and alloys with welding in mind. Thin materials are more resistant to cracking than thicker sections. The size and shape of the weld bead should be properly selected and maintained. Weld profile (penetration depth) can affect cracking. By slowing the cooling of the weld area and inducing plasticity into the material, the tendency to crack can be further reduced. Preheats, postheats, and stress reliefs can be used, along with efforts to remove hydrogen from the weld area.

33. Weldability and joinability are nebulous terms since the performance of a process depends on a number of material and process characteristics. A material may produce a very good quality weld in one process and so be weldable, while in a different welding process the results may be unacceptable and the material is not weldable. Similarly, and even more extreme, a material may be easy to weld and produce a good quality joint at one set of welding conditions and unacceptable results in the same welding process using different conditions.

Problems:

1. The assessment is not fair, because a subsequent examination of the riveted ships revealed a number of similar cracks. These cracks, however, simply traveled to the edge of the plate and stopped. Welding, on the other hand, produces monolithic structures. The cracks can cross the welds and continue into and through adjacent pieces. While the problem was a material problem, it became far more apparent when welding was used to produce the large, one-piece assemblies.

The problem was later identified as a metallurgical one related to the high ductile-to-brittle transition temperatures of the steel being welded. Additional knowledge of the phenomena, coupled with the selection of materials with lower transition temperatures, has permitted the safe use of welded-hull ships under most of the temperatures likely to be encountered.

(NOTE: While not a welded-hull ship, it is this same ductile-to-brittle transition phenomena that is suspected a playing a significant role in the sinking of the Titanic.)

2. Some possible corrective measures to eliminate or reduce cracking include: (1) possible use of a lower carbon steel, (2) substitution of a low-hydrogen type electrode, and (3) use of preheating and possibly some post-heating if the carbon content of the steel cannot be reduced.

3. a. Based on the desire to minimize constraint, one should resist the natural tendency to fabricate the exterior box and then insert the interior subsections. Instead, the preferred sequence would begin with the innermost welds and progress outward. The initial welds might be 4 and 5 -- then 8 and 9. Welds 3, 7, 6 and 10 would follow, and then on to the final assembly at 1 and 2 and 11 and 12.

b. Various "rules" could be proposed, each designed to reduce the amount of restraint on the weld or the number of welds that must be made under restraint. When restrained welds must be made, efforts could be made to maximize the length of material, or distance to the restraint. (NOTE: If 3/100-inch elastic stretching must be provided to compensate for weld shrinkage, this would require a 3% stretch for a 1-inch segment, 0.3% for a 10-inch segment, and 0.03% for a 100-inch segment.)

Case Study: no case study

CHAPTER 36

Review Questions

1.The combustion of oxygen and acetylene involves a two-stage reaction. In the first stage,

$C_2H_2 + 02$ --> $2 CO + H_2$

And in the second stage,

$2C0 + 02$ --> $2C0_2$ $H_2 + 1/2\ 02$ --> H_20

The outer flame region preheats the metal and protects it from the surrounding atmosphere. The inner part of the flame produces the required high temperature.

2. The maximum temperature in an oxyacetylene flame occurs at the end of the inner cone where the first stage of combustion is complete.

3. The outer zone of an oxyacetylene flame serves to preheat the metal and provides shielding from oxidation, since some of the oxygen from the surrounding air is used in the secondary combustion.

4. The three types of oxyacetylene flames that can be produced by varying the oxygen-to-acetylene ratio are: a neutral flame, oxidizing flame (with excess oxygen), and a carburizing or reducing flame (with excess fuel).

5. MAPP, while providing a slightly lower temperature flame, is more dense than acetylene, providing more energy for a given volume. It can be stored safely in ordinary pressure tanks.

6. The tip size of the torch can be varied to control the shape of the inner cone, the flow rate of the gases, and the size of the material that can be welded. Larger tips permit greater flow of gases, resulting in greater heat input without requiring higher gas velocities that might blow the molten metal from the weld puddle. Thicker metal requires larger tips.

7. A filler metal is extra metal added between the two parts being welded. Filler metal is needed since there are usually gaps between the edges being welded and these gaps need to be filled. It is better to add metal to fill the gaps than to use metal from the pieces being welded because that would change the welded section size and shape.

8. Welding flux
- cleans the surfaces to be welded,
- removes contaminants, primarily oxides,
- produces a gaseous shield around the welding zone preventing oxidation,
- produces a slag that as it solidifies protects the cooling weld pool.

9. The low heat input rate in oxyfuel gas welding leads to large heated areas that can cause distortion and changes in metal properties in areas removed from the welded region.

10. The use of oxyfuel processes is attractive since the equipment is portable, inexpensive and versatile. For example, oxyfuel processes can be used in welding, brazing, soldering, cutting and as the heat source for bending, forming, straightening and hardening.

11. When torch cutting nonferrous metals, the metal is merely melted by the flame and blown away to form a gap, or kerf. When ferrous material is being cut, it is heated to a sufficient temperature that the iron will then oxidize (burn) rapidly in the stream of oxygen that flows from the torch. Thus, the oxyfuel flame first raises the temperature of the metal and then the oxygen content is raised to continue the cutting, the iron oxide being expelled from the cut by the gas pressure of the torch.

12. When ferrous metal emerges from a continuous casting operation, its temperature will already be above the necessary 2200^0F, so only a supply of oxygen through a small pipe is necessary to start and maintain cutting. This is known as oxygen lance cutting (LOC).

13. The tip arrangement in an oxyacetylene, cutting torch is different from that of an oxyacetylene welding torch. The cutting torch contains a circular array of holes through which the oxygen-acetylene mixture is supplied for the heating flame. A larger hole in the center supplies a stream of oxygen to promote the rapid oxidation and blow the formed oxides from the cut.

14. Cutting torches can be mechanically manipulated by a number of means, including driven carriages (as for straight cuts), template-tracers, CNC machines, and industrial robots.

15. In order to cut underwater, a supply of compressed air must be added to the torch to provide the secondary oxygen for the oxyacetylene flame and keep the water away from the zone where the burning of the metal occurs.

16. If a curved plate is to be straightened by flame straightening, the heat should be applied to the longer surface of the arc. The hot metal will be upset and will contract upon cooling, reducing the length of that region.

17. Flame straightening cannot be used on thin materials because the metal adjacent to the heated area must have sufficient rigidity to resist transferring the buckle from one area to another.

Problems: no problems

Case Study: no case study

CHAPTER 37

Review Questions

1.Early attempts to develop arc welding were plagued by instability of the arc, requiring great amount of skill to maintain it, and contamination and oxidation of the weld metal resulted from atmospheric exposure at such high temperatures. In addition, the metallurgical effects of such a process were not well understood.

2. The three types of current and circuit conditions used in arc welding are: alternating current, straight polarity direct current (workpiece is positive), and reversed polarity direct current (workpiece is negative).

3. In the consumable electrode processes, the electrode melts to supply the needed filler metal to fill the voids in the joint. With a nonconsumable electrode, such as tungsten, a separate metal wire must be used to supply the filler metal.

4. The three modes of metal transfer that can occur in arc welding are: globular, spray, and short circuit. They are illustrated in Figure 34-2.

5. Arc welding processes require the specification of: welding voltage, welding current, arc polarity, arc length, welding speed, arc atmosphere, electrode or filler material, and flux.

6. The four primary consumable electrode arc welding processes are;
i. shielded metal arc welding,
ii. flux cored arc welding,
iii. gas metal arc welding,
iv. submerged arc welding.

7. Electrode coatings can play a number of roles, among them:

> (1) provide a protective atmosphere, (2) stabilize the arc, (3) act as a flux to remove impurities from the molten metal, (4) provide a protective slag to accumulate impurities, prevent oxidation, and slow the cooling of the weld metal, (5) reduce weld metal spatter and increase the efficiency of deposition, (6) add alloy elements, (7) affect arc penetration, (8) influence the shape of the weld bead, and (9) add additional filler metal.

8. Coated electrodes are classified by the tensile strength of the deposited weld metal, the welding position in which they may be used, the type of current and polarity (if direct current), and the type of covering. A four or five-digit system of designation is used, as presented in Figure 34-3.

9. Shielded metal arc electrodes are baked just prior to welding to remove all moisture from the coating, a source of hydrogen in the welds.

10. The gases that form when the electrode coating melts and vaporizes
- provide a protective atmosphere for the welding zone,
- provide ionizing elements to help stabilize the arc,
- help reduce weld spatter,
- increase deposition efficiency,
- influence weld bead shape.

11. The slag coating in a shielded metal arc weld serves to entrap impurities that float to the surface, protect the cooling metal from oxidation, and slow down the cooling rate of the weld metal to prevent hardening.

12. Electrodes having iron powder in the coating significantly increase the amount of metal that can be deposited with a given-size electrode wire and current.

13. Continuous shielded metal arc welding faces the problem of providing electrical contact (through the coating) to the center filler-metal wire. Electrode length is limited because the current must be applied near the arc to prevent the electrode from overheating and ruining the coating. Thus, while some continuous arc welding processes have been developed, most shielded metal arc welding is performed with finite length stick electrodes.

14. With the flux in the center of an electrode, the electrode is less bulky (since no binder is required to hold it onto the outside) and electrical contact can be maintained directly with the surface of the electrode. Thus, flux-cored arc welding becomes something like continuous shielded metal arc welding.

15. The current in fluxed-core arc welding can be higher than in shielded metal arc welding since overheating of the electrode is less of a problem. With less concern about overheating current can be increased.

16. Compared to shielded metal arc welding, gas metal arc welding provides the advantages of
- there being no need for flux and so the electrode can an uncoated, continuous wire,
- it can be applied to all metals,
- the heat transfer and weld penetration can be controlled to some extent by choice of shielding gas.

17. In gas metal arc welding helium produces the hottest arc and deepest weld penetration and carbon dioxide provides the lowest arc temperatures and shallowest penetration. Argon produces temperatures and penetrations intermediate between helium and carbon dioxide.

18. In the pulsed-arc gas metal arc welding process, a low welding current is first used to create a molten globule on the end of the filler wire. A burst of high current is then applied, which "explodes" the globule and transfers the metal across the arc in the form of a spray.

19. Because of the reduced heat input and temperatures of the pulsed arc technique: thinner material can be welded, distortion is reduced or eliminated, workpiece discoloration is minimized, heat-sensitive parts can be welded, high-conductivity metals can be joined, electrode life is extended, electrode cooling techniques may not be required, and fine microstructures are

20. Some of the primary process variables in gas metal arc welding are type of gas, welding current/voltage and rate of electrode advancement.

21. In submerged arc welding, the flux provides excellent shielding of the molten metal and a sink for impurities. In addition, the unmelted flux provides a thermal blanket to slow down the cooling of the weld area and produce a soft, ductile weld.

22. Submerged arc welds can be performed at high welding speed, with high deposition rates, deep penetration, and high cleanliness. However, submerged arc welds are generally restricted to flat welds because of the need to form an area of molten slag and keep it in place over the molten weld metal. Extensive flux handling, possible contamination of the flux by moisture, the large volume of slag that must be removed, the high heat inputs that promote large grain sizes, and the slow cooling rates are other negative features of the process. The process is not suitable for high-carbon steels, tool steels, aluminum, magnesium, titanium, lead or zinc.

23. In bulk welding, iron powder is deposited into the prepared gap (beneath the flux blanket but on top of the backing strip) as a means of increasing the deposition rate. A single pass can deposit as much weld metal as seven or eight conventional submerged arc passes.

24. Stud welding is a special adaptation of arc welding that has been developed to weld fasteners into place.

25. The ceramic ferrule placed over the stud in stud welding acts to concentrate the arc heat and simultaneously protect the heated metal from the atmosphere. It also serves to confine the molten or plastic metal to the weld area and shapes it around the base of the stud.

26. Carbon dioxide cannot be used in gas tungsten arc welding because it does not adequately protect the tungsten electrode.

27. Since filler metal deposition rate increases with increasing wire temperature, Figure 37-13, deposition rate can be increased by increasing wire temperature. This can be done by electrically preheating the filler wire and oscillating the hot wire in the high temperature zone.

28. Some of the attractive features with gas tungsten arc welding are the production of high quality, clean, localized, symmetric welds without use of flux. Many of the

advantages accrue due to the ability to use various shielding gases and shielding gas efficiency.

29. In gas tungsten arc spot welding the weld nugget begins to form at the surface of the work, In most resistance spot welding processes the weld nugget forms at the interface between the two workpieces, where the resistance is the highest.

30. In plasma arc welding, it is the flow of hot gases that actually transfers heat to the workpiece and melts the metal.

31. In plasma arc welding there is a flow of inert gas through the nozzle where it is heated to form a plasma, called orifice flow. This gas flow is the source of heat to the weld zone. There is also a flow inert gas around the welding zone that provides weld pool shielding.

32. Plasma arc welding offers greater energy concentration, fast welding speeds, deep penetration, a narrow heat-affected zone, reduced distortion, less demand for filler metal, higher temperatures, and a process that is insensitive to arc length. Nearly all metals and alloys can be welded.

33. The primary difference between plasma arc welding and plasma arc cutting is the pressure of the gas flowing out of the orifice. At lower pressures, the molten material simply flows into the joint and solidifies to form a weld. At higher pressures, the molten material is expelled form the region and the process becomes plasma cutting.

34. The kerf in thermal cutting processes is the slit or separation region between the parts of the workpiece being cut.

35. In the oxygen arc cutting process, the stream of oxygen is directed onto the hot, incandescent metal. It reacts with the oxidizable metal, liquifies, and is expelled, producing the cut.

36. Plasma arc cutting is used to cut high-melting-point metals because this process produces the highest temperature available from any practical source. Virtually any material can be melted and blown from the cut.

37. Radial impingement of water on the arc was found to provide the necessary constriction of the arc, producing the intense, highly-focused arc needed to make a narrow, controlled cut in plasma arc cutting. Magnetic fields have also been used to constrict the arc.

38. Compared to the oxyfuel technique, plasma cutting is more economical, more versatile, and much faster. Narrow kerfs and smooth surfaces are produced, and surface oxidation is almost eliminated by the cooling water spray. The size of the heat-affected zone is significantly reduced and heat-related distortion is virtually eliminated.

39. Because of the low rate of heat input, oxyacetylene cutting will produce a rather large heat-affected zone. Arc cutting produces effects similar to arc welding. Plasma arc cutting is so rapid that the heat-affected zone is less than 1/16 inch.

40. Cutting tends to produce surfaces in residual tension. If subsequent machining removes only a portion of the total surface, the resulting imbalance of stresses may cause warping.

41.In addition to the effect of residual stresses, Flame- or arc-cut edges are rough and contain geometrical notches that can act as stress raisers and reduce the fatigue performance and toughness of a product. Thus, it is suggested that the cut surface and heat-affected zone should be removed (or at least subjected to a stress relief) on a highly-stressed machine part.

Problems: no problems

Case Study: “Bicycle Frame Repair”

The adhesive bonding employed in the original construction was selected because the material properties are heat-sensitive, and the heat of an elevated-temperature joining method would significantly diminish the strength of the tubing material.

a.

1. If the material were cold-drawn tubing, the heat-affected zone created by the weld repair would contain regions of recovery, recovery and recrystallization, and possibly recovery, recrystallization and grain growth. (These phenomena are discussed in Chapter 3, and the heat affect section of Chapter 35-39) These structures are significantly weaker than the original cold-drawn material, and would be subject to failure by the ductile overload mechanism. While the weld itself was not really defective, the failure occurred as a result of the welding process -- namely the creation of a heat-affected zone that adversely altered the properties of the base material. Therefore, the second failure was indeed the result of the welding repair.

2. If the tubing had been age hardened material, regions of the heat affected zone would have been hot enough to re-solution treat (and then produce a totally new structure upon subsequent cooldown), while other locations would have been reheated enough to permit overaging. These effects also serve to reduce the strength of the material, and increase the likelihood of ductile overload failure. Once again, the weld itself may have been of high quality, but the welding process was responsible for the alteration of the base material, and the subsequent failure.

3 . The repair of these materials would be limited to low temperature methods, such as adhesive bonding or possibly brazing. Both of these methods gain strength by increasing the area of bonding, so the use of some form of large area internal lug or external sleeve

would be desirable, as opposed to a simple butt joint repair.

b. Bicycle frames could be constructed from titanium or magnesium. Titanium offers clear advantages over magnesium and some advantages over steel. While more costly than steel, titanium has density of about 60% that of steel, modulus of elasticity of about half that of steel and can have comparable strength of steel depending on alloy and heat treatment. The strength-to-weight ratio is attractive for a high performance bicycle engineered for minimum weight. Titanium is very corrosion resistant and so the bicycle frame would not have to be coated, and perhaps the bare metal look would be a selling point. Most likely the titanium tubes would be produced by extrusion and the finished tubing frame members welded. Adhesive joining is possible.

Titanium bicycle frames are in production, e.g.,
www.vanguardtitanium.com
www.morati.com
www.biam.com/ti_bicycle.htm

Magnesium has density about 25% that of steel and a modulus of elasticity of 20% - 25% that of steel. The strength to weight ratio is attractive but to achieve strength near that of a steel bicycle frame thick sections might be required. The use of several different metals in the bicycle could be a problem since magnesium is susceptible to galvanic corrosion. Magnesium has a hexagonal close packed structure so is relative less ductile than metals with other structures and so the tubes for the frame would be extruded in the hot working region. Benefits of strain hardening would no be available. The frame would be assembled by welding under inert gas. Adhesive joining is also possible.

c. With its light weight, modulus of elasticity of about 50% greater than that of steel and strength comparable to steel, beryllium is a likely candidate for a bicycle frame based on mechanical properties. Practical limitations work against its use. It is very expensive in forms useful for bicycle frame construction, is so stiff that it is probably not useful for a bicycle frame and it is toxic.

d. In addition to joining the design of the tubes should be considered. Specifically, the orientation of the reinforcing fibers needs to specified. Bicycle frames are rigid in the plane of the frame due to the geometric design. Torsion of the frame components has to be considered and so fiber orientation in the fiber-reinforced composite tubes should be such as to make the tubes torsionally rigid. The tubes can be assembled into the frame using adhesives and plugs just as the original frame in this case study.

CHAPTER 38

Review Questions

1.In resistance welding, pressure is applied initially to hold the workpieces in contact and thereby control the electrical resistance at the interface. After the proper temperature is attained, the pressure is increased to bring about coalescence of the metal.

2. Because pressure is applied, coalescence occurs at a lower temperature than required for other forms of welding. Many resistance welds are formed without any melting of the base metal.

3. Applying additional pressure after coalescence in resistance welding provides some forging action with some grain refinement due to the deformation, and possibly some strain hardening. Additional heating can also be applied with the intent of tempering and/or stress relieving the weld zone.

4. Fluxes and shielding gases are used in welding to protect the welding zone form undesirable effects due to the ambient, native atmosphere. Since the pressure exerted between the workpieces in resistance welding precludes the introduction of the surrounding atmosphere, no flux or shielding gas is needed.

5. The total resistance between the electrodes consists of three components: (1) the resistance of the workpieces, (2) the contact resistance between the electrodes and the work, and (3) the resistance between the surfaces to be joined, known as the faying surfaces.

6. The resistance between the electrodes and the workpiece can be minimized by using electrode materials that are excellent electrical conductors, by controlling the shape and size of the electrodes, and by using proper pressure between the work and the electrodes .

7. If too little pressure is used, the contact resistance is high and surface burning and pitting of the electrodes can result. If the pressure is too high, molten or softened metal may be squirted or squeezed from between the faying surfaces or the work may be indented by the electrodes.

8. Ideally, moderate pressure should be applied to hold the workpieces in place and establish proper resistance at the interface prior to and during the passage of the welding current. The pressure should then be increased considerably to complete the coalescence and produce the forged, fine-grain structure.

9. The current applied in resistance welding varies through the process. A welding current is used and later in the process a postweld heating current is applied, Figure 38-3. The welding current is usually large, up to about 100,000 A.

10. Resistance spot welding is the simplest and most widely used form of resistance

welding.

11. Spot weld nuggets typically have sizes between 1/16 and 1/2 inch in diameter.

12. The two basic types of stationary spot welding machines are the rocker-arm machine and the press-type machine. The rocker-arm design is used for light-production work where complex current-pressure cycles are not required. Larger machines and those used at high production rates are generally of the press-type design.

13. Spot welding guns allow the process to become portable. The welding unit can now be brought to the work, greatly extending the use of spot welding in applications where the work is too large to be positioned on a welding machine (such as automobiles).

14. A transgun is a spot welding gun with an integral transformer. When accurate positioning is required in an articulated arrangement, such as an industrial robot, transguns may not be attractive because of the added weight of the integral transformer at the end of the arm.

15. The functions of resistance welding electrodes are to conduct current, set current density, apply force and dissipate heat. The electrode should not combine, alloy, with the work materials. In order to effectively accomplish these functions resistance welding electrodes must have appropriate values of electrical and thermal conductivity, hot compressive strength, melting temperature and composition. While not a physical, mechanical or chemical property, electrode shape also is a consideration in electrode selection.

16. Steel is clearly the most common spot-welded metal.

17. The practical limit of thicknesses that can be spot-welded by ordinary processes is about 1/8 inch (3 mm), where each piece is the same thickness. When thicknesses vary, a thin piece can be easily welded to another piece that is much thicker than 1/8 inch.

18. When metals of different thickness or different conductivities are to be welded, they can generally be brought to the proper temperature in a simultaneous manner by using a larger electrode or one with higher conductivity against the thicker or higher-resistance material.

19. In roll-spot welding, the seam is actually a series of overlapping spot welds, generally produced by two rotating disk electrodes. Continuous seam welding, on the other hand, applies a continuous current through rotating electrodes.

20. Projection welding enables multiple spot-type welds to be made simultaneously, and reduces the problems associated with electrode maintenance.

21. The number of projections is limited only by the ability of the machine to provide the required current and pressure.

22. Some of the attractive features of resistance welding processes as techniques for mass production include: (1) they are very rapid, (2) the equipment is semiautomatic or fully automated, (3) they conserve material (no filler metal is required), (4) Skilled operators are not required, (5) Dissimilar metals can be easily joined, and (6) a high degree of reliability and reproducibility can be achieved.

23. The primary limitations to the use of resistance welding are: (1) the high initial coat of the equipment, (2) limitations to the type of joints that can be made, (3) skilled maintenance personnel are required to service the control equipment, and (4) some materials require special surface preparation prior to welding.

24. Because of the rapid heat inputs, short welding times, and rapid quenching by both the base metal and the electrodes, the cooling rates in spot welds can be extremely high. In medium-and high-carbon steels, martensite can readily form, and a post-weld heating is generally required to temper the weld.

25. The forge welds of a blacksmith were somewhat variable in nature and highly dependent on the skill of the individual because his heat source was somewhat crude, temperatures were uncertain, and it was difficult to maintain metal cleanliness.

26. Coalescence is produced in cold welding by only the application of pressure. No heating is used, the weld resulting from localized pressures that produce 30 to 50% cold deformation.

27. By coating portions of one sheet with a material that prevents bonding and then roll bonding with another sheet, products can be made that are bonded only in selected regions. If the no-bond region is then expanded, the expanded regions can form flow channels for fluids.

28. Inertia welding differs from friction welding in that the moving piece is now attached to a rotating flywheel. The flywheel is brought to speed, separated from the driving motor, and the rotating assembly is pressed against the stationary member. The kinetic energy is converted to heat during the deceleration.

In friction welding, the contact is made while the driven piece is connected to the motor, all rotation is stopped, and the pieces are further pressed together.

29. In the friction and inertia welding processes, surface impurities tend to be displaced radially into a small upset flash that can be removed after welding, if desired.

30. Friction and inertia welding is restricted to joining round bars or tubes of the same size, or connecting bars or tubes to flat surfaces. In addition, the ends of the workpieces must be cut true and be fairly smooth.

31. In friction welding one piece of the two-piece workpiece pair is rotated while in contact with the other. The resulting heat and pressure produce welding between the two

workpieces. In friction stir welding there is a three-piece system, two plates or workpieces to be joined and a non-consumable probe, analogous to a tool. The probe rotates while in contact with both workpieces, softened work material flows around the probe and into the workpiece joint area and the workpieces joined.

32. Ultrasonic welding is restricted to the joining of thin materials, such as sheet, foil, and wire, or the attaching of thin sheets to heavier structural materials.

33. Ultrasonic welding can be used to join a number of metals and dissimilar metal combinations (even metals to nonmetals). Since temperatures are low, the process is an attractive one for heat-sensitive materials. The equipment is simple and reliable, and only moderate operator skill is required. Surface preparation and energy requirements are less than for competing processes.

34. Diffusion welding is a solid state bonding that occurs when properly prepared surfaces are maintained in contact under pressure and time at elevated temperature. Quality of the bond is highly dependent upon surface preparation.

35. If the interface of an explosive weld is viewed in cross section, it would exhibit a characteristic wavy configuration at the interface. See Figure 38-20.

36. A thermit weld is quite similar to a metal casting in that molten metal is produced externally and is introduced into a prepared cavity. In the case of the thermit weld, the super-heated metal is produced from the reaction between iron oxide and aluminum, and then flows into a prepared joint providing both heat and filler metal. Runners and risers must be provided, as in a casting, to channel the molten metal and compensate for solidification shrinkage.

37. In thermit welding, heat comes from the superheated molten metal and slag obtained from the exothermic reaction between a metal oxide and aluminum.

38. Thermit welding can be used to join thick sections of material, particularly in remote locations where more sophisticated welding equipment is not available.

39. In electroslag welding, heat is derived from the passage of electrical current through a liquid slag. Resistance heating within the slag causes the temperature increase.

40. In electroslag welding, the molten slag serves to melt the edges of the metal being joined, as well as the fed electrodes supplying the filler metal. In addition, the slag serves to protect and cleanse the molten metal.

41. Electroslag welding is most commonly used to vertical or circumferential joints because of the need to contain the pool of molten slag. The process is particularly attractive for the joining of thick plates (up to 36-inches thick).

42. High vacuum is required in the electron beam chamber of an electron beam welding

machine because electrons cannot travel well through air. In many operations, the workpiece is also enclosed in the high-vacuum chamber and must be positioned and manipulated in this vacuum.

43. In addition to having to position and manipulate production pieces in a high vacuum, there are size and shape restrictions imposed by the size of the actual vacuum chamber. The high vacuum must be broken and reestablished as pieces are inserted and removed, significantly impairing productivity. If welding is performed on pieces that are outside of the vacuum chamber, high capacity vacuum pumps must be used to compensate for leakage through the electron-emitting orifice. The penetration of the beam and the depth-to-width ratio of the molten region are considerably reduced as the pressure increases.

44. High-voltage electron beam welding equipment emits a considerable quantity of harmful X-rays and thus requires extensive shielding and indirect viewing systems for observing the work.

45. Almost any metal can be welded by the electron beam process. Dissimilar metals can be welded. The weld geometry offers a narrow profile and remarkable penetration. Heat input and distortion are low, and the heat-affected zone is extremely narrow. Welding speeds are high, and no shielding gas, flux, or filler metal is required.

46. Compared to electron beam welding, laser beam welding: (1) does not require a vacuum environment, (2) generates no X-rays, (3) can employ reflective optics to shape and direct the beam, and (4) does not require physical contact between the workpiece and the welding equipment (the beam can pass through transparent materials).

47. Laser beams are highly concentrated sources of energy and the resulting welds can be quite small. While the power intensity is quite high, the weld time is extremely small and the total heat input can be quite low. For these reasons, laser beam welds are quite attractive to the electronics industry.

48. In the laser beam cutting process, a stream of "assist gas" is often used to blow the molten metal through the cut, cool the workpiece, and minimize the heat-affected zone.

49. Through the use of a fiber-optic cable, laser energy can be piped to the end of a robot arm, eliminating the need to mount and maneuver a heavy, bulky tool that would produce elastic flexing of the components of the robot arm and affect the accuracy of positioning. Cutting and welding can then be performed with the multiple axes of motion of an industrial robot or CNC machine.

50. Laser spot welding can be performed with access to only one side of the joint. It is a non-contact process, involves no electrodes, and produces no indentations. Weld quality is independent of material resistance, surface resistance, and electrode condition. The total heat input is low, and the heat-affected zone is small.

51. The flashing action in flash welding must be long enough to provide heat for melting

and to lower the strength of the metal to allow for plastic deformation. Sufficient upsetting should occur that all impure metal is squeezed out into the flash and only sound metal remains in the weld.

52. Only the thermoplastic polymers can be welded, since these materials can be melted and softened by heat without degradation. The thermosetting polymers do not soften with heat but tend only to burn or char.

53. Thermoplastic polymers can be welded by methods that use mechanical movement or friction to generate the required heat (such as ultrasonic welding, friction welding, and vibration welding), and methods that employ external sources of heat (such as hot-plate welding, hot-gas welding, and resistive or inductive implant welding) .

54. Surfacing methods are usually used to apply;
- carbon and low-alloy steels,
- high-alloy steels and irons,
- cobalt-based alloys,
- nickel-based alloys,
- copper-based alloys,
- stainless steels,
- ceramics,
- refractory carbides, oxides, borides, silicates.

55. Surfacing materials can be deposited by nearly all of the gas-flame or arc welding methods, including: oxyfuel gas, shielded metal arc, gas metal arc, gas tungsten arc, submerged arc, and plasma arc. Laser hardfacing has also been performed.

56. Several of the thermal spray processes are adaptations of oxyfuel welding equipment involving some form of material feed. Electric arcs can be used to melt the material and produce the molten particles, and plasma spray processes are also quite common .

57. Thermal spraying is similar to surfacing and is often applied for the same reasons. The thermal spray coatings are usually thinner, and the process is more suited for irregular surfaces and heat sensitive substrates.

58. In metallizing, the bond between the deposited material and the base metal is a purely mechanical one. To enhance mechanical interlocking, the surface can be roughened by a variety of methods, including: grit blasting or the machining of grooves followed by deformation to roll over the crests or mushroom the flat upper surfaces.

59.In spraying coatings a material layer is formed so material can be added to a substrate and the material properties of the coating can be controlled to produce desirable surface behavior in use. Applications include
- restoring worn parts to original dimension by spraying material followed by finishing operations,
- producing protective coating such as for corrosion protection,

- hard surfacing to produce wear resistant surface layers while maintain the desirable properties of the substrate, including economic consideration or characteristics,
- applying thin coatings in situations where establishing a plating operation is not warranted,
- applying electrically conduction coatings,
- applying optical coatings,
- applying decorative coatings,
- producing tailored surface characteristics such as specified surface profile or layered structure.

Problems:

1. This is really an open-ended library-type research assignment, and the results will vary considerably with the specific process chosen to investigate.

2. Thermosetting polymers can be joined by such processes as:
adhesive bonding, threaded fasteners, riveting, and other types of mechanical joining. Similar restrictions apply to the elastomers, but threaded fasteners are not as viable. For ceramic materials, the most common method of joining is adhesive bonding. Mechanical joining requires the use of large washers or load distributing devices, and rivets are seldom employed.

Case Study: Field Repair to a Power Transformer Case

1. The primary restriction here is the need for portability. A process, such as oxyacetylene welding requires only bottled gas, flow regulators and an appropriate torch. These can be scaled and are readily portable. The arc welding methods require a power supply, and an AC, plug-in outlet is not likely to be available. Thus, the electrical capabilities will be limited to those that can be provided by a portable generator. These can be truck-mounted and powered by gasoline motor. The finite-length stick electrodes of the shielded-metal arc process would be quite appropriate for this application because of the wide variety of materials, geometries, and applications encountered in field repair. Gas tungsten arc and gas metal arc are also possibilities. The size and geometry (fillet joint) would not be attractive for the electroslag, submerged arc, or thermit processes, and the equipment required for other alternatives would not be sufficiently portable.

2.- 4. This information can be found by surveying various texts and handbooks. Selection is really a matter of preference, with due consideration to material, the need to weld in both downward and upside-down fillet positions, and the probability of oil contamination and possibly even paint (this is a field repair on an installed item).

CHAPTER 39

Review Questions

1.Low-temperature production joining methods include: brazing, soldering, adhesive joining, and the use of mechanical fasteners.

2. The characteristic feature of brazing, and so important in its definition, is the use of a filler material with melting temperature above 450^{o} but below the melting temperature of the materials to be joined. Many processes use heat and filler metal, but brazing implies a certain use (capillary flow into the braze joint) and type of filler material.

3. Brazing employs a filler metal whose melting point is below that of the metals being joined. It differs from welding in that: (1) the composition of the brazing alloy is significantly different from the base metal, (2) the strength of the brazing metal is substantially lower than the base metal, (3) the base metal is not melted during joining, and (4) bonding requires capillary action.

4. Since neither of the base metals are melted during the brazing operation, and the bond is formed by introducing a lower melting temperature metal into the gap, the brazing process is attractive for the joining of dissimilar metals, such as ferrous to nonferrous or metals of widely different melting points.

5. Because brazing introduces a filler metal of different composition from the materials being joined, and the process can be used to join dissimilar metals, brazing can result in the formation of a two-component or three-component galvanic corrosion couple.

6. Braze joint clearance is the most important factor determining joint strength. Joint clearance determines if capillary action will be effective in filling the joint gap. Capillary action is the movement of a fluid into a small space driven by surface attraction force.

If the joint clearance is too small, the filler metal may be unable to flow into the gap and the flux material may be unable to escape. If the gap is too great, capillary action may be insufficient to draw the metal into the joint and hold it in place during solidification.

7. The clearances necessary for good flow and wetting of the joint are those that are present at the temperature of the brazing process. The effects of thermal expansion should be compensated when specifying the dimensions of the joint components.

8. The two most common types of brazed joints are butt joints and lap joints. Butt joints are attractive since they do not require additional joint thickness in the braze region. Lap joints are attractive since the relatively large area compared to butt joints results in high joint strength.

9. Some of the considerations when selecting a brazing alloy include: compatibility with the base materials, brazing temperature restrictions, restrictions due to service or

subsequent processing temperatures, the brazing process to be used, the joint design, anticipated service environment, the desired appearance, the desired mechanical properties, the desired physical properties, and the cost.

10. The most commonly used brazing metals are copper and copper alloys, silver and silver alloys, and aluminum alloys.

11. Silver solder is a brazing filler material.

12. In brazing, a flux is used to: (1) dissolve oxides that may have formed on the metal surfaces, (2) prevent the formation of new oxides during the heating, and (3) lower the surface tension of the molten brazing metal and promote its flow into the joint.

13. Clean surfaces are needed for brazing and while fluxes can remove some surface oxides they are not designed to be exclusively cleaners. To provide a “clean enough” surface so the flux can act as a fluxing agent and secondarily as a cleaner, precleaning by chemical and/or mechanical means is necessary.

14. Brazing is done to provide a joint between materials and one of the functions of the joint is to provide proper geometric relationships between the components of the entire structure. If the geometric relationships are important, positioning of the pieces to be joined before and during brazing can be maintained using jigs and fixtures. Brazing jigs and fixtures are especially important for complex structures since without proper support movements in the joints can produce large errors in final structure configuration.

15. The primary attraction of furnace brazing is that a number of parts/products can be processed simultaneously and so production rates can be high.

16. In furnace brazing, reducing atmospheres or a vacuum are frequently used to prevent the formation of surface oxide and possibly reduce any existing oxides and eliminate the need for a brazing flux. If reactive metals must be brazed, a vacuum may be required.

17. In dip brazing, the entire assemblies are immersed in a bath of molten brazing metal. The braze metal will usually coat the entire workpiece, so such a process is wasteful for all but very small assemblies.

18. Some of the attractive features of induction brazing are: (1) heating is very rapid, (2) the operation can be made semiautomatic (requiring only semi-skilled labor), (3) the heating can be confined to a localized area (reducing scale, discoloration, and distortion), (4) uniform results are readily obtainable, and (5) by changing coils, a wide variety of work can be performed with a single power supply.

19. Since most brazing fluxes are corrosive, the residue should be removed from the work immediately after brazing is completed.

20. Braze welding differs from straight brazing in that capillary action is not used to

distribute the filler metal. Low melting temperature filler metal is simply deposited into a joint by gravity.

21. The distinction between soldering and brazing is one of temperature, soldering being a brazing-type operation where the filler metal has a melting point below 840^0F (450^0C).

22. Solder joints are not strong because low melting temperature, weak materials are used for solders, low soldering temperatures are used and the bonding of the solder to the pieces to be joined is primarily mechanical. There is no strong metallurgical bonding developed as in the case of welding where the work material and filler material are melted and recombine.

23. The most common soldering alloys are composed of lead and tin.

24. Health and environmental concerns about lead are driving the search for and development of leadfree solders.

25. A successful conversion to leadfree solders means that the functions of the solder must be effectively and efficiently provided by the new solder material. Properties related to useful solder characteristics are melting temperature, wettability, electrical and thermal conductivity, thermal expansion coefficient, strength, ductility, creep resistance, thermal fatigue resistance, corrosion resistance, manufacturability and cost. Obtaining adequate solder characteristics and behavior involves a large number of factors and so a number of difficulties. Other difficulties in conversion to leadfree solders are the development of useful fluxes and the design of processes that will use the new solder.

26. Any of the heating methods used for brazing can be used for soldering, but most soldering is still done with electric soldering irons or small torches. For the low-melting-point solders, infrared heaters can be used.

Problems:

1. a. The corroding member of the corrosion cell is the component that gives up electrons (oxidation) – the anode. The driving force for the electrochemical reaction is the voltage that develops between the anode and the cathode at which the reduction reaction occurs. Standard electrochemical cells are used to measure the voltage between a sample material and a standard, platinum, electrode in a standard cell at standard conditions. The electromotive force series is developed from such tests. The metals that are lower on the electromotive series experience oxidation, corrosion, with respect to metals higher on the series. A similar, widely-used indication of corrosion susceptibility is the galvanic series which presents the relative reactivity (no electromotive voltages are provided) of materials in seawater. Again, the more cathodic materials are at the top of the series and more anodic materials toward the bottom of the series.

Electromotive force and galvanic series are available in many textbooks and handbooks (e.g., Corrosion Engineering, M. G. Fontana, McGraw-Hill, 1986) and show that for
i. low-carbon steel – copper-based brazing alloy the anode will be steel
ii. copper wire – steel sheet – lead-tin solder the anode will be steel
iii. tungsten carbide - carbon-steel the anode will be steel since most brazing materials are lead and tin alloys.

2. The tin-antimony and tin-copper solders are expected to be more cathodic than the lead-based solders since lead is below copper and tin (slightly) on the galvanic series.

3. The three general ways to change interactions between materials in a galvanic corrosion situation are to change materials, to change the surrounding environment and to change the galvanic cell by introducing another material(s). The material changes possible are changing the materials that are joined and/or the braze material. The function of the joint will determine if this is feasible. Changing the environment is problematic since this will probably entail significant, qualitative changes in the system in which the brazed joint must function. Inserting a sacrificial body (anodic with respect to all other materials in the joint) into the system may be a possibility.

Case Study: no case study

CHAPTER 40

Review Questions

1. The ideal adhesive bonds to any material, needs no surface preparation, cures rapidly, and maintains a high bond strength under all operating conditions.

2. Structural adhesives are bonding materials that can be stressed to a high percentage of their maximum load for extended periods of time without failure.

3. Some newer applications of adhesive bonding are medical and dental applications (e.g., cosmetic dentistry), bonding composite materials (laminates) and joining major components of automobiles (body panels).

4. Some types of industrial adhesives are epoxies, cyanoacrylates, anaerobics, acrylics, urethanes, silicones, phenolics, polyamides and thermoplastics.

5. Curing of the structural adhesives can be performed by the use of heat, radiation or light (photoinitiation), moisture, activators, catalysts, multiple-component reactions, or combinations thereof .

6. Typical epoxies have use temperatures of –50o C to 250o C (-60^{o} F - 500^{o} F), shear strength of 10 MPa to 70 MPa (1500 psi – 10,000 psi) with strength dependent on temperature and curing time of minutes to days.

7. Trace amounts of moisture on the surfaces promote the curing of cyanoacrylates. The anaerobic adhesives remain liquid when exposed to air. However, when confined to small spaces and shut off from oxygen, as in a joint to be bonded, the polymer becomes unstable. In the presence of iron or copper, it polymerizes into a bonding-type resin.

8. The silicone adhesives form low-strength joints, but can withstand considerable expansion or contraction. Flexibility and sealing ability are other attractive properties. Numerous materials can be bonded, and the bonds resist moisture, hot water, oxidation, and weathering, and retain their flexibility at low temperatures.

9. Nonstructural adhesives include
- evaporative adhesives that are usually organic or water base solvents containing vinyls, acrylics, phenolics, polyurethanes and various kinds of rubber,
- pressure-sensitive adhesives that use rubber compounds as the adhesive media,
- delayed-tack adhesives that usually use rubber based adhesive that require heat activation,
- conductive adhesives that are adhesive binder containing conductive particles,
- radiation curing adhesives such as photocuring polymers used in rapid prototyping and dental applications.

10. Conductive adhesives can be produced by incorporating selected fillers, such as

silver, copper or aluminum flakes or powder. Certain ceramic oxides can provide thermal conductivity.

11. Temperature considerations relating to the selection of adhesives relate to both the temperature required for the cure and the temperatures likely to be encountered in service. Consideration should be given to the highest temperature, lowest temperature, rates of temperature change, frequency of change, duration of exposure to extremes, the properties required at the various conditions, and the differential expansions or contractions.

12. Environmental conditions that might reduce the performance or lifetime of a structural adhesive include: exposure to solvents, water, or humidity, fuels or oils, light, ultraviolet radiation, acid solutions, or general weathering.

13. The stress state in a bonded joint can be tension, shear, cleavage, or peel, as shown in Figure 38-1. Since most adhesives are much weaker in peel and cleavage, joints should be either shear or tension. Looking further, the shear strengths are greater than the tensile strengths, so the best adhesive joint would be one in which the stress state is pure shear.

14. The strength of an adhesive joint depends on the strength of the bond between workpieces and adhesive and the area of adhesion. Butt joints are undesirable since the contact area is small giving relatively low strength joints compared to other joint configurations.

15. Surface preparation procedures vary widely, but frequently employ some form of cleaning to remove contaminants and grease. Chemical etching, steam cleaning, or abrasive techniques may be used to further enhance wetting and bonding.

16. Almost all materials or combinations of materials can be joined by adhesive bonding. The low curing temperatures permit heat sensitive materials and thin or delicate materials to be joined. The resulting bond can tolerate the thermal stresses of differential expansion or contraction.

17. The primary property of structural adhesives is strength. Other attractive properties of various adhesives are

- low curing temperature and so the ability to join temperature sensitive materials and no production of a heat affected zone,
- mechanical flexibility and so the capability to adapt to differential expansion and contraction between the joined components,
- flow during application and mechanical flexibility and so the possibility of reducing susceptibility to fatigue which usually is initiated at sharp surface irregularities,
- low thermal and electrical conductivity and so the ability to be used as insulators,
- high damping compared to solid interfaces and so good shock, noise and vibration insulation,
- low corrosion susceptibility,
- flow during joint formation and so the ability to be used as a sealant,

- potentially low cost.

Some desirable characteristics of the adhesive joint are

- high strength if large areas are joined,
- large adhesion areas and so the ability to distribute load,
- small or no stress raisers.

18. From a manufacturing viewpoint, joint formation does not require the flow of material, as with brazing and soldering, but the adhesive is applied directly to the surfaces. The adhesives can be applied quickly, and useful strengths are achieved in a short period of time. Surface preparation may be reduced, since bonding can often occur with a oxide film on the surface. Rough surfaces are an asset; tolerances are less critical; and no prior holes have to be made. In addition, the process lends itself to robotics and automation.

19. Most industrial adhesives are not stable at temperatures above ~50^0F. Oxidation reactions are accelerated, thermoplastics soften and melt, and thermosets decompose.

Since most adhesives are not stable above 350^0F, the structural adhesives would not be attractive for applications that involve exposure to elevated temperatures. At low temperatures, some of the adhesives become brittle.

20. Adhesives bond the entire joint area. Force equals strength times area. By providing large contact areas, the relatively low strength structural adhesives can be used to produce joints with load-bearing abilities comparable to most alternative methods of joining or attachment.

21. Selection of a specific fastener or fastening method depends primarily upon the materials to be joined, the function of the joint, strength and reliability requirements, weight limitations, dimensions of the components, and environmental considerations. Other considerations include cost, installation equipment and accessibility, appearance, and the need or desirability for disassembly.

22. If there is a need to disassemble and reassemble a product, threaded fasteners or other styles that can be removed quickly and easily should be specified.

23. Integral fasteners are regions of components that are specifically formed to be used as parts of fasteners. An example is the formed parts of the top and tabs on aluminum beverage containers. The top and tab have formed regions that are produced as the top and tab are being manufactured. These regions are aligned and further deformed when the top and tab are joined.

24. A press fit differs from a shrink or expansion fit in that mechanical force produces the assembly, not differential temperatures and thermal expansions and contractions. Both involve a strong interference fit to produce a high-strength mechanical joint.

25. The most common causes for the failure of mechanically fastened joints relate to joint preparation and fastener installation. Hole manufacture and alignment, installation with too much or too little preload, misalignment of surfaces, insufficient area under load-

bearing heads, and vibrations that can lead to further loosening of the joint (and fastener fatigue) are all areas of concern.

26. The use of standard fasteners would enable ready access at reasonably attractive cost. Nonstandard fasteners require scheduled production, possible delays and additional expense. By minimizing the variety of fasteners within a given product, there is a reduced likelihood of mix-up or exchange of pieces during a disassembly and reassembly, or even within the initial production and assembly line. Moreover, inventory costs could be reduced, and by using larger quantities of a given fastener, a reduced price might be available.

Problems:

1. An interesting opportunity is available if elevated temperature can be used to bake coatings and also influence material characteristics such as mechanical properties of the material to be coated. Data is provided at *ussautomotive.com/auto/tech/grades/dual_ten.htm* that shows typical paint-bake temperature of 177^o C (350^o F) and that there is a change in yield strength due to bake-hardening.

In addition to bake temperature the bake time has to be considered since adhesive curing time, as well as temperature, is a concern.

Given the adhesive cure temperatures in Table 40-1, and the belief that using too high a temperature will degrade the adhesive and produce unacceptable joints, the possible adhesives are epoxies, phenolics and urethanes.

The primary pro of such an integration of paint baking and adhesive curing is the elimination of individual operations with separate tooling, facilities and personnel and replacement with a combined, simpler operation. The major con is that with the loss of an individual process the relatively tight control, operation and optimization available for the process is compromised as the integrated process is designed operated and optimized to accomplish two or more operations.

2. When iron (steel) is galvanically coupled with passive aluminum, iron becomes the anode and undergoes preferential corrosion. (Aluminum is below steel in the galvanic series - see Problem 1, Chapter 39) With moisture being the electrolyte that completes the electrical circuit, we have a corrosion cell with very small corroding anodes (the heads of the iron nails) and large cathodic surfaces (the aluminum siding). The heads of the nails will rapidly corrode and the siding will eventually separate from the house. Aluminum siding should be installed with aluminum nails.

3. Hole preparation would be a major area of concern, because we must now produce holes in a fiber-reinforced material. Mechanical means will tend to produce frayed surfaces. Thermal means may damage the fibers and matrix.

Joint design is also a concern. While the composite material may offer attractive strength properties, these properties may not be present around a fastener where the continuity of the fibers has been disrupted. Screws and similar threaded fasteners will be limited by the strength of the polymeric matrix. Compression fasteners, such as bolts and rivets, may require the use of large washers to spread the load over a larger area. A variety of service-type failures could be considered.

Case Study: Golf Club Heads with Insert

1. Since the club head is a martensitic stainless steel, it achieves its strength by a quench and temper heat treatment. Subsequent exposure to temperatures in excess of the tempering temperature will result in a further loss of strength and hardness. In addition, exposure to temperatures near 1000OP will enable the atomically-dispersed carbon and chromium atoms to diffuse and unite to form chromium carbides. The depletion of chromium will leave the adjacent regions with less than 12% chromium free to react with oxygen to form the protective (corrosion-resistant) oxide. The stainless steel is no longer "stainless" and will be subject to red rust. For these reasons, coupled with possible warping of the thin insert, the joining method is limited to low temperature methods. While brazing or, more preferably, soldering might be possibilities, these methods provide metallic joint, and the electrical conductivity coupled with the presence of two or more dissimilar metals creates a galvanic corrosion cell in a product that may be exposed to humidity and moisture as they are stored in car trunks and other locations. Rivets, screws and other fasteners are possible, but the joining becomes localized, and the possibility of gaps and related dampening is a real one. Among the low-temperature methods, it appears that some form of adhesive bonding would be the most preferred means of assembling the components.

2. The same problems with the martensitic stainless steel restrict the temperature of the joint. Most of the above methods continue as options, with brazing or soldering being eliminated because of the polymeric shaft, and shrink or press fits becoming additional alternatives. If the shaft were metallic, brazing or soldering reenter the picture. If the shaft is sufficiently solid, some form of hole and rivet is a possibility.

3. If the same procedure is to be applied to both joints, one between dissimilar metals, and the other between stainless steel and fiber-reinforced epoxy, then some form of adhesive would appear to be preferred. NOTE: It may also be desirable to consider alternative means of creating the composite club face, such as flame-spray deposition of the carbide-containing surface -- which would eliminate the need to bond two dissimilar metals.

4. The general process being proposed is the removal of material from around the carbide particles. The alternative is to add carbide particles to the club face. Particle deposition processes are limited to those that will form a strong bond at the carbide particle-substrate interface and not have adverse effects on the substrate to which the particles are applied.

Adhesives will not be useful since they will not supply strong adhesive forces over the small particle-surface contact areas. Spraying processes such as plasma spraying will not be useful since they will affect club face properties and performance.

Starting with the proposition that using an insert does not affect club performance, it is probably less expensive to produce inserts and add them to the club face, rather than trying to produce a one-piece club head with a specially prepared face. Inserts can be produced in batches. Inserts can be finished by specially designed processes without concern about affecting the rest of the club head, e.g., edge smoothing by sanding without concern about the sanding process extending to the parts of the club face surrounding the inserts.

If there are performance advantages to a single piece club head, and there may very well be effects of the insert-club head interface on performance, then entire club heads should be produced and the hard particles added to only the club face. In addition to selecting the process, process control concerns arise. The particle deposition process must not extend to regions beyond the club face area of interest. This approach probably will be more expensive than producing separate inserts and bonding them to club faces.

The low process temperature, high bond strength requirements lead to consideration of what are fairly exotic processes for mass produced consumer goods, but are much less unrealistic for high end golf clubs that are semi-custom products. Possible processes are,
- electroless composite plating and variations of such processes, Chapter 31,
- laser sintering, Chapter 33,
- low temperature furnace brazing ,Chapter 39

Club heads can be produced in batch mode in plating and brazing processes so unit cost can be low.

The performance of the raised parts/particles themselves is an issue. If these regions wear or are removed, the benefits of them being on the face are lost. Inspection of used clubs with abrasive particles in the face will show a worn region. The carbides are not expected to wear. But they will be removed from the club face either by fracture of the hard, brittle carbide or by separation at the carbide-metal interface. Again the strength of the particle-face bond is critical.

CHAPTER 41

Review Questions

1. The production system includes design engineering, manufacturing engineering, sales, advertising, production, inventory control and the manufacturing system.

2. a. The route sheet is a document which describes the route or path that the parts must take in the production job shop. Each machine is indicated on the route sheet and the parts are transported from machine to machine in tote boxes or carts.
b. The function of the route sheet is to specify the sequence of operations and processes needed to convert the part from raw material into a finished product.
c. Cooking recipes contain route sheets. They are also partly a bill of materials and an operation sheet.
d. The route sheet is also called a traveler since it moves with the parts.

3. Examples of a process flow chart and a bill of materials are given in Figure 41-18. This type of process flow chart outlines the sequence of manufacturing steps to produce the final product in terms of components of the product and their order of use. This description is in contrast to specifying the processes and machines used to produce, manipulate and assemble the components.

The bill of materials lists the materials and components needed to produce one unit of final product. The process flow chart is related to the bill of materials in that it shows where (time and location) in the process the items in the bill of materials are used. This indicates when the items will be needed and determines not only the items to be obtained but also when they are needed enabling rational procurement and production planning.

4. An operations sheet gives more specifics with regard to the processes needed to make the part while the route sheet, a production control device for the job shop, provides information about where the part is to go next for more operations. In the visual factory, operations sheets are posted right at the machine for all to see.

5. The master production schedule is a document that specifies the products to be produced, the quantity to be produced and the delivery date.

6. MRP can mean material requirements planning and is a tool for calculating the quantities of items and/or amounts of material needed for use in each stage in the production process and when they will be needed. Manufacturing resource planning MRP encompasses the same general idea but expands it to include consideration of all resources, not just materials. For example, it is used to specify materials, labor, machines, etc. that are needed and the time and location of the requirements.

The master production schedule specifies products and their time of production and so sets the outcomes, or dependent variables or dependent demands, that are in the production system. Material requirement or resource planning specifies the materials and other resources and when they must be available to meet the dependent demands specified in the master production schedule.

7. The economic order quantity usually refers to materials and components, not to such manufacturing resources as labor, and so is used in material requirements planning. In material requirements planning the amount of material and time it is needed is set. This is an overall system or global set of requirements. The economic order quantity calculation provides a way to decide on the best way to obtain the materials within the larger MRP framework. Materials must be available to the production system when they are needed. However, the cost of the materials depends many factors and the economic order quantity specifies the best way to order the materials that have to be in the system at specified times.

8. The functional objectives of production control are to produce the timing and coordination to ensure that product delivery meets customer demands.

9. The function of inventory control is to ensure that enough products of each type are available to satisfy customer demand. This concept can be applied at any level of the enterprise by changing the definition of the customer. For example, a single machine station can be a customer relying on inventory control to assure that the workpieces supplied to it from the previous step in the process are available when needed.

10. Production control refers to controlling the movement of the materials to the right machines at the right times. Production control deals with when to make the products (scheduling) on which machines in what quantities. Inventory control deals with having the right amounts of materials in the system available at the right places at the right times.

11. The design determines which manufacturing alternatives will be available to make the part. The design along with the needed volume and the material selected for the part all influence the choice of the manufacturing processes. For example standardizing the design of the thread type and hole size greatly simplifies the design of manufacturing cells. Suppose the design calls for 16 RMS finish. The manufacturing system will probably need a grinding operation to meet this design specification. The manufacturing cell design would have to include grinding capability. Design also influences the production system in many ways. Designing things that customers want to buy, that can be readily inspected for quality, that are reliable, and that are safe for the customer to use are all design aspects that impact the production system. Because design occurs before all the other functions described in the manufacturing and production systems, it obviously is the driving force.

12. This statement means that a large expensive piece of software adds a large fixed cost to the total cost of making something in the same way a large expensive piece of hardware adds a large fixed cost to the total. Both costs will require a large volume of parts to be made to cover the cost. The problem is that while hardware (equipment) can be depreciated and some of its cost recaptured through tax savings, software costs are not depreciated and are generally hidden in the overhead costs of the company .

13. The part described in Figure 41-20 is a simple turned part and for a quantity of 25 is produced on an engine lathe, a general purpose machine. As production quantity increases the use of more special purpose machines can be justified based on unit cost to produce the parts. The more specialized machines for this type of turned and threaded part are, in increasing order of specialization, turret lathes, screw machines and turning followed by thread rolling machines. It is doubtful that any advance past use of a turret lathe would be warranted, and perhaps not even use of a turret lathe if one was not already available.

This same kind of question is considered in more detail in Problem 8, Chapter 32.

14. A route sheet lists the processes that are required to produce a part, the sequence of processes and the machines and tooling to be used. An operations sheet lists the sequence of operations to be performed on a single machine, at a single work station or on a given workpiece in a specified group of machines. The operation sheet provides the details needed to carry out the individual processes specified on the route sheet.

15. Ergonomics deals with the mental, physical and social requirements of work and how the work is designed or modified to accommodate human limitations, Section 43.7. The Ergonomics Society (*www.ergonomics.org.uk*) says that, Ergonomics is the application of scientific information concerning humans to the design of objects, systems and environment for human use.

16. The mrp generates orders for the shop, which generates the orders for purchased parts (from the vendors) and the orders for subassembly and component manufacturing. The MPS uses the information in the BOM as one of its inputs. The BOM lists all the parts that are in the product. The MPS uses the information regarding the capacity of the systems compared to the orders for the components and products to generate a master schedule.

17. Computer integrated manufacturing is the use of computers to run machines and to store all the information needed to manufacture a product and to manipulate all the data and information in any activity related to the manufacture of the product. Manufacturing of the product is defined in the very broadest sense, all the way from market study and conceptual design to disposal or recycling.

18. A manufacturing system is a sequence of processes and people that actually produce the desired product(s), Section 41.3.

Manufacturing system characteristic	Comparison in university
processes	lectures laboratory activities research outreach
sequence	progression form lower level to upper level courses
people	faculty staff students
products	education new knowledge service to various communities

Internal customers for faculty are students, internal customers for staff are faculty and students.

Products are educated people, new knowledge and service to communities such as theater and sporting event audiences and professional societies.

19. In a project shop the critical path is the longest path in terms of time through the sequence of steps that are needed to produce a product. The paths show activities needed to produce the product and are formulated on diagrams that show the manufacturing steps, their sequence, interrelationships and the time needed for each.

20. For example, the work boot of a foundry worker has steel toes and a strong arch to protect his toes from heavy objects being dropped on them and provide good support on the hard concrete floors of the foundry. One doesn't wear sandals in the foundry as these are designed for entirely different purposes.

21. The overhead costs include all those costs necessary to run the factory but which are not tied directly to the product. The cost of the foreman or the forklift truck drivers, power, light, heat, indirect materials, and so forth are all totaled into the overhead cost.

22. Manufacturing systems are systems composed of subsystems that interact with each other and with the entire system. Manufacturing systems have inputs such as materials, energy, customer demands social pressure and capital. The system contains people, material being worked, machines, equipment, supplies, information and data systems. Areas of control in the system are production rate, product mix, inventory, quality and machines. The system outputs are goods, services, information and unusable material and data.

Stability usually means a system response that is small compared to the input causing it and that the response to the disturbance decreases rapidly over time. System stability is usually increased in two ways. One is to include feedback into the system controller and operate the system so as to drive the difference between desired behavior and the measured actual behavior to zero. In terms of manufacturing systems this implies producing feedback from the overall system output of product characteristics and quantity, etc. and also from subsystem components such as production and inventory control system and establishing a control system that acts on these feedback signals.

The second way that system stability is increased is at the system design level. It is to design and implement system components and systems that are relatively insensitive to disturbances and/or to operate systems away from operating points that are sensitive to disturbances. The general concept is to design and use subsystems that have a flat response to changes in operating conditions. For example, in terms of cost, inventory systems that have holding cost per unit that does not change appreciably with held quantity are more stable than inventory systems with large dependence of unit holding cost on in-stock quantity. The lower, more constant holding cost system is more stable in the sense of decreasing the importance of uncertainty in economic order quantity considerations for example.

There is also the possibility of decreasing variability of inputs to the system. This is a way to influence system behavior but is not a way to make the system inherently more stable

23. Since there are critical paths in all systems that include preference relations, there is a critical path through the academic job shop.

24.

	Quality	Cost	Delivery	Flexibility
Job shop	high based of worker skill	high product cost due to high throughput time, large inventories, general purpose machines	long due to production of many different kinds of small batch parts and so long many, long changeovers	high due to functional design
Flow shop	high if system stable	high plant cost due to use of specialized machines and equipment	short due to use of specialized equipment and dedication to few products	low due to specialized production and materials handling equipment
Lean shop	high due to local control at cell level	low plant cost due to low inventory		high since cells can be reconfigured and worker flexibility

25. A high-volume transfer line for machining is characterized primarily by a lack of flexibility. The product mix is extremely small and so little flexibility is needed in the individual processes or in the material handling equipment between the processes.

Given the true function of a transfer line as the production of very similar parts at high rate there does not appear to be a reason for considering lean manufacturing concepts that are intended to capitalize on flexibility

However, there are some reasons to expect the need for flexibility to be important in high volume products. Product life in terms of changing product characteristics, not product failure, is becoming shorter. Flexibility in changing large production systems is needed. Product semi-customization is becoming a customer demand calling for production system flexibility. The possibilities for incorporating lean manufacturing concepts into high volume production situations are expanding.

There are some counter-trends. For example, building several car models on one platform is a move toward reducing product variations and so less flexible manufacturing systems are required. The number of models may increase but certain aspects of them become less variable.

26. Mass production plants have been evolving into lean plants designed for flexibility through the

- development of manufacturing and assembly cells linked to each other and to final assembly by specific material control systems,
- production of functionally integrated systems for inventory and production control,
- grouping of cells according to the sequence of operations needed to produce the part.

The intent is to convert the linear, fixed arrangement of flow lines into easily reconfigurable cells with short cell and machine setup times.

27. One way to quantify manufacturing system performance is in terms of profits generated. For a particular product the profit can be calculated from

profit per part = selling price – unit cost

and if this is put in terms to include the production rate and sales rates

profit = (selling price)(number sold) – (unit cost)(number produced).

This indicates that to increase profit efforts should be made to

- increase the selling price, perhaps by controlling production or providing customization,
- increase the number of units sold, perhaps by appealing to, or creating, new markets,
- decreasing the unit cost, as in the best use of mass production, flow lines,
- bring the number of units produced into line with the number sold requiring accurate forecasting of demand.

28. The Ford system was the refinement of the mass production system. The system relied on division of labor, moving assembly lines, real-time stock control and reliance on assembly cycle time predictability and control. A large part of the usefulness and efficiency of such a system is similarity of parts, bordering on complete interchangeability.

The essential feature of the Toyota Production System is a linked-cell manufacturing system with the linking generated by material control systems. With respect to the Ford or mass production system the similarity is that the control of material flow drives the system. The difference is in the way material flow is controlled. Another similarity is the importance of part quality in making the systems successful. Implicit in the mass production, interchangeable part system is the reliance on truly interchangeable parts. In the initial fit and function sense, if not in life cycle performance, this can be viewed as high quality. And this high quality made it possible to assemble a large number of cars in a short time. Quality is also a mark of the Toyota system, but is produced in a different way, based on in-process control, rather than being assumed for the input to work stations on the mass production line.

29. If the unit cost of each operation needed to produce a product is minimized the impact
a. on machine design is minimal whether the machine is considered to be the product or the production machine,
b. on workers' is minimal, unless there is profit-sharing,
c. on the factory as a manufacturing system is probably improved performance since total system production cost may be reduced since it is reasonable to assume that the plant has been run by competent people. However, in the true system wide view this may not be so clear or always the case. The system cost is much more than the sum of the process unit costs. There are costs associated with the factory and parts of it that are not directly related to individual processes. For example, the complexity of the system has a cost and so machines grouped in different ways with produce different costs for the system, even if the unit costs of all individual operations remain the same.

30. The Ford system was the refinement of the mass production system. The system relied on division of labor, moving assembly lines, real-time stock control and reliance on assembly cycle time predictability and control. A large part of the usefulness and efficiency of such a system is similarity of parts, bordering on complete interchangeability. Part interchangeability is a hallmark of the first industrial revolution and the Ford system built on it.

Problems: no problems

Case Study: Fire Extinguisher Pressure Gage

1. A number of questions come to mind. How many failures have been recorded? Are they all from the same batch or production run? How long have the failed components been in service? Under what conditions of temperature, humidity, corrosive environment, etc.? Have they been serviced or recharged? If so has the maintenance been performed properly? what gases or chemicals might be present in the interior of the tube? Are these potentially dangerous or might they react with the tubing? what is the normal internal pressure? Could the chemicals present in the extinguisher have played a role? How was the tube manufactured? Was the starting tubing seamless or seamed tubing? How much cold work was imparted to the tubing? Was a stress relief or anneal incorporated after forming? what was the likely ductility of the tubes when put into service? Were the tubes inspected? If so, how? In the failed components, is the failure by a single crack or multiple cracks? Do the cracks have a branching appearance? Do they follow the flow lines of deformation? Are they intergranular or transgranular? Are any corrosion products observable? Is there evidence of any plastic deformation, such as would be present if the

tubing had burst? Could mishandling have caused the damage?

2. The tubing could have been defective as it came from the original supplier. If the tubing was seamed tubing, this could be the location of a poor bond. Massive inclusions, seams, laps, and other metallurgical defects could produce failures of this sort. If this were the case, there should be some correlation to tubing supplier, date of manufacture or batch, etc. Also, metallographic examination should reveal features that confirm the presence of metallurgical defects in the tubing. In this case, the cracks should have formed as the bourdon tube was being manufactured. Defects of this type should have been detected by the manufacturer.

An overpressurization could have occurred, causing the tubing to burst. In this case, plastic deformation should be observable and the fractured regions should be flared toward the outside of the tubing. A single burst should be present, and the fracture would most likely be transgranular.

Copper-base alloys are also susceptible to stress-corrosion cracking, especially when present in moist or humid environments. If this were the case, metallography would reveal the crack to be brittle in appearance, following grain boundaries in the direction of prior working, and be a branching crack (most likely, multiple cracks should be present). The absence of a prior anneal or stress relief would be noted. Standard tests could be conducted to determine the susceptibility of the particular material to stress-corrosion cracking.

Mechanical abuse might also be considered, but for an expectedly ductile material, there should be signs of plastic deformation that would have preceded final fracture.

3. Of the mechanisms proposed above, only stress-corrosion cracking would account for a satisfactory product being made at the manufacturer and the defect forming at a later time when the product is in service. Cracking due to defective tubing should have occurred during the process of forming the bourdon tube. Overpressurization would likely have occurred during either the initial manufacture (failure should have been noted), or during recharging (a correlation of failures and service record should be noted) . Mechanical abuse should come with accompanying signs of prior deformation.

4. Assuming that the failure mechanism is indeed stress-corrosion cracking, possible alternatives would be to subject all formed bourdon tubes to a stress-relief or anneal heat treatment. Elimination of the corrosive environment would be extremely difficult, so the problem should be addressed through the stress approach. Another alternative would be to change the material in the bourdon tube to a metal or alloy with reduced susceptibility to this particular mode of failure.

CHAPTER 42
System and Cell Design

Review Questions

1. An enterprise or production system is a system that supports the value-adding work of the manufacturing system, see Question 2.

2. A manufacturing system is a system that converts a product of material from one state to another with higher value. Manufacturing systems consist of people, machines, equipment, facilities, etc.

3. Manufacturing system design is using system design principles (logic) and system implementation processes (definite actions or steps) to create a manufacturing system.

At a very general level, part design can be viewed as using principles to specify materials and their distribution in space to fulfill a function. Analogously, manufacturing system design is the use of principles to specify manufacturing system content, configuration and operation and the steps needed to implement it.

4. The enterprise system supports the manufacturing system, even though the manufacturing system exists within the enterprise, see Question 1. The enterprise system provides support to make possible the value-adding activity in manufacturing.

5. The six functional requirements of a stable manufacturing system are,
i. Right quantity
ii. Right mix
iii. Right quality
iv. Robust
v. Rapid problem solving
vi. Safe, Ergonomically sound

a. Standardized work (Question 9) is the definition of work methods to be used to operate the manufacturing system. It specifies what to do, how to do it and why it is being done. With clear definitions of what is expected, abnormal situations are easily identified as those not fitting with the specific, definite expectations.

b. In order for a system to be robust it must contain components that are
- inherently insensitive to disturbances, to the extent possible,
- system elements specifically designed to deal with, and minimize the effects of disturbances, such as process, subsystem and total system control systems.

c. For stable systems cost is reduced by
- focusing on what the system is to achieve, not simply on the end results of the system,
- realizing that the operation’s cost is not simply the sum unit cost for each operation,
- considering the effects of flow complexity on cost.

6. A value stream map depicts the processes and activities in material and information flows in the system.

McDonalds is typical, and prototypical, of many fast food restaurants.

Functional Requirement	Function Requirement Achieved?
Right quantity	At the store, products are produced individually at time of order and so, yes the right quantity is produced. However, products are available from store inventory and so the question of inventory level arises. From observation of one store there is no way to judge enterprise quantity management.
Right mix	As above, that is there is no easy way to judge store and enterprise inventory mix.
Right quality	Yes, success of the business attests to this – the acceptable quality is based on definite expectations held by the customers.
Robust	No – disturbances in the form of large rushes of customers are seen to have large effects on line length – probably due to size of staff.
Rapid problem solving	Yes, returned items are quickly replaced with quick disposal of returned items.
Safe, Ergonomically sound	Yes, most obviously in heights of work areas and drive through service window.

7.

Functional Requirement	Function Requirement Achieved?
Right quantity	Yes, given acceptance of curriculum planners expertise and seemingly similar quantity worldwide.
Right mix	Yes with specific and "broadening" courses in curriculum, given acceptance of curriculum planners expertise.
Right quality	Yes, the institution remains open – individual course quality depends greatly on instructor.
Robust	Yes, establishment of new programs, departments occurs slowly except in cases of truly new disciplines or large changes in demand.
Rapid problem solving	Yes, instructors and advisors available at least five days per week.
Safe, Ergonomically sound	Yes, most universities have security and environmental health and safety divisions.

8. System designs should be robust since perturbations or disturbances of the system are to be expected. The system should continue to function effectively in realistic situations and these include disturbances around the steady state.

9. Standardized work is the definition of work methods to be used to operate the manufacturing system. It specifies what to do, how to do it and why it is being done. Standardized work covers all aspects of system operation, e.g., how to handle problem situations as well as normal work.

10. Takt time is the length of time set to accomplish a task so that the task fits into a planned, controlled system. In part manufacturing takt time is the time set to produce a part and is

available daily production time / daily part demand

11. Given that the cell has to meet the necessary cycle time and the general rule that all individual processing times in a cell must be less than the cell cycle time, the part that the machine is producing has to be made in less time. The alternatives are to reduce the machine's processing time to below the cell cycle time or to decrease the part production time by adding processing capabilities, probably by the addition of another machine(s).

12. Single piece flow is necessary in a cell because it is the basis for production control in the cell. Single piece flow enables
- implementation of checking the output of each processing and assembly step before the part is moved to the next step and
- ability of workers to move through the cell doing different operations.

13. The machines in cells have to operate in such a way that the individual process time is less than the cell cycle time, single piece flow is possible and operators can run the cell, rather than individual machines. This means operators load, unload and inspect parts at several machines and so the individual machines must run automatically between loading and unloading. Machine design requirements include walkaway switches meaning the machine is started and it runs through its cycle and switches off, indicators that show the machine as running or not, machine fault indicators showing premature stopping and cycle completion indicators. The machine should have part checking capabilities and workpiece loading devices where warranted. Machines have to meet all health and safety requirements.

More general machine requirements are described in Section 43.5.

14. The key role of the worker in the cell is to control production by implementing single-piece flow.

15. a. The finishing process can be removed from the cell and included in the decoupler between the cell and the next cell, or perhaps included in the subsequent cell if there is another processing cell for the product. The decoupler would have to be designed to be capable of doing the finishing process in a processing time amenable with the rest of the manufacturing system.

b. Compared to the total cost of the cell and its operation $5000 seems very small and so calls for only a quick analysis of the machine based on added cost per part. Present cost per part is known and new cost per part can be estimated from the known machine cost and part production rate. The overarching cell design rule that individual process times have to be less than cell cycle time provides real impetus to new machine acquisition and may over ride some cost concerns.

c. With the increased cost a more detail cost analysis is required. A cost-benefit analysis should include consideration and quantification of the benefit of adhering to the all-process-times-less-than-cell-cycle-time rule.

16. Parts are pulled through a cell. That is, what drives part movement through the cell is the demand for a part from a process further down stream.

17. a. A mistake-proof device is one designed so that mistakes, or the production of defects in manufacturing, cannot occur. The device can be operated only in ways that make mistakes impossible without completely overriding certain aspects of the device. See Figure 43.12

b. Mistakes result in defective parts and/or machine malfunctions. Lost time and lost quality can be avoided is mistakes can be kept from happening.

18. The number of products per year should be estimated since even for short lived products there may be a large demand and so the need for large scale available

automation. That is, it may be necessary to achieve very high production rates in a very short time to take advantage of a new, large, expected short life product market. This will require the use of available automation, rather than the development of automation. Process automation development is unrealistic for the short time of one year.

A reasonable starting point for dicsussiion is the typical situation of one year life meaning relatively small demand and the availability of machines and equipment to set up a manufacturing cell to meet the demand.

a. There is probably no need or advisability for automation. Designing automation, specifying equipment, setting it up and testing and qualifying it in less than one year is a dubious undertaking.

b. In a machine cell the major, general functions are providing parts to the cell, moving parts between machines, loading parts on machines, unloading parts from machines, inspecting parts and moving parts out of the cell. Depending on the part value (precision, material, cost of failure in use, etc.) part inspection requirements and inspection equipment can vary widely. The other cell functions are easier to assess.

The simplest tasks to automate, and those with equipment that is most likely to be generally useful after the five year product life, are the candidates for automation. These are

- machine loading and unloading. Given the machines will probably remain after the five years the automated loading and unloading equipment will probably be general purpose, reconfigurable.
- inspection equipment. Again, this automated equipment may be useful after initial product life, especially it can be on-machine probing or inspection.

Material handling equipment usually involves larger, more complicated, more expensive equipment with little flexibility with respect to different products – it should not be automated. Movement of work into and out of the cell should not be automated since it probably interacts with other parts of the manufacturing system and those may not be concerned with the particular product of interest.

c. For reasonable, consistent annual demand over fifty years probably all the automation opportunities listed above should be implemented.

19. Fine furniture, boats and buildings have long product lives and are built in large annual quantities. They are made in variations of the general job shop, Section 41.4.

20. Single-cycle automatic machines are used in cells so that the worker(s) can load, unload and inspect parts at several machines. After one machine is loaded it has to run automatically so the worker can move to another machine to perform one of the required functions before returning to unload the machine.

Problems:

1.Takt time = available production time / daily demand
Takt time = { (480 min/shift)(2 shifts/day) } / { (160 + 120 + 200) products / day }
Takt time = 2 min

a. With 97% yield the number of products that have to be made to meet demand is (160 + 120 + 200) products / day / 0.97 = 495 products
and the cell cycle time is 960 min/day / 495 products/day = 1.94 min = 116 seconds

b. With no unload times and assuming one worker follows each part through the cell and waits for the processing of it to be completed at each machine the time is 283 seconds – this is essentially the time that the part spends in the cell.

Operation	Time Increment	Cumulative Time
Start		0
Load M1	3	3
Process at M1	42	45
Walk to 2	3	48
Process at 2	17	65
Walk to M2	3	68
Load M2	4	72
Process at M2	53	125
Walk to 4	3	128
Process at 4	4	132
Walk to M3	3	135
Load M3	4	139
Process at M3	18	157
Walk to M4	3	160
Load M4	6	166
Process at M4	50	216
Walk to M5	3	219
Load M5	9	228
Process at M5	47	275
Walk to 8	3	278
Process at 8	5	283

Once a flow of parts through the cell is established, i.e., steady state operation, then the worker can move parts and do the manual operations while the machines are running. The order of the worker's moves is not orchestrated by the table above. That is, the worker can move between various tasks while the machines are running. What is necessary is that parts on which to work be available

c. The takt time almost assuredly cannot be met. Consider the truly ideal situation of perfect synchronization. The sum of the times for the manual operations is (17 + 4 + 5) = 26 seconds and the machine load times are (3 + 4 + 4 + 6 + 9) = 26 seconds. There has to be at least one set of moves through the system so walking time is (7 walks)(3 sec/walk) = 21 seconds. The ideal worker time is then 73 seconds and this can only occur if parts are finished and available at just the right time at all machines. The large variation on processing times between the machines means this will not happen and the takt time will not be met.

d. A possible improvement is to decrease the processing times for the long processing time operations to approach the degree of synchronization necessary.

e. The implementation of the improvement should be based on a factory simulation. That is, with the available data and using different processing times the operation of the cell can be easily simulated, including expected variability in all the operations. The results used to justify committing to the improvement.

f. The cell design depends on the improvements proposed. What should be done is a quantitative description of the cycle time with the proposed cell design.

2. a. Yes this is a problem. An important, necessary aspect of cell design and operation is standardized work. With no provision for moving material into and out of the cell this aspect of the cell operation is not standardized work and so not part of the cell and so the cell will not function.

b. There are two parts to the solution to the problem. The first is to include running the input and output in the list of standard work for the cell. The second part of the solution is to have workers A and E operate the input and output stations. When there is insufficient input material a control signal has to be sent to preceding parts of the system to supply more material, this type of pull system is described in detail in Chapter 43. When cell output is sufficient finished parts has to be moved out. With the U-shaped ccell layout both workers A and E can be involved with both input and output stations since these stations are close together.

Case Study:

Snowmobile Accident

This case was fictionalized from an actual case in which one of the authors of the text was involved as an expert witness. In real cases of this sort, there will always be conflicting evidence and many explanations presented for the same set of evidence. Often, the truth may never be presented to the jury and the actual cause of the accident may never be known. Such was the situation here.
